Oxidatively damaged proteins accumulate with age in almost all cell types and tissues. The activity of chaperone-mediated autophagy (CMA), a selective pathway for the degradation of cytosolic proteins in lysosomes, decreases with age. We have analyzed the possible participation of CMA in the removal of oxidized proteins in rat liver and cultured mouse fibroblasts. Added to the fact that CMA substrates, when oxidized, are more efficiently internalized into lysosomes, we have found a constitutive activation of CMA during oxidative stress. Oxidation-induced activation of CMA correlates with higher levels of several components of the lysosomal translocation complex, but in particular of the luminal chaperone, required for substrate uptake, and of the lysosomal membrane protein (lamp) type 2a, previously identified as a receptor for this pathway. In contrast with the well characterized mechanism of CMA activation during nutritional stress, which does not require de novo synthesis of the receptor, oxidation-induced activation of CMA is attained through transcriptional up-regulation of lamp2a. We conclude that CMA is activated during oxidative stress and that the higher activity of this pathway under these conditions, along with the higher susceptibility of the oxidized proteins to be taken up by lysosomes, both contribute to the efficient removal of oxidized proteins.

INTRODUCTION

Accumulation of oxidized protein is a common feature of aged cells (Dunlop et al., 2002; Grune and Davies, 1997; Grune et al., 2001, 2002b; Stanford, 2001). Many physiological and pathological processes lead to the generation of free radicals and consequent damage of intracellular components, including proteins. In most of these oxidative events, damaged proteins are removed from the cell through degradation by proteases (Dunlop et al., 2002). The activity of different intracellular proteolytic systems decreases with age (Terman, 1995; Cuervo and Dice, 1998a; Friguet et al., 2000; Carrard et al., 2002; Donati et al., 2001; Merker et al., 2001; Friguet, 2002; Keller et al., 2002; Ward, 2002), and this impaired activity is considered responsible for the deficient removal of oxidized proteins in old organisms (Grune, 2000; Merker and Grune, 2000; Dunlop et al., 2002; Szweda et al., 2002).

The susceptibility of oxidized proteins to proteases changes with the duration and degree of oxidative damage (Dunlop et al., 2002; Mehlhase and Grune, 2002). Thus, mild oxidation induces partial protein unfolding and facilitates proteolytic cleavage (Grune et al., 1995, 1997). However, persistent or extensive oxidative damage usually promotes protein aggregation, due to the exposure of patches of hydrophobic amino acids. Once a protein aggregates, it becomes less susceptible to proteolytic cleavage (Hoff et al., 1993; Grune et al., 1997; Davies, 2001; Demasi and Davies, 2003). Kinetics of degradation of oxidized proteins in vitro have been analyzed using different types of proteases (Merker and Grune, 2000; Dunlop et al., 2002; Szweda et al., 2002). One of the most extensively analyzed protease in this respect has been the proteasome. Although most of the studies linking the proteasome to the degradation of oxidized proteins have been carried out in vitro (Rivett, 1985; Davies, 2001), recent evidence supports the participation of the proteasome in the removal of oxidized proteins in vivo also (Hosler et al., 2003; Shringarpure et al., 2003). Thus, treatment of culture cells with proteasome inhibitors or antisense oligonucleotides against essential proteasome subunits results in accumulation of oxidized proteins inside cells and diminished rates of cell survival during oxidative stress. The degradation of most oxidized proteins by the proteasome is ATP and ubiquitin independent (Shringarpure et al., 2003), suggesting that the exposure of hydrophobic regions in the surface of the protein acts as recognition signal for this protease.

The lysosomal system, the other major proteolytic system in cells, has not been often considered as a possible candidate for the removal of oxidized proteins because of its lack of selectivity. In mammalian cells three different main mechanisms contribute to the degradation of intracellular components inside lysosomes (autophagy) (Dice, 2000; Reggiori and Klionsky, 2002; Wang and Klionsky, 2003; Cuervo, 2004a,b). Two of those mechanisms, macroautophagy and
microautophagy, result in the degradation of complete regions of the cytosol, including organelles, in the lysosomal lumen. Although degradation of organelles by these autophagic pathways can be selective (i.e., specific removal of damaged mitochondria sparing normal functioning ones) (Lemasters et al., 2002), there is no evidence supporting selectivity for the degradation of soluble cytosolic proteins. In contrast, the main characteristic of a third form of autophagy, chaperone-mediated autophagy (CMA), is its selectivity regarding the substrates (cytosolic proteins) degraded through this pathway (Cuervo and Dice, 1998b; Dice, 2000; Dice et al., 2003).

CMA is a generalized form of autophagy present in most cell types and tissues (Massey et al., 2004). All the CMA substrate proteins described to date are soluble cytosolic proteins containing a targeting motif biochemically related to the pentapeptide KFERQ (Chiang and Dice, 1988; Dice et al., 2003). This motif, present in ~30% of the proteins in the cytosol, is recognized by a cytosolic chaperone, the heat shock cognate protein of 73 kDa (cyt-hsc70) (Chiang and Dice, 1988; Chiang et al., 1989). The interaction with this chaperone, modulated by the hsc70 co-chaperones (Agarraberes and Dice, 2001), targets the substrate to the lysosomal membrane, where it interacts with the lysosomal membrane protein (lamp) type 2a (Cuervo and Dice, 1996). Substrates need to be unfolded before translocation into the lysosomal lumen, and several cytosolic chaperones associated to the lysosomal membrane have been proposed to assist in the unfolding (Agarraberes and Dice, 2001). Translocation of the substrate requires the presence of a variant of hsc70, lys-hsc70, in the lysosomal lumen (Agarraberes et al., 1997; Cuervo et al., 1997) and is followed by the rapid proteolysis of the substrate by resident lysosomal proteases (half-life in the lysosomal lumen of 5–10 min).

Although some basal level of CMA activity is probably present in most cells, nutritional stress has been shown to maximally activate this pathway (Wing et al., 1991; Cuervo et al., 1995). Activation during nutrient deprivation is associated with higher levels of lys-hsc70 in the lysosomal lumen and of lamp2a at the lysosomal membrane (Cuervo et al., 1995; Agarraberes et al., 1997; Cuervo and Dice, 2000b). Because the interaction of substrate proteins with lamp2a is a limiting step for this pathway, changes in levels of lamp2a at the lysosomal membrane modulate CMA activity (Cuervo and Dice, 2000b,c). Interestingly, all the conditions known to activate CMA, up-regulation of the lysosomal levels of lamp2a does not require de novo synthesis of the protein, but instead it is attained through down-regulation of its degradation and by relocation of a fraction of the protein from the lysosomal lumen into the membrane (Cuervo and Dice, 2000b).

In addition to starvation, activation of CMA has also been observed in rat liver and kidney after exposure to gasoline derivatives (Cuervo et al., 1999); in fibroblasts from galactosialidosis patients, which lack the protective protein/cathepsin A (Cuervo et al., 2003); and in cells overexpressing lamp2a (Cuervo and Dice, 1996). CMA activity is reduced during renal tubular cell growth (Franch et al., 2001) and in aging (Cuervo and Dice, 2000a). The decrease in CMA activity in old cells, known to accumulate oxidized proteins (Cuervo and Dice, 2000a), combined with the fact that activation of CMA during toxic exposure results in the selective degradation of a protein altered by the toxic compound (Cuervo et al., 1999), and with our finding that in the presence of antioxidants degradation of the inhibitor of the nuclear factor κB by CMA decreases (Cuervo et al., 1998), prompted us to analyze a possible role of CMA in the removal of oxidized proteins from cells. We show in this work that oxidation of CMA substrates facilitates their translocation into lysosomes for degradation via CMA and also that CMA itself is activated during oxidative stress. Unexpectedly, the oxidative stress-mediated activation of CMA is attained through a novel mechanism, different from the previous well-characterized activation of CMA in response to nutritional stress.

**MATERIALS AND METHODS**

**Animals and Cells**

Male Wistar rats (200–250 g) were fed ad libitum or starved for 20 or 48 h before sacrifice. An age-controlled rat strain (Fisher 344) was used for the study of age-related changes and 3–12, and 22-mo-old rats were compared. Mild oxidative stress was induced in rats with two single i.p. injections of paraquat (40 mg/100 g body weight) separated by 24 h. Lysosomal isolation was carried out 24 h after the last injection. Mouse fibroblasts (NIH3T3) were from the American Type Culture Collection (Manassas, VA). Cells were maintained in DMEM (Sigma-Aldrich, St. Louis, MO) in the presence of 10% newborn calf serum. To deprive cells from serum, plates were extensively washed with Hanks’ balanced salt solution (In vitrogen, Carlsbad, CA), and fresh medium without serum was added. Mild oxidative stress was induced in culture cells by supplementation of the culture medium with 100 μM H2O2 or 40 μM paraquat for 1 h. Assays were carried out 12–24 h after removing the oxidizing compound.

**Chemicals**

Sources of chemicals and antibodies were as described previously (Cuervo and Dice, 1996; Cuervo et al., 1997; Cuervo and Dice, 2000a; Martin et al., 2002). The antibodies against the cytosolic tail of rat and mouse lamp2a and lamp2c were prepared in our laboratory (Cuervo and Dice, 1996; Zhang, Bandhyopadhyay, Kiffin, Massey, and Cuervo, unpublished data). The antibody against mouse lamp1 (1D4B) was from the Developmental Studies Hybridoma Bank (University of Iowa, Iowa City, IA), and antibodies against hsp90 (SPA-810), hsp40 (SPA-400), hsp72 (SPA-810), hsp40 (SPA-400), hsp72 (SPA-810), Bag-1 (AAM-400F) were from Stressgen Biotechnologies (Victoria, BC, Canada). Carbonyl groups in oxidized proteins were detected using the OxyBlot oxidized protein detection kit from Chemicon International (Temecula, CA). Glyceroldehyde-3-phosphate dehydrogenase (GAPDH) and ribonuclease A (RNase A) were radiolabeled with [14C]formaldehyde by reductive methylation as described previously (Jentoft and Dearborn, 1983). Cytosolic proteins from mouse fibroblasts in culture were metabolically radiolabeled by incubation with [14C]bicarbonate (2 μCi/ml) at 37°C for 2 d (Cuervo et al., 1997). Cells were disrupted by nitrogen cavitation, and the cytosolic fraction was the supernatant of a centrifugation at 100,000 × g for 1 h at 4°C. Oxidized radiolabeled cytosolic proteins were prepared by the same procedure from cells treated with different prooxidants for 24 h before isolation.

**Isolation of Lysosomal Fractions**

Rat liver lysosomes were isolated from a light mitochondrial-lysosomal fraction in a discontinuous metrizamide density gradient (Wattiaux et al., 1978). Lysosomal fractions with different activities for CMA were separated as described previously (Cuervo et al., 1997). Lysosomes from cultured cells were isolated as described previously (Sterritt and Madden, 1990). Preparations with more than 10% broken lysosomes, measured as described previously (Terlecky and Dice, 1993; Cuervo et al., 1997), were discarded. Lysosomal matrices and membranes were isolated after hypotonic shock (Ohsami et al., 1983).

**Uptake and Degradation of Proteins by Isolated Lysosomes**

GAPDH or RNase A were incubated in MOPS buffer (10 mM 3-(N-morpholino)propanesulfonic acid [MOPS] pH 7.3, 0.3 M sucrose) with chymostatin-treated lysosomes as described previously (Cuervo et al., 1997). Transport was measured after proteinase K treatment of the samples, SDS-PAGE, and immunoblotting as the amount of GAPDH associated to lysosomes resistant to the protease. In another group of experiments, to overcome any possible changes in the proteolytic susceptibility of the oxidized proteins to proteinase K, oxidized proteins were incubated with chymostatin-treated or untreated lysosomes, and uptake was calculated as the difference between the amount of substrate associated to lysosomes (chymostatin-treated lysosomes) and the amount of substrate bound to their membrane (untreated lysosomes) (Salvador et al., 2000). Degradation of [14C]GAPDH (260 nM; 1.5 × 106 dpm/nmol), [14C]RNase A (150 nM; 0.9 × 106 dpm/nmol), or a pool of radiolabeled cytosolic proteins (500 dpm/μg) by intact lysosomes or lysosomal matrices was measured as described previously (Terlecky and Dice, 1993; Cuervo et al., 1997). For incubation for 30 min at 37°C in MOPS/dithiothreitol (DTT) buffer (10 mM MOPS pH 7.3, 0.3 M sucrose, 5.4 μM cysteine, and 1 mM DTT) (for intact lysosomes) or in 0.03 M sucrose (for lysosomal matrices), samples were disrupted by nitrogen cavitation, and the cytosolic fraction was the supernatant of a centrifugation at 100,000 × g for 1 h at 4°C. Oxidized radiolabeled cytosolic proteins were prepared by the same procedure from cells treated with different prooxidants for 24 h before isolation.

4830 Molecular Biology of the Cell
were precipitated in 10% trichloroacetic acid and filtered through a multi-
screen assay system (Millipore, Bedford, MA) using a 0.45 µm pore filter. 
Radioactivity in the flow through and in the filter was converted to disinte-
gracted counts per minute in a Wallac 1414 liquid scintillation analyzer 
(PerkinElmer Life and Analytical Sciences, Boston, MA) by correcting for 
quenching using an external standard. Protein labeling was expressed as the 
percentage of the initial acid-insoluble radioactivity (protein) transformed into 
acid-soluble radioactivity (amino acids and small peptides) at the end of the 
crude degradation.

Rates of degradation of lamp2a in the isolated membranes were followed 
by immunoblot with a specific antibody against the cytosolic tail of lamp2a as 
described previously (Cuervo and Dice, 2000b). Briefly, isolated lysosomal 
membranes were incubated in MOPS buffer at 37°C, and at different times 
aliquots were removed and subjected to SDS-PAGE and immunoblot for 
lamp2a.

**GAPDH Oxidation**

Metal-catalyzed oxidation of rabbit muscle 3-glycerolphosphate-3-phosphate 
dehydrogenase EC 1.2.1.12 (Roche Diagnostics, Indianapolis, IN) was carried 
out as described previously (Rivett and Levine, 1990). GAPDH (10 µg of 
protein) was dialyzed against 50 volumes of HEPES buffer (50 mM HEPES, 
PH 7.2, 100 mM KCl, 10 mM MgCl2) supplemented or not (Mock) with 25 mM 
ascorbic acid and 0.1 mM FeCl3 at 37°C. The oxidative reaction was stopped 
adding 1 mM EDTA, and the samples were dialyzed against HEPES buffer for 
24 h with four changes. The two first changes were supplemented with 1 mM 
EDTA. The efficiency of oxidation was monitored by measuring the enzymatic 
activity of GAPDH after being exposed to the oxidative mixture for different 
periods of time. As described in Figure 2, incubation of GAPDH with the 
oxidant mixture for 30 min resulted in 70% decrease of its enzymatic activity.

**Immunocytochemical Staining**

Immunofluorescence staining of cultured cells was performed following con-
ventional procedures (Cuervo and Dice, 2000c). Cells grown on coverslips 
until confluent and kept in the presence or absence of serum for 20 h were 
fixed with 3% formaldehyde solution, blocked, and then incubated with the 
primary and corresponding fluorescein isothiocyanate or Cy3-conjugated 
secondary antibodies as described previously (Cuervo and Dice, 2000c).

Mounting medium containing 4,6-diamidino-2-phenylindole staining to high-
light the cellular nucleus. Images were acquired with an Axiovert 200 fluo-
resent microscope using a 40× objective. The image processing was carried 
out using the manufacturer's software. Colocalization was determined 
determining MetaMorph (Universal Imaging, Downingtown, PA). All digital micro-
scopic images were prepared using Adobe Photoshop 6.0 software (Adobe 
Systems, Mountain View, CA).

**mRNA Quantification**

Total RNA was extracted from rat livers using the RNAeasy mini kit (QIAGEN, 
Valencia, CA) following the manufacturer's indications and stored at 
−80°C until use. The first strand cDNA was synthesized from 1 µg of the 
total RNA using the SuperScript II RNase H Reverse Transcriptase (Invitrogen) 
and oligo-(dT)12-18 primer. A region of the exon of 5 lamp2a and of actin 
was amplified with specific primers (lamp2a, 5'-GTGCTCAAGGCCCCTC-
CATACAG-3'/3'-CTCTCTCCGCTTCGAAACGCA-3'; actin, 5'-AAGGACTCCTATAGTGGGTGACGA-3' [forward] and 5'-ATCTTCTCATGTATGTTGGTGAGC-3' [reverse]) by using the SYBR green 
polymerase chain reaction (PCR) kit (PE Biosystems, Warrington, United 
Kingdom). Amplification of the lamp2a and actin DNA products (120 and 108 
bp, respectively) was measured in real time in a light cycler (SmartCycler: 
Cepheid, Sunnyvale, CA). For both genes, the presence of a single amplified 
product was verified by agarose gel electrophoresis, and by analysis of the 
melting curves of the reverse transcriptase-PCR reaction. The expression 
levels of lamp2a in different samples were normalized with respect of those of 
actin, and differences of the cycle numbers to reach a certain fluorescence 
level were used as reported previously (Storrie and Madden, 1990). After SDS-PAGE 
(Laemmli, 1970) and immunoblotting (Towbin et al., 1979), the proteins recognized by the specific antibodies were visualized by chemi-
luminescence methods (Renaissance; PerkinElmer Life and Analytical Sci-
ences). Oxidized proteins were visualized after derivatization with DNPH by 
immunoblot with an antibody against the DNP moiety following the manu-
facturer's recommendation. Densitometric quantification of the immuno-
blotted membranes and stained gels was done with an Image Analyzer 
System (Sil800; Inotech, Sunnyvale, CA). Student's t test was used for statis-
tical analyses.

**RESULTS**

**Oxidized Proteins in Lysosomes**

To test the contribution that the lysosomal system, and in particular CMA, might play in the removal of oxidized cytosolic proteins, we first analyzed the presence of those 
proteins inside lysosomes after oxidative stress. We induced mild oxidative stress in rats by treatment with bleomycin, 1,1′-dimethyl-4,4′-bipyridinium dichloride (paraquat), a su-
peroxide-generating drug with well-characterized prooxi-
dant effects (Haly, 1979). To verify the oxidative effect of 
paraquat in rat liver we compared the content of cytosol-
containing proteins in the cytosol of untreated and para-
quat-treated rats (Figure 1A, lanes 1 and 2). Although some 
oxidized proteins can be observed in the cytosol of untreated 
rats, we found a significant increase in the content of these 
molecules in the cytosol of rats injected with a sub-
lethal dose of paraquat for two consecutive days. Lysosomes 
active for CMA can be isolated from rat liver based on their 
high content of the luminal chaperone lys-hsc70 required 
for substrate uptake (Cuervo et al., 1997). When we isolated 
this particular lysosomal population from treated and un-
treated rats and separated their membranes from their ly-
sosomal content, we found carbonyl-containing proteins in 
both the membrane and luminal fraction of the lysosomes 
from paraquat-treated rats (Figure 1A, compare lanes lanes 
3 and 5 to lanes 4 and 6). Washing the lysosomal membranes 
with 1 M NaCl released most of the oxidized proteins (Fig-
ure 1A, lanes 7 and 8), suggesting that they were likely 
cytosolic proteins associated to the membrane, rather than 
the result of oxidation of integral lysosomal membrane pro-
teins. Likewise, when we incubated the lysosomal matrices 
at 37°C before electrophoresis to promote the degradation of 
nonlysosomal proteins in the lysosomal lumen, the level of oxidized 
proteins in this fraction decreased drastically (Figure 1A, 
lanes 9 and 10). Note that the new lower molecular 
weight bands detected in the matrices of paraquat-treated animals 
after the incubation at 37°C could be proteolytic products of the proteins detected in the freshly isolated 
lysosomes. These results support that the oxidized proteins 
detected inside the lysosomes were most likely nonlyso-
somal proteins delivered there to be degraded. Interestingly, 
despite of their cytosolic origin, the electrophoretic pattern 
of the oxidized proteins associated with the lysosomal frac-
tion differs from the ones in the cytosol. Because these differ-
ences are also observed in the membrane associated pro-
teins, we do not think that they are due to distinct 
susceptibility of some of the oxidized proteins to proteases; 
instead we consider it an indication that a subset of oxidized 
proteins is selectively taken up by lysosomes.

As reported previously, even in the absence of treatment 
with a prooxidant agent, oxidized proteins can be detected 
in normal liver and their content increases with age (Figure 
1B). When we analyzed the association of oxidized proteins 
to lysosomes from livers of 3- and 9-mo-old rats, we found 
an increase in the content of oxidized proteins in the lyso-
osomal lumen with age, similar to the one observed in the 
cytosol (Figure 1B, compare lanes 1 and 2 and 4 and 5). In 
contrast, in the oldest animals (22 mo old), for which we have previously described a severe decrease in CMA activity 
(Cuervo and Dice, 2000a), despite the high content of 
oxidized proteins in the cytosolic fraction, in proportion, 
the amount of oxidized proteins detected in lysosomes was
lower than in the 9-mo-old animals (Figure 1B, compare lanes 5 and 6). Similar assays to the ones described above confirmed that the oxidized proteins were of extralysosomal origin and could be degraded by the lysosomal proteases (our unpublished data). The last panel of Figure 1B shows the specificity of the antibody used in these studies against the carbonyl groups, which in nnderivatized samples only weakly cross-reacted with a single protein (compare signal in derivatized (lane 7) and nnderivatized samples (lane 8). Although macroautophagy, a nonselective form of autophagy, also decreases with age (Terman, 1995; Donati et al., 2001), the fact that the lysosomal population analyzed has been shown to be very active for CMA and that only a subset of oxidized proteins was detected in lysosomes encouraged us to analyze the role of CMA in the removal of oxidized proteins.

**Oxidation of CMA Substrates**

We first analyzed whether the oxidation of known CMA substrates facilitated their degradation by CMA. We oxidized GAPDH, a well-characterized CMA substrate (Aniento et al., 1993), by incubating this protein with an ascorbic acid/iron oxidizing mixture. After 30 min of incubation with this mixture, ~70% of GAPDH activity was lost (Figure 2A), and carbonyl groups were easily detectable in the purified protein (our unpublished data). We have previously optimized an in vitro system that allows the analysis of binding and uptake of CMA substrates by isolated lysosomes (Aniento et al., 1993; Cuervo et al., 1997, 1999). When we compared the association to lysosomes of untreated GAPDH or of GAPDH exposed for increasing periods of time to the oxidizing mixture, we found an increase in both the amount of protein bound to the lysosomal membrane and translocated into the lysosomal lumen (proteinase K resistant) with longer oxidation times of GAPDH (Figure 2B). Oxidation of ovalbumin, a protein that does not contain a KFERQ-like motif and consequently is not a CMA substrate, did not increase its association to lysosomes (our unpublished data). The higher amount of GAPDH detected in the lysosomal lumen could also result from an increased resistance of the oxidized protein to degradation, either by the lysosomal proteases or by proteinase K, which removes the protein associated to the cytosolic side of the lysosomal membrane. However, as shown in Figure 2C, the oxidized protein was even more readily degraded by both the pool of proteases located in the lysosomal lumen and by exogenously added proteinase K.

An increase in lysosomal translocation of oxidized proteins was also evident when instead of using a specific CMA substrate, we compared the degradation of a pool of oxidized cytosolic proteins, in which ~30% of them are possible CMA substrates (contain KFERQ-related motifs) (Figure 2D). Radiolabeled cytosolic proteins isolated from fibroblasts exposed to H2O2 (Figure 2D, left) or paraquat (Figure 2D, right) were degraded faster than cytosolic proteins from untreated fibroblasts when incubated with intact rat liver lysosomes. Because these differences were greatly reduced when the lysosomal membranes were disrupted before the incubation with the cytosolic proteins, giving free access of the proteases to the substrates, we conclude that, as shown for GAPDH, increased degradation of the oxidized proteins resulted from their higher rates of translocation via CMA into lysosomes. These results support that oxidation of proteins that are substrates for CMA facilitates their degradation through this pathway.

**Activation of CMA during Oxidative Stress**

Independently of the effect of oxidation on CMA substrates, which makes them more susceptible to degradation by this pathway, we found a constitutive activation of CMA during oxidative stress. We isolated lysosomes from rats treated with a sublethal dose of paraquat for two consecutive days to generate a mild oxidative stress response. Under these conditions, we did not find significant differences with control in lysosomal membrane stability assessed by measuring β-hexosaminidase latency (Supplemental Figure 1) (Storrie...
with intact rat liver lysosomes (25 treated fibroblasts were prepared and incubated for 30 min at 37°C (*p
peptides). Values are the mean activity (protein) transformed in acid soluble (amino acids and small
teolysis was calculated as the amount of acid precipitable radioac-
tivity under standard conditions. At the end of the incubation pro-
disrupted by a hypotonic shock (broken lysosomes; 15

eolysosomal proteolytic activity (Aniento et al., 1993). Lysosomes isolated from rats exposed
to paraquat degraded larger amounts of unmodified
and Madden, 1990) and extralysosomal proteolytic activity (Aniento et al., 1993). Lysosomes isolated from rats exposed
to paraquat degraded larger amounts of unmodified
GAPDH than lysosomes isolated from untreated animals (Figure 3A, left). Similar results were observed for RNase A, another well-characterized CMA substrate (Terlecky and Dice, 1993; Cuervo et al., 1994) (Figure 3A, right). In both
cases, the increase in substrate degradation was no longer observed if the lysosomal membrane was disrupted. In fact,
the degradation of both substrates by lysosomal proteases was slightly lower in the paraquat-treated animals. This
decrease could result from a decrease in the activity of some lysosomal proteases during oxidative stress, as reported pre-
viously (O’Neil et al., 1997; Carr, 2001; Crabb et al., 2002). In any case, the higher ability to degrade substrates of the
intact lysosomes from paraquat-treated animals was thus a consequence of increased binding/uptake rather than of
higher proteolysis in the lysosomal lumen.

We then determined whether oxidative stress could increase CMA-mediated degradation of proteins by acting on
both the substrates, increasing their ability to be taken up by
the lysosomes, and on the lysosomes, increasing their ability
to take up substrates. For that purpose, we verified first that,
as described above for GAPDH and RNase A, cytosolic
proteins from untreated fibroblasts were more readily de-
graded by intact lysosomes from paraquat-treated rats than by lysosomes from untreated rats (Figure 3B). Then, we analyzed the effect of combining lysosomes and cytosolic proteins that had been both exposed to the prooxidant. When we incubated the lysosomes from paraquat-treated rats with the cytosolic proteins isolated from fibroblasts treated with H₂O₂ (Figure 3B, left) or with paraquat (Figure 3B, right), we found that these proteins were degraded even faster. We obtained similar results using lysosomes isolated from H₂O₂-treated fibroblasts (our unpublished data). Based on this additive effect, we conclude that not only oxidation-induced changes in the substrate proteins, but also in the lysosomal compartment, are responsible for the higher rates of CMA observed during oxidative stress.

We further analyzed the activation of CMA during oxidative stress by separately analyzing binding and uptake of unmodified substrate proteins by lysosomes isolated from paraquat-treated rats. In these studies, to eliminate any possible differences in the ability of exogenous proteases to remove the protein bound to the cytosolic side of the lysosomal membrane, we compared instead the amount of substrate associated to lysosomes previously treated or not with a strong cocktail of protease inhibitors. In the absence of protease inhibitors the substrate that translocates inside the lysosomal lumen is rapidly degraded by the lysosomal proteases (half-life of proteins in the lysosomal lumen is 5–7 min; Aniento et al., 1993). Consequently, the protein associated to the lysosomes at the end of the incubation represents the protein bound to the cytosolic side of the lysosomal membrane (Salvador et al., 2000). In contrast, if lysosomal proteases are inhibited, the protein recovered associated to lysosomes corresponds to both protein bound and internalized into the lysosomal lumen. As described previously, the amount of internalized substrate can then be calculated by subtracting the protein bound from the amount of protein associated (Salvador et al., 2000). Consistent with our previous results, the amount of GAPDH and RNase A bound to the lysosomal membrane was significantly higher (4- to 5-fold increase) in lysosomes from paraquat-treated rats (Figure 4A). A two- to threefold increase was also detected in the uptake of both substrates by these lysosomes, when calculated as described above (Figure 4A, bottom). We have previously shown that CMA is activated under starvation conditions (Cuervo et al., 1995). When we compared both stimuli, starvation and paraquat, we found that treatment with the prooxidant agent resulted in stronger activation of CMA. Levels of binding and uptake of both substrates were significantly higher in lysosomes isolated from fed rats treated with paraquat than in lysosomes from 48-h starved animals. To determine whether the observed increase in CMA during paraquat treatment could be due, at least in part, to some degree of starvation in this group of animals, we measured food-intake in the animals exposed to paraquat. However, we did not find significant differences in food consumption between the paraquat-treated and untreated animals when maintained in ad libitum conditions, suggesting that activation of CMA after paraquat treatment was not due to starvation, but to the oxidative stress.

Activation of CMA is associated with the relocalization toward the perinuclear region of the lysosomes with higher CMA activity (those with higher levels of lys-hsc70 and lamp2a) (Agarraberes et al., 1997; Cuervo and Dice, 2000c). As shown in Figure 4B, in culture fibroblasts maintained in the presence of serum, lamp2a colocalized with other lysosomal membrane proteins (lamp1 is shown here), displaying a typical vesicular punctated pattern. When serum was removed from the culture medium, the lamp2a-enriched lysosomes preferentially localized in the perinuclear region. Treatment with paraquat displayed a similar perinuclear pattern for lamp2a even when the cells were maintained in the presence of serum (Figure 4B, right).

These results are consistent with a constitutive activation of CMA during oxidative stress in the two experimental models in which CMA has been better characterized, rat liver and fibroblasts in culture (Terlecky and Dice, 1993; Cuervo et al., 1997).
Oxidative Stress-induced Changes in Lysosomes Active for CMA

Several cytosolic chaperones associate with the lysosomal membrane and are required for CMA substrate binding/uptake into lysosomes (Agarraberes and Dice, 2001). Although the specific function of each of these cochaperones in CMA remains unknown, studies with human fibroblasts in culture have revealed that the levels of some of them are up-regulated when CMA is activated by removal of serum, whereas others remain unchanged (Agarraberes and Dice, 2001). In lysosomes isolated from livers of rats starved for 48 h, in addition to the previously reported increase in lys-hsc70, we found higher levels of hsp90, and, in less extent, of Hip, compared with lysosomes from control-fed animals (Figure 5A). Treatment with paraquat (in fed rats) resulted in similar increase in the lysosomal content of lys-hsc70 and of Hip, but only a discrete increase in the content of hsp90, when compared with untreated animals. None of the treatments modified the levels of other associated chaperones (hsp40 or Bag-1), nor did they result in lysosomal association of the inducible form of the hsp70 family, hsp72, which was however elevated in the cytosol after paraquat treatment (Figure 5A). Because the function of hsp90 in lysosomes is not known, it is not clear why the increase in its lysosomal levels is not as pronounced as the one observed during starvation or aging, which correlates with an increase in their lumenal levels of lys-hsc70 (Cuervo et al., 1997; Agarraberes and Dice, 2001). The main difference found, so far, between these two groups of lysosomes is the enrichment of lys-hsc70 in the lumen of the lysosomes with higher CMA activity (Cuervo et al., 1997). These two groups of lysosomes are normally purified together (they contribute 75 and 25% high activity and low activity, respectively, to the fraction that we used in these studies), but can be physically separated by further density and differential centrifugation (Cuervo et al., 1997).

The lysosomes with lower CMA activity can become more active under specific conditions, such as prolonged (88-h) starvation or aging, which correlates with an increase in their lumenal contents of lys-hsc70 (Cuervo et al., 1997). The percentage of lys-hsc70 in the membranes or matrices of the less active group. Accordingly, the ability of this group of lysosomes to selectively take up CMA substrates did not change in paraquat-treated rats (our unpublished data). The percentage of hsc70-enriched lysosomes, determined as recovery of hexosaminidase activity in this fraction, was similar in untreated and paraquat-treated rats (our unpublished data). For the more active group of lysosomes, as observed during starvation, levels of lys-hsc70 at the lysosomal membrane remained constant, whereas levels of lys-hsc70 in the lysosomal lumen increased approximately fourfold. Separation of the lysosomal membranes and matrices also revealed that hsp90 increased in both compartments during starvation.
and after paraquat treatment (Figure 5B, top), but the increase in the lumen of lysosomes from paraquat-treated rats was smaller than in starved animals. These differences in the luminal content of hsp90 could explain why, when working with total lysosomes (Figure 5A), we found that paraquat induced a lower increase in lysosomal levels of hsp90 than starvation. Whether this hsp90 in the lysosomal lumen is functional, or whether it is only internalized to be degraded (amino acid sequence analysis of hsc90 revealed the presence of two KFERQ-related motifs) remains unknown.

Levels of lamp2a at the lysosomal membrane directly correlate with CMA activity (Cuervo and Dice, 2000b). Lysosomes isolated from mouse fibroblasts treated with H$_2$O$_2$ (Figure 6A) or from livers of rats exposed to paraquat (Figure 6B) had higher levels of lamp2a at their membrane than lysosomes isolated from the corresponding untreated controls. This increase seems selective for lamp2a, because levels of other lysosomal membrane proteins (lamp1 shown here) remained unchanged. In agreement with the binding and uptake data (Figure 4A), the increase of lamp2a in the lysosomal membrane induced by paraquat was higher than the one induced by starvation (Figure 6C). For the two other lysosomal membrane proteins analyzed, levels of lamp1 remained unchanged in both conditions, and levels of lamp2c were not affected by the treatment with paraquat, but decreased significantly during starvation. Whether this decrease in lamp2c content is related to the increase in lamp2a or it happens independently is currently under investigation.

**A Novel Mechanism for Activation of CMA during Oxidative Stress**

We have previously shown that CMA activity can be modulated by changes in the levels of lamp2a at the lysosomal membrane (Cuervo and Dice, 2000b). In fact, overexpression of lamp2a results in higher rates of CMA proportional to the increase in the receptor protein (Cuervo and Dice, 1996, 2000c). During starvation, the most extensively studied stimuli for CMA, the increase of lamp2a at the lysosomal membrane does not result from de novo synthesis of the protein. Instead, a decrease in the degradation rate of lamp2a, along with the relocation of part of the lamp2a resident in the lysosomal lumen toward the lysosomal membrane account for most of the lamp2a increase in the membrane (Cuervo and Dice, 1996, 2000c). To determine whether similar mechanisms were responsible for the increased levels of lamp2a during oxidative stress, we first compared the rates of degradation of lamp2a in membranes of lysosomes from rats fed, starved, or treated with paraquat. In contrast with the significant reduction in lamp2a degradation induced by starvation, degradation of lamp2a was only slightly slower in rats treated with paraquat than in untreated fed rats (Figure 7A). Likewise, the distribution of lamp2a between membrane and matrix was not significantly affected by the treatment with paraquat, suggesting that the increased levels of lamp2a in the membrane were not the result of recruitment of the lamp2a normally present in the lumen (Figure 7B).

Contrary to starved animals, levels of lamp2a mRNA in the liver of rats treated with paraquat were significantly higher than in untreated rats. We used both a dilution-based quantitative PCR method (Figure 7C) and real-time PCR (Figure 7D) to compare levels of lamp2a mRNA in livers from fed, starved, or paraquat (fed)-treated rats. Treatment with paraquat induced an increase in lamp2a mRNA levels of approximately sixfold in fed animals, whereas starvation resulted in a slight decrease in lamp2a mRNA levels. Therefore, contrary to starvation, where the increase in lamp2a levels did not require new protein to be synthesized, most of...
Figure 7. A novel mechanism for activation of CMA during mild oxidative stress. (A) Degradation of lamp2a in isolated membranes from normally fed rats, 48-h starved rats, or fed rats treated with paraquat (PQ), as indicated under Materials and Methods. Degradation of lamp2a was followed by immunoblot of the lysosomal membranes with an antibody specific against its cytosolic tail, at different times of the incubation. Values are the mean ± SD of the densitometric quantification of immunoblots from four different experiments. A representative immunoblot is shown in the top insets. (B) Distribution of lamp2a between the lysosomal membrane and the matrix in lysosomes isolated from normally fed rats, treated or not with PQ. Values are mean ± SE of the densitometric quantification of four immunoblots similar to the one shown in Figure 6B. (C) A 120-nucleotide fragment of lamp2a and a 108-nucleotide fragment of actin were amplified, through PCR, from increasing concentrations of total mRNA isolated from the livers of normally fed, 48-h starved, or paraquat-treated fed rats. The electrophoretic pattern of the products is shown in a 2% agarose gel. (D) Semi-quantitative real-time PCR was used to compare mRNA expression levels for lamp2a in the same samples as detailed in C. Values were corrected for actin amplification in each samples and are expressed as fold increase compared to mRNA lamp2a values in fed untreated rats (that was given an arbitrary value of 1). Values are mean ± SD for four different experiments. *, differences compared with fed animals (**p < 0.01, ***p < 0.001).

The increase in lamp2a levels detected in paraquat-treated animals was a consequence of de novo synthesis of the protein.

We conclude that activation of CMA is part of the normal oxidative stress response and it contributes to the selective removal of oxidized proteins from the cytosol. The higher rates of CMA observed under these conditions are the combined result of an increase in the susceptibility of the proteins to be taken up and degraded by lysosomes, and an enhanced ability of the lysosomes for substrate uptake. Unexpectedly, during mild oxidative stress, activation of CMA is mediated by a novel mechanism different from the previously characterized activation of CMA during nutritional stress.

DISCUSSION

Our results provide for the first time evidence for the participation of lysosomes in the removal of oxidized proteins during mild oxidative stress through CMA. This novel role for CMA is supported by the fact that 1) oxidized proteins can be detected in the lumen of lysosomes active for CMA (Figure 1); 2) in conditions with declined CMA, such as aging, the amount of oxidized proteins translocated into lysosomes is reduced (Figure 1B); 3) oxidized CMA substrates bind and are taken up more efficiently by isolated lysosomes than their unmodified forms (Figure 2); 4) lysosomes from cells or rats exposed to prooxidants display higher rates of binding and uptake of CMA substrate proteins (Figures 3 and 4); and 5) blockade of CMA in cultured cells increases their susceptibility to prooxidant compounds and decreases their viability (Massey, Kiffin, and Cuervo, unpublished data). Activation of CMA during oxidative-stress is attained through the up-regulation of specific components of the lysosomal translocation complex (lysosomal chaperones and the lysosomal membrane receptor) (Figures 5 and 6). Interestingly, although these changes are similar to the ones described when CMA is activated by nutritional stress, the mechanism involved in the up-regulation is different. Therefore, this finding suggests that stress-mediated activation of CMA varies depending on the nature of the stress.

Most of the previous studies on the lysosomal role during oxidative stress have focused on the contribution of this subcellular compartment to the oxidative damage, rather than on a possible protective role. In fact, the destabilizing effects of severe oxidative stress (>350 μM hydrogen peroxide) on lysosomes have been well documented (Brunk et al., 1995; Ollinger and Brunk, 1995), showing that the release of lysosomal enzymes plays a major role in intracellular damage and in cell death under these conditions. Lower concentrations of hydrogen peroxide (250 μM for 30 min) still cause leakage of some lysosomal enzymes, although the lysosomal damage is reversible (Brunk et al., 1995; Ollinger and Brunk, 1995). In our study, we did not find changes in the stability of the lysosomal membrane, assayed either as release of specific enzymes or with a more sensitive proteolytic method. It is possible that the lower doses of hydrogen peroxide and paraquat used in our study (100 μM and 40 mg/100 g body weight, respectively) were enough to originate cytosolic protein damage, but they did not alter the lysosomal compartment. Other possibility is that the initial lysosomal damage still takes place, but due to its reversibility under these conditions (Brunk et al., 1995; Ollinger and Brunk, 1995), it is not longer detectable by the time the lysosomes are isolated (24 h after the second injection).
because most of the studies regarding lysosomal stability and oxidative stress have been performed in intact cells, analyzing the leakage of fluorescent probes from the lysosomal compartment, we cannot discard that different lysosomal populations might be differently affected by prooxidants. In our assays, the cell fractionation method used has been optimized to isolate a subset of intracellular lysosomes active for CMA (10–15% of total) (Cuervo et al., 1997). Particular characteristics of the CMA-active lysosomes, such as, for example, a lower concentration of iron in their lumen, could explain their higher resistance to prooxidants. Our studies on CMA-active lysosomes in old animals also support their unique characteristics. Thus, although accumulation of lipofuscin in lysosomes is a commonly used biomarker of aging, CMA-active lysosomes from old rat livers rarely accumulate this pigment (Cuervo and Dice, 2000a).

The ability of proteasomes to degrade oxidized proteins has been previously well documented in vitro (Rivett, 1985; Davies, 2001), and more recently in vivo (Grune et al., 2002a; Hosler et al., 2003; Shringarpure et al., 2003). Most of the studies assessing oxidation-induced changes in lysosomal proteolytic behavior have focused in the analysis of the enzymatic activity of cathepsins, the lysosomal proteases. Moderate oxidative stress does not significantly change the activity of most cathepsins, whereas more severe oxidizing conditions result in increased or decreased cathepsin activity depending on the cellular conditions (Sitte et al., 2000a,b). This lack of correlation between the intracellular accumulation of oxidized proteins and the activity of lysosomal enzymes sets the basis for arguments against the lysosomal participation in removal of oxidized proteins (Sitte et al., 2000a). However, the activity of the lysosomal proteases is a nonlimiting step for any of the forms of autophagy. The intralysosomal concentration of cathepsins is such that, once substrates reach the lysosomal lumen, they are rapidly degraded. This makes the delivery of substrates the limiting step. Bergamini and colleagues were one of the first groups to point out that, if the degradation of proteins by lysosomes, instead of the enzymatic activity of lysosomal proteases, is considered, there is a good inverse correlation between lysosomal proteolysis and intracellular content of oxidized proteins (Vittorini et al., 1999). Our current study also supports a good correlation between the intracellular content of oxidized proteins and the delivery of substrate to lysosomes via CMA (binding/uptake).

We have previously shown that, in the group of lysosomes active for CMA, the activity of most lysosomal enzymes does not change significantly with age, and yet rates of CMA are lower in aged cells (Cuervo and Dice, 2000a). The impaired ability of this group of lysosomes to take up substrates in older animals could explain why there is a lower content of oxidized proteins in their lumen, despite the higher level of oxidized cysteic proteins (Figure 1B). It is unlikely that the lower levels of oxidized proteins detected in the lysosomal lumen of old rats, result from faster degradation of these proteins inside lysosomes, because even when we inhibited lysosomal degradation in rats, before lysosomal isolation (by i.p. of leupeptin; our unpublished results), we still found lower content of oxidized proteins in the lysosomes from the oldest animals.

The contribution of proteasomes to the removal of oxidized proteins in vivo has been demonstrated by analyzing the consequences of blocking its catalytic activity in oxidized protein removal (Grune et al., 2002a; Hosler et al., 2003; Shringarpure et al., 2003). This approach, however, cannot be used to evaluate the contribution of autophagy in this process. Even if the lysosomal proteases are inhibited (either with specific protease inhibitors or by raising the intralysosomal pH), we do not expect to find changes in the cytosolic content of oxidized proteins, because only their proteolysis, but not their translocation into the lysosomal lumen, would be blocked. The accumulation of undegraded products in the lysosomal lumen can be tolerated for a long time without affecting their translocation ability. An alternative approach would be to directly inhibit the delivery of the substrates. No chemical inhibitors are available to block CMA. We have recently succeeded in blocking substrate translocation by using RNA interference against the lysosomal receptor in cultured fibroblasts (Massey, Kiffin, and Cuervo, unpublished data). As mentioned before, these cells have a lower resistance to oxidative stress. However, even in this system, it is difficult to assess lysosomal versus proteasome contribution, because blockage of CMA results in changes in the composition of the 20S/26S proteasomes and, consequently, in its proteolytic activities (Massey, Kiffin, and Cuervo, unpublished data). Likewise, chronic inhibition of proteasomes, similar to the one that occurs in aging, alters the ability of the cells to activate autophagy in response to stress (Ding et al., 2003). Although an experimental challenge, this cross-talking among the different proteolytic systems offers perhaps a more physiological view of what is really happening in the cells during oxidative stress. In the same way that the relative contribution of proteasomes and lysosomes to total protein degradation varies depending on the cell type and on the cellular conditions (Fuertes et al., 2003), participation of these two systems in the removal of oxidized proteins is probably also dynamic. In fact, there are now numerous examples of proteins that can be degraded by more than one proteolytic pathway (Cuervo et al., 1998; Lenk et al., 1999). Future studies should be directed at understanding how those fluctuations are regulated and to identify possible ways of stimulating one system to compensate for the failure of another.

Whereas during severe oxidative stress, protein aggregation and cross-linking are common events, mild oxidative stress has been shown to generate excellent proteolytic substrates (Grune et al., 1995; Gomes-Marcondes and Tisdale, 2002). Our work supports that in the case of CMA, mild oxidation of CMA substrates facilitates not only their degradation by lysosomal proteases but also their binding/translocation across the lysosomal membrane (Figure 4A). Although the exact mechanism behind this facilitated uptake is still elusive, we hypothesize that protein unfolding, likely to occur during oxidation (Imai et al., 2003), could accelerate uptake, by diminishing the time required for substrate unfolding before translocation. Oxidized substrates were taken up faster by lysosomes even when we did not add cytosolic hsc70 in the translocation cocktail (our unpublished data). However, because the isolated lysosomes contain significant amounts of hsc70 in the cytosolic side of the membrane, we cannot discard that partial unfolding might make the KFERQ-motif more accessible for the interaction with hsc70 and facilitate in this way unfolding/translocation of the substrate. Our unpublished data showing that manipulations, such as partial denaturation of CMA substrates or extensive truncation, increase their rates of uptake into lysosomes via CMA (Salvador, Aguado, Cuervo, and Knecht, unpublished data), also support the proposed facilitating role of partial protein unfolding under mild oxidative conditions. Whether the activation of CMA under these conditions is a response to the presence of these partially unfolded proteins in the cytosol, or it is mediated by other cytosolic components generated during the oxidative stress remains to be elucidated.

An interesting remaining question is how the cells decide whether an oxidized protein should be degraded by the proteasome or in the lysosomal compartment. About 30% of
cytosolic proteins contain a KFERQ-motif, suggesting that, in theory, this would be the subset of proteins degraded through CMA during mild oxidative stress (Figure 1A). However, a very intriguing idea proposed by Gracy et al., 1998 is that some amino acid modifications, such as deamination and oxidation, could result in the generation of KFERQ-like containing motifs in proteins previously lacking this sequence. As other targeting motifs, the KFERQ-like motif is degenerate, resulting from the combination of a basic, a hydrophobic and an acidic residue with a fourth basic or hydrophobic residue, flanked on either side by a glutamine. Oxidation for example of a histidine to aspartic acid could provide the acid residue necessary to complete a KFERQ-like motif. On the other hand, the same process could eliminate KFERQ-like motifs in proteins that normally are substrates for this pathway, resulting in their impaired degradation in conditions such as aging. This modification of the targeting motif, added to the fact that CMA activity decreases with age, could explain the lower content of oxidized proteins in the lumen of CMA active lysosomes in old rats, despite the higher levels of oxidized proteins in their cytosol. Our laboratory is currently trying to identify changes in the targeting motif of CMA substrates with age using a shot-gun proteomic approach.

Particularly exciting is the finding that although activation of CMA during oxidative and nutritional stress have the same consequences on the levels of the lysosomal translocation components, up-regulation, at least for the lysosomal receptor, obeys different mechanisms. During starvation CMA is activated to supply the cells with amino acids required for the synthesis of essential proteins. Under these conditions, de novo synthesis of lamp2a to increase CMA rates is probably not a reasonable option due to the shortage of amino acids. Instead, more conservative mechanisms (down-regulation of lamp2a degradation and intralysosomal relocation) are adopted (Cuervo and Dice, 2000b). If oxidative damage takes place under normal nutritional conditions, as the supply of amino acids would not be compromised, de novo synthesis of lamp2a is up-regulated to activate CMA (Figure 7C). De novo synthesis might be advantageous under these conditions, because it provides a faster mechanism for CMA activation.

In conclusion, we have identified for the first time a role of CMA as part of the oxidative stress response. Because CMA activity is severely impaired during aging, we hypothesize that part of the accumulation of oxidized proteins observed in old organisms may result from the malfunctioning of CMA. Future efforts aimed to restore normal CMA activity in old cells would help to understand the relevance of the cross-talk among different proteolytic pathways, and the compensatory mechanisms activated when the activity of one or more of these pathways is compromised.

ACKNOWLEDGMENTS
We gratefully acknowledge Dr. Fernando Macian and the other members of our laboratory for valuable suggestions and comments. This work was supported by the National Institutes of Health/National Institute on Aging grant AG-021904, by an Ellison Medical Foundation Aging Research Award (to A.M.C.), and by the Ministerio de Ciencia y Tecnologia of Spain grants BMC2001-0816 and SAF2002-0026 and Fondo de Investigación Sanitaria grant RGDM-G031212 (to E.K.).
