Although sphingosine 1-phosphate (S1P) has been considered a potent regulator of skeletal muscle biology, acting as a physiological anti-mitogenic and prodifferentiating agent, its downstream effectors are poorly known. In the present study, we provide experimental evidence for a novel mechanism by which S1P regulates skeletal muscle differentiation through the regulation of gap junctional protein connexin (Cx) 43. Indeed, the treatment with S1P greatly enhanced Cx43 expression and gap junctional intercellular communication during the early phases of myoblast differentiation, whereas the down-regulation of Cx43 by transfection with short interfering RNA blocked myogenesis elicited by S1P. Moreover, calcium and p38 MAPK-dependent pathways were required for S1P-induced increase in Cx43 expression. Interestingly, enforced expression of mutated Cx43A130–136, used gap junction communication and totally inhibited S1P-induced expression of the myogenic markers, myogenin, myosin heavy chain, caveolin-3, and myotube formation. Notably, in S1P-stimulated myoblasts, endogenous or wild-type Cx43 protein, but not the mutated form, coimmunoprecipitated and colocalized with F-actin and cortactin in a p38 MAPK-dependent manner. These data, together with the known role of actin remodeling in cell differentiation, strongly support the important contribution of gap junctional communication, Cx43 expression and Cx43/cytoskeleton interaction in skeletal myogenesis elicited by S1P.

INTRODUCTION

Skeletal muscle formation during development requires several cellular and molecular events that lead to the maturation of myoblasts into multinucleated myofibers. The onset of the terminal differentiation process is characterized by cell cycle withdrawal and myogenin synthesis followed by the expression of muscle-specific genes including sarcomeric proteins and creatine kinase (CK; Lassar et al., 1989). Adult skeletal muscle has the ability to regenerate after injury from quiescent mononucleated satellite cells which, lying between the sarcolemma and the basal lamina, use the same differentiation program as developing myoblasts (Hawke and Garry, 2001; Grounds et al., 2002). Although much remains to be learned on the inductive factors and molecular mechanisms involved in the myogenesis, it is well established that diverse intercellular signaling pathways may influence the regulation of myoblast differentiation during development and regeneration of skeletal muscle. One of them is mediated by gap junctions, specialized membrane regions composed of aggregate of intercellular channels connecting directly the adjacent cells (Simons and Goodenough, 1998). Each intercellular channel is formed by the conjunction of two hemichannels composed of six protein subunits belonging to the connexin family, whose connexin (Cx) 43 is the most widely expressed member (Shez et al., 2003). Although absent in adult skeletal muscle fibers, Cx43 is present in the early stages of myogenesis, and Cx43-containing gap junctions are required for determining the correct cellular specification during myogenesis (Araya et al., 2003). Indeed, Cx43 is transiently expressed in myoblasts being down-regulated before their fusion into multinucleated myotubes (Gorbe et al., 2005). Moreover, the application of connexin channel blockers (Proulx et al., 1997a) as well as the inducible deletion of Cx43 protein (Araya et al., 2005) have been shown to dramatically affect myogenic differentiation, whereas the overexpression of Cx43 by rhabdomyosarcoma cells has been described as enhancing the differentiation capacity (Proulx et al., 1997b). In general, the effects of Cx43 expression have been attributed to the role of gap junctions in the establishment of organized pathways for the intercellular transfer of small metabolites and messenger molecules necessary for the coordination and guide of the interacting myoblasts to their final differentiation (Goldberg et al., 1999). However, evidence is accumulating that connexins may have additional functions independent of their gap channel-forming ability (Giepmans, 2004; Stout et al., 2004; Jiang and...
Sphingosine 1-Phosphate Induces Myoblast Differentiation

Gu, 2005). Indeed, several lines of evidence have shown that Cx43 regulates cell growth and migration by mechanisms that do not require intercellular communication in normal and transformed neuronal and epithelial cells (Huang et al., 1998a, 1998b; Omori and Yamasaki, 1998; Moobry and Patel, 2001; Qin et al., 2002). Moreover, the exogenous expression of mutant nonfunctional connexins has been reported to protect glial cells against injury and apoptotic cell death (Lin et al., 1998). So far, no evidence of the existence of a direct action of the Cx43 protein on the regulation of cell differentiation and skeletal muscle formation has been reported.

Sphingosine 1-phosphate (SIP) is a bioactive lipid that participates in the regulation of numerous cellular processes, such as cell proliferation, differentiation, migration, and apoptosis, and acts as intracellular mediator and ligand for specific SIP receptors (Saba, 2004). We have recently shown that SIP is a potent inducer of skeletal muscle differentiation (Donati et al., 2005), and its specific Edg5/SIP2 receptor is down-regulated during myogenesis (Meacci et al., 2003). Notably, we have also demonstrated that the activity and protein content of sphingosine kinase, the enzyme catalyzing the formation of SIP, is greatly enhanced in differentiating C2C12 myoblasts, and its silencing delays myoblast maturation, thus implicating a physiological role of SIP in myogenesis (Meacci, E., Nuti, F., Donati C., Cencetti, F., Farnararo, M., and Bruni, P., unpublished results).

On the basis of the above reported observations, in the present study we investigated whether the regulation and assembly of Cx43 into gap junctions could represent a critical event in C2C12 myoblast differentiation elicited by SIP and whether Cx43 protein per se could contribute to this process.

MATERIALS AND METHODS

Cell Cultures

Murine C2C12 myoblasts (American Type Culture Collection, Manassas, VA) were routinely grown in Dulbecco’s modified Eagle’s medium (DMEM; Sigma, St. Louis, MO) supplemented with 10% fetal calf serum (FCS, Sigma). For proliferation experiments, cells were seeded in 96-well plates and utilized when ~50% confluent. For myogenic differentiation experiments, cells were grown in 100-mm dishes or six-well plates until 95% confluent and induced to differentiate by switching to differentiation medium (DMEM containing 2% horse serum (HS, Sigma) for different times (24, 48, and 72 h and 5 d) in the presence or absence of SIP (1 μM, 2 mM stock solution in dimethyl sulfoxide, Calbiochem, La Jolla, CA).

Cell Treatments

C2C12 cells were challenged with 5 μM of the specific p38 MAPK inhibitor SB203580 (Calbiochem) prepared in 0.05% DMSO, 30 min before agonist addition. The specific effect of the various inhibitors was tested by Western blot analysis evaluating the phosphorylation status of p38 MAPK and ERK1/2. To investigate calcium-dependent events, inhibitors was tested by Western blot analysis evaluating the phosphorylation of 2% horse serum (HS, Sigma) for different times (24, 48, and 72 h and 5 d) in the presence or absence of SIP (1 μM, 2 mM stock solution in dimethyl sulfoxide, Calbiochem, La Jolla, CA).

Silencing of Cx43 by siRNA

To silence the expression of Cx43, short interfering RNA duplexes (siRNA) were used (Santa Cruz Biotechnology, Santa Cruz, CA) corresponding to three distinct regions of the DNA sequence of mouse Cx43 gene (NM_010288; 5’CCCCAACUGACUACUGACAGA3’, 5’CCCCACAAAAGU UCUUC3’, and 5’CCUCCAGUUUCUUCCAGU3’). The sequences were evaluated against the database using the NIH Blast program to test for specificity. A non-specific scrambled (SCR) siRNA was used as control. C2C12 cells grown in 60-mm dishes in DMEM supplemented with 10% FCS were transfected with the mixed combination of the above reported three RNA duplexes, using Lipofectamine 2000 reagent (1 mg/ml; Invitrogen, Carlsbad, CA) according to the manufacturer’s instructions. Briefly, lipofectamine 2000 was incubated with Cx43 siRNA (ratio 2:1) at room temperature for 20 min, and successively the lipid/RNA complexes were added with gentle agitation to C2C12 cells. Twenty-four hours after transfection, cells were shifted to DM in the presence or absence of SIP for a further 48 h and used for the experiments. Longer incubation times had deleterious effects on C2C12 cell viability and survival, as evaluated by visual inspection and MTS-dye reduction assay (Promega, Madison, WI). To evaluate the specific knock-down of Cx43, cell lysates from myoblasts transfected with Cx43- or SCR-siRNA were immunoblotted, and protein was detected using specific anti-Cx43 antibodies.

Construction of GFP-wtCx43 and Mutated GFP-Cx43A130–136 Expression Vectors

Cx43 cDNA was obtained by reverse transcription of 1 μg of total RNA extracted from C2C12 myoblasts using TRIREAGENT (Sigma), according to the manufacturer’s protocol and amplified using SuperScriptOne-Step RT-PCR (Invitrogen) as described in the manufacturer’s protocols. Different expression vectors designed in the coding region: forward primer 1: 5’ATGGGTGACTGGACCGACGCCCTTG3’ and reverse primer 1: 5’GGCACGTGTGATGTC- AAGCTGCTG3‘ and A cDNA fragment corresponding to mouse Cx43 with a deletion of 2 amino acids 130–136 (Krutovskikh et al., 1998a, 1998b; Upham et al., 2003) was obtained by the amplification of two overlapped fragments: fragment A was amplified using forward primer 1 and the reverse primer 2 (5’TCAAATCCGAAATCTGTCGACATG3‘) and fragment B amplified using forward primer 2 (5’GGCACGTGTGATGTC-AAGCTGCTG3‘) and reverse primer 1. Cx43 (wtCx43) or Cx43A130–136 (DNcx43) cDNAs were subcloned into the mammalian expression vector pDNA3.1/NT-GFP-TOPO using the TA cloning kit and following the manufacturer’s supplied protocol (Invitrogen). The nucleotide sequences of all PCR products were confirmed by automated DNA sequencing.

Stable Cell Transfections

To obtain cells stably overexpressing GFP-wtCx43 or GFP-DNCx43, myoblasts were plated onto 60-mm dishes and transfected using Lipofectamine 2000 reagent (1 mg/ml) mixed with pGFP-wtCx43, pGFP-DNCx43, or plasmid alone. After 36 h, the cells were replated in the presence of G418 (500 μg/ml; Invitrogen) and expanded under selective conditions. Selected bulk population was used to avoid potential phenotypic changes due to selection and propagation of clones from single individual cells. Ectopic Cx43 expression levels were routinely monitored by Western blot analysis using specific anti-Cx43 or anti-GFP antibodies (Invitrogen). Empty vector-transfected cells were utilized as control. Because previous studies have shown that enforced expression of connexins can affect cell survival, MTS-dye reduction assay (Promega) in vector control and GFP-wtCx43– or GFP-DNCx43–transfected cells was performed. The capability of reducing MTS dye after 24 h of S1P deprivation evaluated in GFP-wtCx43– or GFP-DNCx43–expressing myoblasts was not significantly different from that in control cells transfected with empty vector alone (0.76, 0.81, and 0.79 arbitrary units, respectively; data are media ± SEM; n = 3 for independent experiments performed in quadruplicate, with SEM always <15%.

Reverse Transcription and cDNA Amplification

Total RNA (1 μg), isolated using TRIREAGENT (Sigma) from cells incubated in the presence or the absence of SIP for 24, 48, and 72 h was added to 4 μl of 2.5 mM dNTP and 1 μl of 0.5 μg/ml random primers. Reverse transcription was performed at 42°C for 60 min using Superscript II reverse transcriptase (Invitrogen) as described in the manufacturer’s protocols. Different amount of reverse transcription reaction was used for semiquantitative PCR in the presence of mouse Cx43 gene-specific primers designed in the coding region: forward primer 1 (5’ATGGGTGACTGGACCGACGCCCTTG3‘) and the reverse primer 2 (5’TCAAATCCGAAATCTGTCGACCATG3‘). Amplified DNA was separated by electrophoresis onto 1.8% agarose gel, and exact size was evaluated by comparison with PCR 100-base pair Low Ladder (Sigma), β-actin, was amplified using specific primers (forward: 5’TCACTGCTGCTGGTACCC3‘ and reverse: 5’GATGAAATGGTGAAGTCTC3‘). Intron) and used as an internal reference control to normalize relative levels of gene expression.

Lysate Preparation and Western Blot Analysis

Native, silenced, and stable overexpressing C2C12 myoblasts were incubated in the presence of the absence of SIP and/or inhibitors, washed twice in cold PBS, scraped, and lysed for 30 min at 4°C in lysis buffer containing 50 mM Tris, pH 7.5, 120 mM NaCl, 1 mM EDTA, 6 mM EGTA, 15 mM Na2PO4, 20 mM NaF, 1% Nonidet, and protease inhibitor cocktail (1.04 mM Aprotinin, 0.08 mM leupeptin, 0.02 mM bestatin, 15 μM pepstatin A, and 4897

Vol. 17, November 2006
Figure 1. Effects of S1P on Cx43 expression and protein localization in C2C12 myoblasts. (A) RT-PCR analysis. Total RNA (1 μg), prepared from C2C12 myoblasts incubated in DM at the indicated times in the absence (−) or presence (+) of 1 μM S1P, was used for reverse transcription and semiquantitative PCR analysis. An ethidium bromide–stained 1.8% agarose gel showing a band corresponding to Cx43 of the expected size (390 base pairs) is reported. Quantitative analysis of Cx43 mRNA expression is shown in the graphic as relative.
Lucifer Yellow Dye Transfer Analyses

To reveal functional gap junctions, the gap junction-permeant dye Lucifer yellow (20% in PBS; Molecular Probes) was microinjected into single cells under a phase-contrast microscope using a pressure injection system (Femtotest InjectMan NIZ, Eppendorf, Hamburg, Germany) as previously described (Bodnar et al., 2004). Lucifer yellow fluorescence was detected using a Nikon Diaphot 300 microscope equipped with fluorescence illumination and FITC filters (excitation 488 nm, emission 512 nm) and photographed using a Nikon digital camera (1 image per second). The specificity of dye transfer was tested by pretreatment with heptanol (1 mM, Sigma), a blocker of gap junction coupling. The extent of gap junction intercellular communication was quantified by counting the number of fluorescent cells surrounding each injected cell (number of dye-coupled cells/microinjection). At least 20 independent microinjections were performed for each sample (n = 3).

Electrophysiological Measurements

Electrophysiological properties of both gap junctions and hemichannels were investigated. Experiments aimed to study gap junction channels were accomplished in C2C12 cell pairs by dual whole cell patch-clamp, as previously described (Formigli et al., 2005a, 2005b). C2C12 myoblasts were used after 24 h of culture in DM in the presence or absence of S1P. Initially, the membrane potentials of cell 1 (V1) and 2 (V2) were clamped to the same value, V1 = V2. V was then changed to establish a transjunctional voltage V1 - V2 = V. Current I1 was stepped using a bipolar pulse protocol. The pulses were 4.7 s long. Currents recorded from cell 1 represented the sum of two components: the transjunctional current (I1) and the membrane current of cell 1. Currents recorded from cell 2 corresponded to -I1. The electrophysiological properties of connexin hemichannel, Igap, current, and Ggap, conductance, and the I-V relationship were studied in single cells using a single pulse protocol. The currents were 4.7 s long. The membrane potential was -60 mV. The amplitudes of Igap, were determined at the beginning (Igap,initial) and at the end of each pulse (Igap,final) to estimate the conductances Ggap,initial and Ggap,final. The normalized Ggap,initial values were calculated from the ratios Igap,final/V, normalized to the maximal Igap,final at 70 mV, averaged, and plotted versus V. The normalized Ggap,initial-V plots were fitted by the Boltzmann equation: Ggap,initial = (Ggap,max - Ggap,min)/(1 + e(A(V - V0))/V2), where Ggap,max and Ggap,min are the maximal and minimal conductances at large positive and negative V, respectively. V0 corresponds to V at which Ggap,initial is half-maximally activated. In some experiments, we used the Tyrode solution or a bath solution as that previously reported by Valius et al., (2002). In the presence of both solutions we observed an outward K+ current that appeared at positive potentials. This indicated that some voltage-dependent K+ channels were not activated by an holding potential of 0 mV (Kondo et al., 2000). Therefore, to block K+ channels and to improve the open state of hemichannels (Valius et al., 2002), a bath solution containing TEA and low Ca2+ concentration: 122.5 mM NaCl, 0.5 mM CaCl2, 20 TEA-Cl, and 10 mM HEPES was used.

Creatine Kinase Assay

After 72 h of culture, cells were washed with PBS and homogenized in 20 mM Tris-HCl buffer, containing 1 mM EDTA, pH 7.2. The 20,000 x g supernatant was used to measure the activity of muscle creatine kinase (CK), as previously described (Naro et al., 1999). CK-specific activity was calculated and expressed as arbitrary units/mg.

Immunoprecipitation

Stable overexpressing myoblasts were grown in DMEM supplemented with 10% FCS to confluence and switched to DM. Nonmyocytes were incubated in growing medium and switched to DM in the presence or absence of 5 mM SB239063, 30 min before S1P stimulation. After 24 h both cell preparations were washed in PBS and harvested on ice in 200 μl of precipitation buffer containing 1 mM EDTA, 50 mM NaCl, 50 mM NaF, 500 μM Na3VO4, 0.5% Triton X-100, and protease inhibitors (Sigma), and 2 mM phenylmethylsulfonyl fluoride, pH 7.2) as previously described (Singh et al., 2005). Lysates were cleared by centrifugation at 10,000 x g for 10 min, and the cell supernatant was used. For immunoprecipitations, polyclonal anti-Cx43 antibodies were incubated with cell lysates for 3 h followed by immunoprecipitation with protein A-Sepharose beads for 1 h. The beads were washed extensively in PBS, and bound proteins were eluted in Laemmli sample buffer followed by separation on SDS-PAGE and immunodetection using anti-cortactin and anti-actin antibodies (Cytokeleton) or anti-Cx43 as described in Western Blot Analysis above.

Presentation of Data and Statistical Analysis

Results are expressed as mean ± SEM. Statistical significance was determined by Student’s t test, with a value of p < 0.05 considered significant. In RT-PCR and immunoblot experiments, densitometric analysis of the band intensities
was performed using Imaging and Analysis Software by Bio-Rad (Quantity-One), determined by calculating the Cx43/β-actin ratios as percentage of control (set at 100), and reported as means ± SEM. Densitometric analysis of the intensity of the immunostaining for Cx43 was carried out on digitized images using NIH ImageJ software (NIH). In electrophysiological experiments, statistical analysis of differences between the experimental groups was performed by one-way ANOVA and Newman-Keuls post-test (p < 0.05 was considered significant). Calculations were made with Graph Pad Prism statistical program (GraphPad Software, San Diego, CA), pClamp9 (Axon Instruments, Foster City, CA), SigmaPlot and SigmaStat (Jandel Scientific, San Francisco, CA).
Figure 3. Effect of inhibition of calcium increase, ERK1/2, and p38 MAPK on S1P-induced Cx43 and myogenin expression in C2C12 myoblasts. (A) Confluent C2C12 cells were treated with 15 μM BAPTA/AM or 10 μM PD98059 or 5 μM SB239063 or each specific vehicle for 30 min before incubation in DM in the presence (+) or absence (−) of 1 μM S1P for 48 h. The content of Cx43 and myogenin were analyzed on cell lysates by Western blot. Equally loaded protein (30 μg) was checked by expression of the nonmuscle specific β-actin. Band intensity was determined by densitometry and relative percentage to control arbitrarily normalized to 100 is shown in the graphic. A blot representative of at least three independent experiments is shown.

Data were obtained from C2C12 cells incubated in DM for 24 h in the absence (−) or presence (+) of S1P. The parameters were obtained by fitting normalized Gj,ss and GCh,ss vs. voltage data (20–24 for each experimental condition).

Note that Boltzmann parameters at negative Vj, Vj(−), are significantly different with respect to those at positive Vj, Vj(+), in control but not in S1P-stimulated cells; ³ p < 0.05 for Vj(−) vs. Vj(+); ⁴ p < 0.05 for S1P-stimulated cell pairs vs. controls.

For hemichannel analysis, the value A representing the GCh,ss voltage sensitivity is significantly increased in S1P-stimulated cells with respect to their control counterpart; ⁵ p < 0.05. Data are presented as mean ± SEM.
**RESULTS**

**SIP Induces Cx43 Protein Expression and Gap Junctional Communication in Differentiating Myoblasts**

We first sought to determine whether Cx43 could be a possible target of S1P-induced C2C12 myoblast differentiation by RT-PCR and Western blot analysis in differentiating cells. As reported in Figure 1, A and B, Cx43 was greatly up-regulated at the mRNA and protein levels in differentiating cells and, particularly, in those treated with SIP, indicating that the bioactive lipid acted as a potent inducer of Cx43 expression in C2C12 myoblasts. In particular, the expression of the gap junction protein gradually increased from 24 h up to 72 h and then declined with the progression of myogenesis, being barely detected in cells at 5 d of differentiation and in fully differentiated cells (unpublished data). Cx43 was found as a prevalent band of 43 kDa in control cells and as multiple bands of 40–46 kDa in S1P-treated myoblasts, suggesting that the bioactive lipid could also affect Cx43 posttranslation modifications. Parallel experiments were performed to verify whether SIP treatment affected the expression of other connexin such as Cx39, an isoform recently identified in differentiating myoblasts (von Maltzahn et al., 2004, 2006; Belluardo et al., 2005). As shown in Figure 1B, Cx39 was weakly detectable in C2C12 myoblasts, and its expression was not affected by SIP, at least in the early stages of differentiation.
hours of differentiation (24–48 h). However, the expression level of Cx39 increased significantly in differentiating cells starting from 72 up to 120 h of incubation in DM, especially in the presence of S1P (Figure 1).

Confocal immunofluorescence confirmed the temporal regulation of Cx43 protein expression detected by Western blot analysis (Figure 1C). Confluent C2C12 myoblasts expressed some Cx43 immunostaining, distributed as small green fluorescent dots both in the cytoplasm—in the perinuclear regions—and at the cell surface. However, after 24 and 48 h of S1P stimulation, the expression of Cx43 appeared remarkably increased compared with the levels detected in untreated cells. The immunofluorescent dots were abundantly found in the cytoplasm, likely within the protein synthesis pathway, as well as among regions of intimate cell-to-cell contacts, compatible with the formation of gap junction plaques. Of interest, the quantification of the fluorescent signal indicated that cells treated with S1P for 5 h and left in DM in the absence of the bioactive lipid for additional 20 h, showed higher levels of Cx43 than the untreated cells, consistent with an effect of S1P on the protein expression in the early hours of incubation (Figure 1C).

The increase of immunoreactive Cx43 at the appositional plasma membranes between adjacent myoblasts after S1P stimulation was consistent with the functional differences in the gap junction permeability, as detected by Lucifer yellow dye-transfer assay (Figure 2A). The efficacy of dye spreading in control was very low, with ~20% of the cells showing dye coupling with only one neighboring cell. After 24 and 48 h of incubation in DM the extent of dye transfer slightly increased, with ~30% of the cells showing 1–2 or 2–3 coupled cells, respectively. The long-term treatment with S1P significantly increased the extent of gap junction communication over that evaluated in controls, with ~50 and 70% of the cells showing 1–2 and 3–4 coupled cells per injection, after 24 and 48 h of stimulation, respectively.

To further investigate the role of S1P on intercellular communication, we characterized the biophysical properties of gap junctional current by dual whole cell voltage-clamp. Figure 2B shows transjunctional current traces (Ij) in representative cell pairs in control condition and after 24 h of treatment. Interestingly, the amplitude of Ij and transjunctional conductance (Gj,ss) increased significantly at all the voltage values in cells treated with S1P. The dependence of this current and conductance on junctional channels was established by assessing its sensitivity to heptanol, a commonly used gap junction channel blocker. As expected, heptanol (1 mM) was able to inhibit both Ij and Gj,ss within
3–5 min (Figure 2B), since \( G_{j,ss} \) at +10 mV ranged from 0.62 ± 0.04 \((n = 8)\) to 0.72 ± 0.05 \((n = 9)\) nS in control and stimulated cell pairs, respectively. Of interest, best-fit Boltzmann parameters showed that control cells had a slight asymmetrical voltage-dependent currents (Table 1). In keeping with our data that Cx39 was only weakly detectable in C2C12 myoblasts and in consideration that ambiguous data exist on the expression of Cx45 in these cells (Araya et al., 2005; von Maltzahn et al., 2006), we suggested that the asymmetric Boltzmann parameters were predominantly due to the inside-outside voltage dependence of Cx43 Gj previously described (White et al., 1994). However, the plot became symmetric after treatment with SIP and showed a slower inactivation compared with control, suggesting that SIP could affect the inside-outside voltage-dependence of Cx43-containing gap junctions, by reducing the fast gating, acting in the same manner as other chemicals (Bukauskas et al., 2001). Finally, we demonstrated that SIP affected the hemichannel permeability during the early phases of myogenesis.

Calcium Increase and p38 MAPK Activity Are Involved in SIP-induced Cx43 Expression

Because gap junctions are required for normal myogenesis (Araya et al., 2005), we next investigated whether known mediators of the myogenic program and known targets of SIP, such as Ca\(^{2+}\) and p38 MAPK (Meacci et al., 2002a; Porter et al., 2002; Cabane et al., 2003; Donati et al., 2005), could also play a role in the regulation of Cx43 expression induced by the bioactive lipid. To this end, we used BAPTA/AM (15 \(\mu M\)), a calcium chelator capable of preventing intracellular calcium increase, or SB239063 (5 \(\mu M\)), a specific inhibitor of p38 MAPK, and focused our observations on the time period where the effect of SIP on protein expression was predominant (48 h). As shown in Figure 3, depletion of Ca\(^{2+}\) by BAPTA/AM as well as inhibition of p38 MAPK activity by SB239063 prevented SIP-induced Cx43 up-regulation and strongly reduced expression of myogenin (Figure 3) and myosin heavy chain (MHC) and caveolin-3 (cav-3; unpublished data). Notably, no significant change was observed in the expression of Cx43 as well as of the other myogenic markers in myoblasts treated with PD98057 before SIP addition, suggesting that ERK1/2 activity was not required for Cx43 expression and myogenesis. Moreover, BAPTA/AM or PD98057 was unable to affect basal Cx43 and myogenin expression, whereas SB239063 strongly reduced Cx43 expression below the control. Taken together, these results indicated that SIP regulated the expression of Cx43 through the activation of both Ca\(^{2+}\)- and p38 MAPK-dependent pathways.

Cx43 Protein Expression Is Required for Myoblast Differentiation Promoted by SIP

To investigate whether Cx43 expression represented an essential step in the myogenesis elicited by SIP, C2C12 myoblasts were transfected with a mix of specific siRNA duplexes directed against three distinct regions of mouse Cx43 mRNA or with plasmids encoding either for dominant negative mutant Cx43A130–136 or wild-type Cx43 fused to GFP (GFP-DNCx43, GFP-wtCx43) and examined for myogenic marker expression after 48 h of incubation in DM. Preliminary experiments were performed to verify the expression level of Cx43 in silenced and stable overexpressing myoblasts. As shown in Figure 4, A and B, Cx43 was significantly

Data were obtained from vector, GFP-DNCx43 and GFP-wtCx43 cells incubated in DM for 24 h in the absence (−) or presence (+) of S1P. The parameters were obtained by fitting normalized Gj,ss and GhCh,ss vs. voltage data (15-20 recordings for each experimental condition). Gj,ss is asymmetrical in unstimulated and S1P-stimulated cells. As regards hemichannel parameters, in vector control cells, the value A, representing the GhCh,ss voltage sensitivity, is significantly increased in S1P-treated cells with respect to their control counterpart (p < 0.05). In GFP-DNCx43 and GFP-wtCx43 cells, the voltage sensitivity are significantly decreased or increased, respectively, with respect to vector control cells (p < 0.05). Data presented as mean ± SEM.

down-regulated in Cx43-siRNA-treated myoblasts both in unstimulated and stimulated cells. A band of ~75 kDa, consistent with the predicted molecular weight of Cx43 protein fused to GFP, was immunodetected in GFP-DNCx43 as well as in GFP-wtCx43-overexpressing myoblasts, and its expression appeared not to be affected by S1P treatment (Figure 4C). Confocal microscopy, performed to reveal the in situ localization of recombinant Cx43, showed that both GFP-wtCx43 and GFP-DNCx43 were present in the cytoplasm as well as at the plasma membrane. However, the localization of the mutated protein at cell–cell contacts, was less clear than that of wild-type Cx43, indicating some alterations in the organization of gap junctional plaques in GFP-DNCx43 myoblasts (Figure 4D).

Interestingly, the down-regulation of the endogenous Cx43 protein or the enforced expression of mutated form dramatically reduced myogenic differentiation in control and S1P-stimulated cells, as judged by Western blot analysis for the expression of the myogenic markers (Figure 5, A and B) and by CK assay (3.3 ± 0.04 vs. 8.2 ± 0.09 U/mg in S1P-treated GFP-DNCx43 cells vs. S1P-stimulated C2C12 cells, p < 0.05, n = 3). In addition, both Cx43-siRNA-treated or GFP-DNCx43 cells showed a delay in myoblast maturation, retaining spherical or star-shaped morphology at 48 h of differentiation in the presence or absence of S1P (Figure 4B). By contrast, as shown in Figure 5B, enforced expression of GFP-wtCx43 accelerated C2C12 myoblast differentiation. All these data indicated that Cx43 expression and plasma membrane localization were required for skeletal muscle differentiation.

To understand the mechanisms by which Cx43 protein could regulate S1P-induced myogenesis, myoblasts overexpressing GFP-wtCx43 and GFP-DNCx43 were analyzed for the ability to form functional channels. Electrophysiological recordings of myoblast pairs cultured in DM in the presence or absence of S1P (Figure 5C) indicated that the highest values of gap junction and hemichannel conductance were recorded in cells transfected with the wild-type connexin, suggesting that the overexpressed recombinant protein assembled correctly into functional connexons. Both basal gap junction and hemichannel conductance were reduced by ~60% in GFP-DNCx43 myoblasts as compared with those of vector and C2C12 cells (Figure 6). In particular, C2C12 myoblasts overexpressing GFP-wtCx43 showed a symmetrical current-voltage plot, whereas those overexpressing GFP-DNCx43 exhibited an asymmetrical relationship as in control cells (Figure 6, Table 2). Similarly, the hemichannel voltage sensitivity increased in GFP-wtCx43- and decreased in GFP-DNCx43-expressing myoblasts (Figure 6, Table 2). Collectively, these data indicated a channel-dependent role for Cx43 in the regulation of skeletal myogenesis.

The treatment with S1P caused a significant elevation of both the gap junction and hemichannel conductance in GFP-DNCx43 compared with vector cells (about twofold vs. 4–5-fold). Interestingly, the amplitude of Gj,ss and the Boltzmann parameters in S1P-treated GFP-DNCx43 cells did not differ from that of unstimulated vector and control myoblasts. However, it was of interest to note that 1) the residual gap junction and hemichannel conductance in GFP-DNCx43 cells stimulated with S1P showed, differently from control, a more pro-
nounced asymmetrical behavior, suggesting the formation of connexons containing different combinations of the mutated and endogenous proteins in these experimental conditions; and 2) GFP-DNCx43 myoblasts were unable to undergo normal differentiation compared with control cells. Furthermore, the inhibition of p38 MAPK activity by the treatment with SB 239063 had effects on myogenin and gap and hemichannel conductance similar to those induced by the overexpression of GFP-DNCx43 (Figures 3 and 7 and Table 3).

**Association of Cx43 with Cytoskeletal Proteins**

In search of a possible explanation of the apparent discrepancy between the extent of gap junction permeability and myogenesis, and in consideration of the recent findings showing that Cx43 can affect cell function independently of gap junctional communication, we analyzed the ability of Cx43 protein to interact with other cellular proteins known to positively influence skeletal myogenesis, such as cytoskeletal proteins (Komati et al., 2005; Formigli et al., 2007).

Colocalization of Cx43 with F-actin and cortactin, an F-actin–binding protein present in the cortical structures (Wu and Parsons, 1993; Wu and Montone, 1998), was investigated by confocal immunofluorescence followed by high-resolution deconvolution of the fluorescence images. Colabeling with Cx43 and anti-cortactin antibodies and/or TRITC-phalloidin revealed that the gap junctional protein colocalized with cortactin and, to a lesser extent, with F-actin in GFP-wtCx43–overexpressing cells (Figure 8A). By contrast, mutated Cx43 did not colocalized with F-actin and cortactin in basal conditions (unpublished data) as well as after S1P stimulation (Figure 8A). Similarly, the treatment with SB was able to prevent the interactions between F-actin and Cx43 in native C2C12 myoblasts (Figure 8B). The physical association of Cx43 with cytoskeletal proteins was verified by coimmunoprecipitation experiments. As shown in Figure 8C, endogenous Cx43 and GFP-wtCx43, but not GFP-DNCx43, coimmunoprecipitated with cortactin and skeletal actin. Of note, we found that S1P positively affected Cx43 interaction with cortactin in native C2C12 cells and such association was dependent on the activation of p38 MAPK pathways.

Data were obtained from unstimulated or S1P-stimulated C2C12 cells incubated in DM for 24 h with SB239063, which was added to the medium 30 min before S1P addition. The parameters were obtained by fitting normalized $G_j$,ss and $G_{hCh}$,ss vs. voltage data (16–20 recordings for each experimental condition). Note that SB239063 does not modify $G_j$,ss, which remains asymmetrical after S1P treatment (p < 0.05). Moreover, S1P is unable to significantly change $G_{hCh}$,ss. Data are presented as mean ± SEM.
All these data, taken together, were consistent with the idea that C2C12 myoblast differentiation could depend on the intercellular coupling as well as on an additional function of Cx43 protein per se, likely involving its physical interaction with proteins of cytoskeleton.

**DISCUSSION**

In the present study we identified Cx43 as a key regulatory protein of C2C12 myoblast differentiation elicted by S1P and proposed a novel mechanism by which Cx43 protein, in addition to form functional channels, may regulates skeletal muscle differentiation through other mechanisms requiring actin cytoskeletal remodeling and actin–Cx43 protein interaction.

In line with previous reports (Proulx et al., 1997a; Constantin and Cronier, 2000; Gorbe et al., 2005), Cx43 protein was transiently up-regulated in differentiating C2C12 myoblasts: Cx43 appeared early in proliferating cells, followed by a progressive increase in the cytoplasm and cell-membrane domains of adjacent myoblasts until fusion into myo-
tubes, where the expression decreased rapidly. Moreover, we demonstrated that S1P was a potent inducer of Cx43 expression in these cells. This finding, together with our previous data showing that S1P is a stimulator of myogenesis in C2C12 cells (Donati et al., 2005), provides the basis for considering Cx43 protein as a new intracellular target of S1P action during myogenesis. Enhanced expression synthesis of Cx43 by S1P was accompanied by increased gap junctional communication, as demonstrated by Lucifer yellow dye transfer after microinjection and the evaluation of gap junctional conductance using dual patch-clamp method. In particular, the transjunctional currents between undifferentiated myoblastic pairs exhibited an asymmetrical voltage dependence, indicating the involvement of heterotypic gap junctional channels in C2C12 intercellular coupling as previously reported (Beyer, 1990; Brink et al., 1997; Sakai et al., 2003; Yao et al., 2003). Interestingly, the transjunctional current showed a symmetrical behavior in S1P-stimulated cells, consistent with the prevalence of Cx43-homotypic channels and the ability of the bioactive lipid to affect preferentially the expression of only one connexin isoform (i.e., Cx43). In agreement, the expression of Cx39, weakly detectable at basal level, was not affected by S1P in the early stages of myoblast differentiation. However, consistent with previous reports (von Maltzahn et al., 2004, 2006; Belluardo et al., 2005) the level of this protein increased in differentiated C2C12 cells, especially upon S1P treatment. We also demonstrated that S1P-dependent up-regulation of Cx43 was dependent on the intracellular p38 MAP kinase signaling and Ca^{2+} mobilization, in agreement with our previous data showing a clear correlation between Ca^{2+} concentration and Cx43 protein expression (Formigli et al., 2005a). On the other hand, we showed that S1P likely affected the degradative process of Cx43 in conditions where Ca^{2+} had been depleted and p38 MAP kinase was inhibited. Despite the evidence suggesting a role for ERK1/2 signaling pathway in the regulation of Cx43 expression (Warn-Cramer et al., 1998; Hossain et al., 1999), we showed here that ERK1/2 inactivation by PD98057 treatment did not modify the synthesis of the protein in C2C12 cells stimulated with S1P consistently with the reported inability of ERK1/2 inhibition to affect S1P-induced myogenesis in C2C12 cells (Donati et al., 2005).

Gap junctional communications have been long thought to play an important role in the coordination of numerous cell functions, including maintenance of the cellular homeostasis and the regulation of cell growth, differentiation, and development. In particular, several studies have proposed that gap junctions are required for skeletal muscle development and regeneration, because the blockade of the intercellular coupling with channel blockers, octanol and 18beta-glycyrrhetinic acid, or the inducible deletion of Cx43 in transgenic mice, inhibit the expression of myogenic markers in differentiating myoblasts (Kaldener et al., 1977; Araya et al., 2003). Based on these findings, it has been proposed a possible role for gap junctions in allowing the intercellular spread of second messengers and coordination of the cell functions in a network of cells (Simon and Goodenough, 1998). To verify whether the intercellular communication was critical during myogenesis in C2C12 cells, we silenced Cx43 expression, and prepared myoblasts expressing a dominant negative form of Cx43, which formed gap junction channels with reduced permeability. In both conditions we found that cells expressing mutated Cx43 failed to enter the myogenic program elicited by the bioactive lipid, supporting the idea that gap junction functionality was essential for the promotion of myogenesis by S1P. However, myogenesis appeared not to be fully dependent on the extent of gap junctional communication. In fact, it was found an almost complete inhibition of the expression of myogenic markers in GFP-DNCx43–expressing cells despite a 50% decrease in the transjunctional conductance compared with that of controls. Such discrepancy was even greater in GFP-DNCx43 myoblasts incubated with S1P for one d, in which the gap junctional conductance was increased upon the basal levels and similar in amplitude to that of native unstimulated cells, which, instead, underwent normal differentiation. We explained the persistence of the cell-to-cell coupling in S1P-stimulated GFP-DNCx43 myoblasts by the ability of mutated connexin to form with the endogenous protein, up-regulated by the bioactive lipid, an ample range of connexons, whose function was dependent on the proportion of the endogenous and mutant form. It was likely that the different structure of connexons in S1P-treated GFP-DNCx43 cells compared with that of control cells (heteromeric vs. homomeric), despite the similar residual conductance, could explain the different capability to differentiate observed in the two cell populations. We suggested the possibility that Cx43 expression per se, in addition to its channel forming ability, could influence skeletal myogenesis of C2C12 cells elicited by S1P. Consistent with this assumption, several lines of evidences have recently shown that the expression of mutated Cx43 with no intrinsic channel activity are as effective as the wild-type protein in the regulation of several biological processes, including cell growth and survival (Lin et al., 1998; Dang et al., 2003). In such a view, it is very likely that Cx43, similarly to other proteins localized at the intercellular junctions, such as E-cadherin and beta-catenin (Giepmans, 2004), may exert multiple functions with different domains and play an important role as intermediate protein in the transduction of signals from the membrane to nucleus.

Recent investigations have suggested an involvement for actin and actin-binding proteins in the regulation of myogenesis, and several mechanisms have been proposed to explain the effect of cytoskeleton on skeletal differentiation (Qu et al., 1997). Accumulating data have demonstrated a direct interaction of the Cx43 C-terminus, with cytoskeletal proteins displaying signal transduction activity, including drebrin (Butkevich et al., 2004), ZO-1 (zonula occludens 1 (Toyofuku et al., 2001), and c-Src (Giepmans et al., 2003). Therefore, we analyzed the ability of the mutated and wild-type protein to interact with the cytoskeleton. Of note, endogenous connexin and recombinant wild-type Cx43, but not DNCx43, were physically associated with skeletal actin as well as cortactin, strongly supporting the idea that the interaction between Cx43 protein and cytoskeleton may be involved in the accomplishment of myogenesis in C2C12 cells. We also showed that the interaction between the gap junction protein and cortactin is regulated by S1P and is dependent on p38 MAPK activation, pointing to the phosphorylation of Cx43 as an additional step in S1P regulation of gap junction protein function. The physical association of Cx43 with F-actin modulated by S1P is of particular interest in view of our recent observations, showing that actin remodeling is crucial for myogenic process elicited by S1P in the same cells (Formigli et al., 2005a; Formigli et al., 2007). Collectively, these data in combination with those reported in the literature showing that the lack of a correct gap-junctional assembly of Cx43 on the cell surface hampers several cellular processes, including growth, proliferation, and differentiation (Moorthy and Patel, 2001; Dang et al., 2003; Li et al., 2006), are consistent with the emerging idea that Cx43 may also act as an adaptor protein and function through gap-independent mechanisms.
In conclusion, the results of the present study provide the first experimental evidence that up-regulation of Cx43 protein and the subsequent increase in gap junction functionality are important mechanisms by which S1P promotes myogenesis in C2C12 myoblasts. Notably, our data, although not excluding that the exchange of molecules through functional gap junctions plays a dominant role in skeletal muscle differentiation, suggest that the interaction between Cx43 and cytoskeletal proteins may represent a possible molecular mechanism by which Cx43 per se affects cellular differentiation.
