1 Science without Borders
T. R. Ceci, Howard Hughes Medical Institute, Chevy Chase, MD
Borders between disciplines. Borders between science and medicine. Borders that wall-off women and minority scientists from full participation. Those are some of the borders that we need to erase - or, failing that, at least make it easier to cross. With respect to interdisciplinarity, I’ll mention my own research experiences, talk about the challenges to cross-discipline research in the universities, and then discuss HHMI’s efforts. For example, HHMI’s Janelia Farm Research Campus now has physicists and computer scientists working shoulder-to-shoulder with neuroscientists. With respect to Science/Medicine, I’ll discuss our programs in research and in medical student and graduate student training. Finally, I’ll share some thoughts about women in science, and I’ll review HHMI’s Exceptional Research Opportunities Program.

2 In Vivo Interactions between Migrating Cells and the Micronvironment
D. J. Montell, J. McDonald, X. Wang, A. Jung, M. Starz-Gaiano, J. Kim, H. Yin, T. Bridges, M. Melani, Y. Chang, W. Yoon, M. Prasad; 1Department of Biological Chemistry, Johns Hopkins Medical School, Baltimore, MD, 2Department of Cell Biology, Scripps Research Institute, La Jolla, CA
My laboratory studies the molecular mechanisms that control cell migration in development and disease. We have developed the border cells in the Drosophila ovary as a model system to study the developmental regulation of cell migration and its coordination with other developmental events. We have described multiple extracellular signals that are required for the correct cells to move in the proper direction, at the appropriate stage. These signals include a steroid hormone (ecdysone), growth factors that activate receptor tyrosine kinases, and a cytokine that stimulates the JAK/STAT pathway. Each signal emanates from a distinct anatomical source, insuring proper coordination of border cell migration with other cell types and developmental events. We have recently shown that spatial localization of Notch activity can be achieved by localized Kuzbanian gene expression, a previously unrecognized mechanism by which Notch activity can be localized during development. Ongoing screens continue to identify new genes, including Par-1, that control additional aspects of border cell migration. We have also shown that a number of these genes contribute to ovarian cancer. Recently we have defined conditions that allow us to observe border cell migration directly, in living organ culture, using time-lapse movies. This allows us to combine powerful genetic manipulations with live-imaging to decipher and observe the mechanisms by which cell migration is regulated in vivo.

3 Integrating the Dynamics of Actin, Myosin, and Adhesions in Cell Migration
C. M. Waterman-Storer; Department of Cell Biology, Scripps Research Institute, La Jolla, CA
Cell migration is driven by forces generated by myosinII-based tension in an actin filament (F-actin) network linked via molecularly complex focal adhesions (FAs) to the extracellular matrix (ECM). The relationship between myosinII activity, F-actin and FA dynamics, and the nature of the molecular linkages between F-actin and the ECM via FAs are unclear. It is established that cells exhibit a biphasic migration velocity response to increasing adhesion strength, with fast migration occurring at intermediate adhesion strength and slow migration occurring at low and high adhesion strength. A simple mechanical model has been proposed to explain this, in which too little adhesion does not provide sufficient traction whereas too much adhesion renders cells immobile. We sought to determine if distinct organizational states of F-actin, myosin II, and FAs accompany adhesion-dependent changes in cell velocity. We characterize a unique phenotype for optimal migration, entailing rapid F-actin flow convergence and local depolymerization, local myosin II activation, rapid renewal of FA components, and intermediate FA lifetime and turnover rates. We recapturate this phenotype and fast migration at non-optimal adhesion strength by manipulating myosinII activity. Thus, in contrast to simple models, we find that a complex spatiotemporal feedback between the F-actin, myosin II, and FAs mediates the biphasic migration velocity response to increasing adhesion strength, so that a specific balance between adhesion and contraction induces maximal migration velocity. We also developed Correlational Fluorescence Speckle Microscopy to measure the coupling of FA proteins to the actin cytoskeleton during cell migration. Different classes of FA structural and regulatory molecules exhibit varying degrees of correlated motions with actin filaments, indicating differential transmission of actomyosin motion through FA. Our results suggest that transient interactions between FA proteins and actin filaments constitute a friction clutch between the cytoskeleton and the extracellular environment that is regulated during morphodynamic transitions of cell migration.

4 Integrin and 3D Matrix Dynamics in Cell Migration and Morphogenesis
K. M. Yamada; CDBBB, NIH/NIDCR, Bethesda, MD
Cell adhesion, migration, and tissue remodeling depend critically on coordinated interactions of integrins and the cytoskeleton with the extracellular matrix. These interactions are highly dynamic, with integrins, cytoskeletal proteins, and matrix proteins all undergoing distinct translocalizations. Particularly central roles are played by integrin α5β1, actin, and myosin IIA in coordinated integrin-matrix and myosin-microtubule functions that regulate cell adhesion and migration. Conversely, whether cell interactions with the extracellular matrix occur in two-dimensional (2D) versus 3D matrix microenvironments has substantial effects on cell adhesion, migration, proliferation, and signaling. For example, human fibroblasts in a 3D matrix show altered total Rac activity, which activates a general cellular mechanism that switches cell migration from random and exploratory to directionally persistent using a mechanism distinct from chemotaxis. At the tissue level, developmentally regulated, local production and movements of a 3D matrix were found to regulate organ formation. Highly directional, local translocation of a cytokine that stimulates the JAK/STAT pathway. Each signal emanates from a distinct anatomical source, insuring proper coordination of border cell migration with other cell types and developmental events. We have recently shown that spatial localization of Notch activity can be achieved by localized Kuzbanian gene expression, a previously unrecognized mechanism by which Notch activity can be localized during development. Ongoing screens continue to identify new genes, including Par-1, that control additional aspects of border cell migration. We have also shown that a number of these genes contribute to ovarian cancer. Recently we have defined conditions that allow us to observe border cell migration directly, in living organ culture, using time-lapse movies. This allows us to combine powerful genetic manipulations with live-imaging to decipher and observe the mechanisms by which cell migration is regulated in vivo.

5 Working Together to Improve Life Science Education
A. Campbell; Department of Biology, Davidson College, Davidson, NC
Life science education, like basic research, is a collaborative venture. I have benefited from many collaborations, but those associated with the Genome Consortium for Active Teaching (GCAT; www.bio.davidson.edu/GCAT) have been among the most enjoyable and productive. GCAT began in 2000 and during its first six years, GCAT has provided DNA microarrays to over 5,000 undergraduates on campuses serving diverse populations. These students show significant learning gains in knowledge, and improved attitudes towards research. Faculty enjoy the network of colleagues and the excitement of genomics in their teaching. Now GCAT is branching out to new areas. Collaborating with Dr. Sarah Elgin at Washington University, undergraduates will sequence genomes as part of original research projects. Working with Dr. Drew Endy at MIT, GCAT students participated in the 2006 International Genetically Engineered Machines Jamboree (http://parts2.mit.edu/wiki/index.php/Main_Page) along with students from 36 schools around the world. GCAT is working with high school teachers to develop genomics curriculum for high school students. It is important to assess these educational innovations, both to guide the development process and to demonstrate the strength of this lab-intensive, research-oriented approach to teaching in life sciences. By establishing a publishing standard that requires assessment, CBE Life Sciences Education has grown to be an important journal for sharing our educational resources and outcomes. (Supported by NSF, HHMI, Waksman Foundation for Microbiology, and Davidson College).

6 Bringing Research into the Undergraduate Curriculum
S. C. R. Elgin, C. Shaffer, W. Leung; 1Department of Biology, Washington University, St. Louis, MO; 2Department of Computer Science & Engineering, Washington University, St. Louis, MO; 3Department of Genetics, Washington University, St. Louis, MO; 4Department of Psychology, Grinnell College, Grinnell, IA
Undergraduate research experiences are a critical part of our biology curriculum, enabling students to understand how new knowledge is generated in their field. Undergraduate students often enter research through an individual apprenticeship during the summer. This has been found to generate a spectrum of intellectual and social gains, including greater understanding of the research process and the strategies and tools that scientists use to work on real problems (SURE survey data; D. Lopatto, 2004, Cell Biol. Educ. 3: 270). An alternative to summer research is a one semester, upper-level laboratory course built around a research problem. Bio 4342, Research Explorations in Genomics, is taught by collaborating faculty at Washington University from Biology, Computer Science, and the WU Genome Sequencing Center (see http://www.nslc.wustl.edu/elgin/genomics). Students in Bio 4342 join a research team working on sequencing and annotating the distal portion of a dot chromosome from a Drosophila species. The region is of interest because chromatin packaging in this region varies among the different species (resulting
publication: Slawson et al, 2006, Genome Biology 7: R15). Students report similar intellectual gains, particularly in developing problem-solving skills, but gain greater confidence in working as a group rather than individually. They are enthusiastic about the course, and particularly like the practice in reasoning from evidence, defending their conclusions in written and oral reports. Similar research-oriented courses elsewhere have focused on using other genomics tools, for example microarrays to sample gene expression (see A.M. Campbell, 2003, Cell Biol. Edu 2: 98).

An effort is underway to expand Bio 4342 through participation of students and faculty at other colleges and universities. As sequencing becomes cheaper, and the need for finishing and annotation increases (activities requiring human input that students can provide), the time is right for a student-scientist partnership in genomics. Funded by grants from HHMI.

8 Endless Flies Most Beautiful: The Role of Cis-Regulatory Sequences in the Evolution of Morphological Diversity

S. Carroll, HHMI/Laboratory of Molecular Biology, University of Wisconsin, Madison, WI

One of the general issues concerning the evolution of form is the relative contribution of gene duplication, protein sequence evolution, and regulatory sequence evolution to the generation of morphological variation and diversity. We have analyzed the gain, loss, and modification of pigmentacion patterns in Drosophila as models of morphological evolution. Six cases have involved regulatory changes at the pleiotropic pigmentation gene yellow. These include the surprising independent gains of similar wing patterns via the co-option of distinct cis-regulatory elements and the gain and loss of abdominal patterns via the gain and loss of Hex binding sites. Our results demonstrate how the functional diversification of the modular cis-regulatory elements of pleiotropic genes contributes to evolutionary novelty and the independent evolution of morphological similarities.

9 Fishing for the Secrets of Vertebrate Evolution

D. Kingsley, Department of Developmental Biology, HHMI/Stanford University, Stanford, CA

The molecular mechanisms that underlie the diversity of living organisms are still unknown. We have been developing stickleback fish as a model system for studying how new traits evolve in natural populations of vertebrates. These fish have undergone a dramatic radiation in postglacial lakes and streams throughout the Northern Hemisphere. Ancestral marine sticklebacks can still be crossed with newly established freshwater populations, making it possible to carry out a detailed study of the genetic basis of many dramatic morphological, physiological, and behavioral differences that have evolved in the last 10,000 years. We have developed a large set of genetic and genomic resources for mapping and isolating the genetic changes that underlie evolutionary change in sticklebacks. Whole genome linkage mapping shows that both gain and loss traits can be traced to particular chromosome regions, with a distribution of phenotypic effects much larger than predicted by "infiniteisles" models of evolutionary change. Detailed cloning and sequencing studies have revealed the actual genes that control major changes in pelvic development and arm plate patterning. In both cases, major evolutionary change has occurred by making regulatory alterations in key developmental control genes. Comparative studies suggest that many of the conclusions from initial study populations can be generalized to mechanisms that underlie evolution of similar traits over wide geographic and evolutionary distances. Further application of forward genetic approaches should thus help elucidate general rules about the number, location, and type of genes and mutations that control evolutionary change in nature.

10 The Molecular Evolution of Neural Circuits for Vocal Learning

E. D. Jarvis; Department of Neurobiology, Duke University Medical Center, Durham, NC

Vocal learning, the behavioral substrate for human language, is a rare trait found to date in only three distantly related groups of birds (parrots, hummingbirds, and songbirds) and four distantly related groups of mammals (humans, bats, cetaceans, and elephants). We have been studying the molecular biology and evolution of vocal learning brain systems. Here I will present our findings on the dynamic cascades of behaviorally regulated genes in vocal learning neural circuits and the implications these findings have for understanding the evolution of these circuits. We found that production of learned vocalizations is accompanied by activation of cascades of genes involved in both plastic and homeostatic cellular functions. These cascades consist of overlapping, but unique sets of genes in each vocal nucleus in different brain subdivisions. We believe that these genes are used to shape and maintain cellular homeostasis and circuits specific to each brain subdivision so that the animal is ready to produce learned vocalizations or other behaviors in other circuits at a moments notice. The differences between vocal learning and non-vocal learning circuits are not in the presence or absence of specific genes, but in the specialized expression of ancient genes in new ways in the vocal learning circuits. These gene activation patterns revealed remarkably similar vocal learning neural pathways across distantly related vocal learning birds, and have helped gain insight in the neural pathways for vocal learning in humans. The resultant hypothesis suggest that it may take just a few genetic mutations to convert a pre-existing non-vocal brain circuit into a vocal learning brain circuit that then uses an ancient set of genes in new ways to regulate the learning and production of vocalizations.

12 The Nuclear Membrane Protein Nesprin-2 Giant Plays a Key Role in Nuclear Positioning during Centrosome Reorientation and Cell Migration

E. R. Gomes, E. C. Vintinner, I. Karakesisoglou, G. G. Gundersen, Anatomy and Cell Biology, Columbia University, New York, NY; Center for Biochemistry, Medical Faculty, University of Cologne, Cologne, Germany

Migrating fibroblasts reorient their centrosome towards the leading edge by moving the nucleus away from the leading edge while the centrosome remains at the cell center. The rearward movement of the nucleus is mediated by Cdc42, myotonic dystrophy kinase-related Cdc42-binding kinase and myosin II-dependent actin retrograde flow, while the maintenance of the centrosome at the cell center is mediated by Cdc42, Par3, aPKC and dynein (Gomes et al., Cell 2005). Most nuclear movements are mediated by microtubules raising the question of how actin retrograde flow moves the nucleus away from the leading edge in migrating cells. We found that the outer nuclear membrane protein nesprin-2 giant is required for rearward nuclear movement during centrosome reorientation in 3T3 fibroblasts. Nesprin-2 giant is the largest nesprin-2 isoform and contains a transmembrane KASH domain at its C-terminus, which targets it to the outer nuclear membrane. We have performed the first live imaging of subcellular events to examine the two-stroke model in brain slices using cerebellar granule cells or tangentially migrating neurons as models of morphological evolution. Six cases have involved regulatory changes at the pleiotropic pigmentation gene yellow. These include the surprising independent gains of similar wing patterns via the co-option of distinct cis-regulatory elements and the gain and loss of abdominal patterns via the gain and loss of Hex binding sites. Our results demonstrate how the functional diversification of the modular cis-regulatory elements of pleiotropic genes contributes to evolutionary novelty and the independent evolution of morphological similarities.

13 Triple Labeling of Migrating Neural Progenitor Cells in Live Brain Tissue Reveals Novel Roles for Cytoplasmic Dynine and LIS1 in Centrosomal, Nuclear, and Microtubule Behavior

J. Tsai, R. B. Valle; Pathology and Cell Biology, Columbia University, New York, NY

During neocortical development, neurons arising at the ventricular zone migrate along radial glial fibers to the cortex. In vitro studies using cerebellar granule cells or tangentially migrating neurons have shown that the movement is saltatory and comprises two "strokes": forward centrosomal movement into a swelling in the leading process, followed by the soma (Nat Neurosci, 7:1195; J Neurosci, 25:103652). We previously reported that LIS1 RNAi inhibits somal movement but not process growth of neural progenitors in vivo (JCB, 176/935), suggesting the importance of cytoplasmic dynein in somal movement; however, its specific role remained underdetermined. By electrophoretically raising the stroke model in brain slices and its underlying motor machinery. Nuclei exhibited both rapid jumps and slower continuous movements. However, centrosomes moved at relatively constant rates. GFP-EB3 imaging revealed microtubules to concentrate from and move in association with the centrosome. Nuclei showed microtubule-dependent distortion prior to advancing into the migratory process, indicative of strong, discontinuous pulling forces. In cells expressing LIS1 or dynine siRNAs, centrosomal and nuclear movements were both disrupted. In partially-inhibited cells, remarkable wandering excursions of the centrosome toward the swelling were seen, whereas nuclear movement was independently inhibited. Blebbistatin blocked somal translocation as previously reported, but centrosomal movement was unaffected. Immunocytochemistry showed dynine specifically concentrated in the swelling and the leading process of freely migrating neurons. These data have led to a comprehensive model for the unique migration mechanism used by neural progenitors: cytoplasmic dynine pulls from the leading process on the centrosome-anchored microtubules; the nucleus is then transported cooperatively by dynein as cargo along the trailing microtubules and by myosin II acting from the rear. Supported by HD40182.
The EGF receptor (EGFR) is essential for the growth and differentiation of many types of epithelial cells. To understand how signaling through this receptor is regulated, we are developing models of the ERK pathway have previously indicated the possibility of oscillations because of the negative feedback loop between ERK and

Regulation of chemotaxis requires the proper control of cell adhesion and cell movement to the substrate. We have investigated the role of Rap1 in Dictyostelium and demonstrate that Rap1 is required for proper regulation of cell adhesion and chemotaxis through the control of Myosin II (MyoII). Rap1 is activated rapidly and transiently in response to chemotactant stimulation and activated Rap1 is preferentially found at the leading edge of chemotaxing cells. The spatial distribution of Rap1-GTP extends more laterally than that of Rac-GTP and the kinetics of activation are slower. Cells expressing constitutively active Rap1 (Rap1CA) are highly adhesive and flattened. These cells chemotax very slowly and produce a large number of lateral pseudopodia. Like wild-type cells, Rap1CA cells rapidly disassemble myosin in response to chemotactant stimulation but reassemble MyoII very slowly. Consistent with this, we observe a very delayed reassociation of GPP-Mysillin response to chemotactant stimulation in Rap1CA cells. These results suggest that Rap1 negatively controls MyoII assembly. In Dictyostelium, MyoII assembly/disassembly is regulated by phosphorylation of 3 Thr residues in the MyoII tail. We show that the kinase Phg2, a putative Rap1 effector, colocalizes with Rap1-GTP at the leading edge of chemotaxing cells and is required for MyoII phosphorylation in vitro assay. Phg2 null cells exhibit defects in MyoII assembly in vivo and show severe chemotaxis defects. We suggest that Phg2 is a new component of the rapidly-activated, leading edge regulatory network that, in this case, controls MyoII phosphorylation and its assembly/disassembly. In conclusion, our findings suggest that Rap1 is a key upstream spatial regulator of MyoII assembly, and the function of Rap1, in part, is mediated by Phg2. Our results provide new insights into the function of Rap1 in controlling the leading edge and posterior of chemotaxing cells.

The Biology of FAK: Implications in the Maintenance of Cell Tension and Polarity

R. W. Tilghman, Z. Rajfur, M. Iwanicki, C. R. Cowan, K. Jacobson, J. T. Parsons. Microbiology, University of Virginia, Charlottesville, VA, 2University of North Carolina, Chapel Hill,

Focal adhesion kinase (FAK) plays an important role in cell migration during key physiological processes such as cancer metastasis, wound healing, and embryonic development, yet the mechanism by which FAK regulates cell migration is unclear. Fibroblasts derived from FAK -/- mice are highly contractile and show an increased amount of large Rho-dependent focal adhesions, suggesting that FAK is a negative regulator of the Rho pathway, and FAK is required to release adhesions to promote focal adhesion turnover. However, in wild-type fibroblasts and endothelial cells, FAK is highly active when cells are under tension, suggesting that FAK may also play a role in focal adhesion growth or maintenance. To resolve this apparent paradox in FAK signaling, we employed two ways of activating FAK in wild-type cells: siRNA of FAK to rapidly inhibit its expression, and the inhibition of FAK activity using a novel specific small compound kinase inhibitor (PF-228). Treatment of fibroblasts with FAK siRNA or PF-228 did not produce the morphology that is characteristic of the FAK -/- cells; rather, they formed a proper leading edge, and instead they formed multiple thin protrusions and became elongated. Both treatments resulted in cells that lost their ability to spontaneously polarize on fibronectin. Surprisingly, treatment of fibroblasts with PF-228 resulted in a decrease in myosin light chain phosphorylation, suggesting that FAK is important in the generation or maintenance of contractility. To measure changes in cellular tension, fibroblasts were grown on flexible polyacrylamide substrates embedded with beads to measure forces exerted by the cells. Treatment with PF-228 resulted in a rapid decrease in cellular tension, suggesting that FAK activity is required to maintain tension across the cell. These results point to FAK’s role in mechanotransduction to establish cell polarity during cell migration by inducing resistance at critical points in the cell.

2006 ASCB Annual Meeting Abstracts
Quantitative Models of Embryonic Development
S. Y. Shvartsman, Lewis Sigler Institute and Department of Chemical Engineering, Princeton University, Princeton, NJ
The development of tissues and organs is regulated at a variety of levels, from gene sequence to anatomy. At this level of complexity, modeling becomes essential for integrating data and guiding future studies. Any attempt to establish quantitative models of embryogenesis is confronted by the high level of structural and parametric uncertainty, a large number of components, and the multiscale nature of development. At the same time, an expanding arsenal of experimental tools can constrain models and directly test their predictions, making the modeling efforts not only necessary, but feasible. I will illustrate this paradigm using two examples from our work on the quantitative analysis of fruit fly development. Both examples are related to the concept of a morphogen, a chemical that induces multiple cell fates in a concentration-dependent manner. In the first case, we will use a parameter estimation approach to infer the experimentally inaccessible concentration profile of the Gurken morphogen in a developing egg. In the second case, a combination of imaging, genetic, and modeling approaches will be used to probe the information processing capabilities of the Torsos signaling cascade in the early embryo.

Multicellular patterns and structures emerge as cells execute instructions received from multiple cues in their microenvironment. How cells integrate these cues to achieve an organized, functional structure is a fundamental question in development biology with important biomedical implications. Developing strategies to guide multicellular structure formation is a central challenge in tissue engineering and regenerative medicine. Thus, our lab seeks to understand how cellular and molecular networks qualitatively interpret pattern-guiding environmental cues. In this talk, I will present our study of cell patterning during adult-phase development in C. elegans, a process that involves molecular signals with close homology to those underpinning human development and disease. A feature of this system is that patterning depends not only on a spatial gradient of a soluble factor (a morphogen gradient), but also on direct cell-cell contact. Our computational analysis shows that the signaling network coupling neighboring cells amplifies cellular perception of the morphogen gradient, thereby enhancing fate segregation beyond that achieved in an uncoupled system. In addition to elucidating how the topology of the signaling network confers qualitative advantages in signal processing, our mathematical model accurately predicts wild-type and mutant phenotypes. This ability to predict phenotypes has allowed us to conduct in silico genetics experiments, offering answers to intriguing questions such as what new phenotypes are possible, and what perturbations render such phenotypes.

Automatic Parameter Identification via the Adjoint Method, with Application to Understanding Planar Cell Polarity
R. Raffard, K. Amontlirdviman, I. Axelrod, C. Tomlin; Stanford University, Stanford, CA
A key focus of systems biology has been the development of models, at the appropriate level of abstraction, to help understand different biological processes. This development usually proceeds in iterative fashion, in which the structure of the model is chosen to represent certain hypotheses about how the system operates and parameters for this structured model are chosen. Often, the first experiment is to ask if a robust set of parameters exists so that the model reproduces all or most of the observed biological data. The model is tested against this actual data and for its predictive capabilities. As new data and/or new understanding arises, the structure of the model may be altered, and new parameters selected. In protein regulatory networks, the number of states to model is typically large and depends on the number of proteins of interest, the parameter spaces are large, and the most appropriate models are nonlinear functions of the states. Thus it is becoming increasingly important to develop fast, efficient, scalable methods for large scale parameter identification. This paper presents an adjoint-based algorithm for performing automatic parameter identification on differential equation based models of biological systems. The algorithm solves an optimization problem, in which the cost reflects the deviation between the observed data and the output of the parameterized mathematical model, and the constraints reflect the governing parameterized equations themselves. Results of the application of this algorithm to a previously presented mathematical model of planar cell polarity signaling in the wings of Drosophila melanogaster are presented.

Functional Grouping of Kinetochore Proteins Based on Their Regulation of Kinetochore Microtubule Dynamics
K. Jaqaman,1 J. F. Dorn,2 E. Marco,2 G. S. Jelson,3 P. K. Sorger,2 G. Danuser1; 1Department of Cell Biology, The Scripps Research Institute, La Jolla, CA, 2Department of Biology, Massachusetts Institute of Technology, Cambridge, MA
To test the hypothesis that kinetochore proteins regulate kinetochore microtubule (kMT) dynamics, we measured single kMT dynamics in the budding yeast S. cerevisiae and compared them between wild type (WT) and strains carrying kinetochore protein mutations. We established autoregressive moving average (ARMA) model parameters as a unique and complete set of descriptors of kMT dynamics that allowed us to distinguish between subtle phenotypes associated with gene deletions and temperature-sensitive mutations. ARMA models extracted the dependence of kMT length on its history and on a related white noise series which embodied the stochastic nature of kMT dynamics. Multiple kMT length series from each condition were fitted together, taking into account observational error and missing observations, to achieve robust parameter estimation. We also estimated the variance-covariance matrices of ARMA descriptors and used them to compare descriptors between different conditions within a statistical hypothesis testing framework. The p-values from the statistical tests revealed which conditions had different dynamics, and also provided us with a proximity measure that we used for clustering kMT dynamics. This allowed us to classify kinetochore proteins within functional groups. We found that kinetochore proteins do indeed regulate kMT dynamics. For instance, kMT dynamics in the mutants okp1-5 and kip3- delete are different from those in WT. Furthermore, we found that the proteins Ipl1p, Dam1p and Kip3p form one functional group, where the dynamics resulting from their mutation are equivalent and significantly different from dynamics in WT. In addition to their classification power, ARMA descriptors are ideal intermediate statistics for matching experimental and simulated kMT dynamics for calibrating stochastic mechanistic models of kMT regulation by kinetochore proteins.

System Level Analysis Identifies Timing of Force Integration during Mitosis
R. Wollman, G. Civelekoglu-Scholey, J. M. Scholey, A. Mogilner; Center for Genetics and Development, University of California, Davis, Davis, CA
Mitotic spindle development is characterized by consecutive transitions between distinct morphological states that can be characterized by increasing spindle length and distances between sister chromatids. For example, during Drosophila embryonic development, the spindle poles and chromosomes separate in a well-defined and quantitatively reproducible fashion. While a number of molecular perturbations have revealed the basic mechanisms of multiple motor and microtubule actions underlying spindle elongation, a complete picture of how motor and microtubule forces are integrated is still lacking. We performed an In Silico model screen to identify all potential mechanisms of force integration that will reproduce Drosophila's pole and chromosome separation phenotype. We 'trained' the computer to assemble a set of models based on different combinations of forces and molecular on/off switches regulating motor and microtubule dynamics. We screened the models in a 39-dimensional parameter space (11 timing parameters and 28 kinetic and mechanical parameters). To identify models that fit experimental data we used stochastic optimization and genetic algorithms. We found that only 1000 different models that can quantitatively describe pole and chromosome separation in Drosophila. Cluster analysis of these different models shows that there are potentially 11 qualitatively different ways to integrate spindle forces and reproduce experimental results of wild-type embryos. We show that in all 11 strategies, the timing of force activity must be fine tuned, in contrast to the kinetic and mechanical parameters that show robustness to change. Using additional data from mutant embryos and inhibition experiments we show that changes in sliding forces, structure of the microtubule mid-zone overlap region, and microtubule pole depolymerization must be integrated in a particular way to reproduce both wild type and mutant data. System modeling results in quantitative understanding of force integration in the spindle and is the crucial step toward elucidating the regulatory biochemical network governing transitions during mitosis.

The Epigenetics of Cancer Etiology
A. Feinberg; Department of Medical Genetics, Johns Hopkins University School of Medicine, Baltimore, MD
In over 20 years since the discovery of altered methylation in cancer, many epigenetic alterations have been found in human cancer, including global and specific gene hypomethylation, hypermethylation, altered chromatin marks, and loss of genomic imprinting. Cancer epigenetics has been limited by questions of cause and effect, since epigenetic changes can arise secondary to the cancer process and associated changes in gene expression. Furthermore, mutations in the DNA methylation machinery have not been observed in tumors, while they have for chromatin modification. To address the issue of human cancer etiology, we have more recently focused on identifying epigenetic changes in normal cells that predispose to cancer. One line of investigation has been to investigate loss of imprinting (LOI) of the insulin-like growth factor-II gene (IGF2) associated with a personal history of colorectal neoplasia, as well as a family history of colorectal cancer (CRC). We developed an animal model showing that LOI of IGF2 increases the frequency of neoplasms caused by mutations in the Apc gene, suggesting that a major component of cancer risk involves epigenetic changes in normal cells that increase the probability of cancer after genetic mutation. Furthermore, we found that LOI increases and alters the progenitor cell compartment, likely accounting for this increased risk. These data are consistent with an “epigenetic progenitor” model of human cancer, and they suggest a model of cancer prevention that involves the epigenetic analysis of normal cells for risk stratification and cancer prevention strategies, similar to the widely used approach of modifying risk of cardiovascular disease by treating apparently healthy individuals with detectable biochemical indicators of enhanced risk.

Suz12 Silences Large Regions of the Genome in a Cell Type-specific Manner
P. J. Farnham,1 S. Squazzo,1 H. O'Geen,2 V. Komashko,3 V. Jin, R. Green, Genome & Biomedical Sciences Facility, University of California, Davis, Davis, CA, 2NimblerGen Systems Inc, Madison, WI
Suz12 is a component of the Polycomb Group Complexes 2, 3, and 4 (PRC 2/3/4). These complexes are critical for proper embryonic development, but very few target genes have been identified in either mouse or human cells. Using a variety of ChIP-chip approaches, we have identified a large set of Suz12 target genes in several different human and mouse cell lines. Interestingly, we found that Suz12 target promoters are cell type-specific, with transcription factors and homeobox proteins predominating in embryonal cells and glycoproteins and immunoglobulin-related proteins predominating in adult cells. We have also characterized the localization of other components of the PRC complex with Suz12 and investigated the overall relationship between Suz12 binding and markers of active vs. inactive chromatin, using both promoter arrays and custom tile arrays. Surprisingly, we find that the PRC complexes can be localized to discrete binding sites or spread through large regions of the mouse and human genomes. Current studies are focused on determining the site-specific factors that are involved in recruiting Suz12 to discrete sites vs. large chromosomal domains. Towards this goal, we have shown that some Suz12 target genes are bound by OCT4 in embryonal cells and suggest that OCT4 maintains stem cell self-renewal, in part, by interacting with PRC complexes.

DNA Methylation Regulates Insulin Gene Expression
T. Yoshioka, S. Shinya, O. Jun, S. Kunio; Faculty of Agriculture, The University of Tokyo, Tokyo, Japan
There are two insulin genes in mouse; Ins1 on chromosome 19 and Ins2 on chromosome 7. Ins2 has the same exon-intron-structure as human INS while Ins1 is different. Ins2 expression is specific to beta cells of the islet of Langerhans in pancreas. Ins2 has a promoter (~400 bps) with a TATA box and several transcription factor binding sites such as Pdx1(-209), HNF4 (-231, -106) and Maf(-122). DNA methylation profile of the tissue-dependent differentially methylated regions (T-DMRs) is unique in each tissue or cell type including embryonic stem cells (ESCs), somatic cells and germ cells. Therefore, DNA methylation profiles of T-DMRs are useful to evaluate and characterize the cells. In present study, the DNA methylation status of the upstream region (~440 to ~65) of Ins2 which includes the promoter region was examined in insulin-producing MIN6 cells and non-producing ESCs using bisulfite sequencing. All the three CpGs (-408, -176, -171) within the region were unmethylated in MIN6 but were hypermethylated in ESCs. In addition an ectopic expression of Ins2 was induced in ESCS after a two-day culture with a DNA methylation inhibitor, 5-aza-2'-deoxycytidine. Thus, we found that Ins2 has a T-DMR. We analyzed DNA methylation status of the Ins2 promoter in the islet of Langerhans by laser microdissection and confirmed that the Ins2 T-DMR was totally unmethylated in the islet, in contrast it was hypermethylated in whole pancreas. The methylation status of the pancreas reflected insulin-non-expressing exocrine cells, since they account for more than 95% of the pancreatic cells. Besides that, the T-DMR was also hypermethylated in other non-expressing tissues including kidney, liver and heart. Promoter assays using lac-reporter system in MIN6 cells showed that the promoter activity was severely decreased when the promoter construct that was methylated in vitro was used. In conclusion, the Ins2 expression is regulated by DNA methylation.

Tumor Suppressor P16INK4A Regulates Polycomb-mediated DNA Hypermethylation
T. D. Tlsty,1,2 P. A. Reynolds,1,2 M. Sigaroudinia,1,2 G. Zardo,1,2 M. B. Wilson,1,2 G. M. Benton,1,2 C. J. Miller,1,2 C. Hong,1,2 J. Fridlyand,1 J. F. Costello; 1Comprehensive Cancer Center, University of California, San Francisco, San Francisco, CA, 2Department of Pathology, University of California, San Francisco, San Francisco, CA, 3The Brain Tumor Research Center and Department of Neurological Surgery, University of California, San Francisco, San Francisco, CA
To understand dynamic changes in gene expression mediated by steroid receptors, our laboratory has taken a direct visualization approach to analyze steroid hormone action. Using GFP-tagged glucocorticoid receptor and RNA polymerase II supports formation of chromatin loops in the interphase nucleus of living mammalian cells. As the ligand-bound receptor functions to regulate steroid hormone-responsive gene transcription, we have analyzed the ability of the glucocorticoid receptor to recruit steroid receptor co-activators, basal transcription factors, and RNA polymerase II to an amplified array of a specific target gene. While different fluorescently labeled factors are recruited at varying efficiencies following hormone treatment, two different types of localization are observed—diffuse or highly localized. For a basal transcription factor, hormone treatment results in its recruitment to the amplified array. Interestingly, we found that Suz12 target promoters are cell type-specific, with transcription factors and homeobox proteins predominating in embryonal cells and glycoproteins and immunoglobulin-related proteins predominating in adult cells. We have also characterized the localization of other components of the PRC complex with Suz12 and investigated the overall relationship between Suz12 binding and markers of active vs. inactive chromatin, using both promoter arrays and custom tile arrays. Surprisingly, we find that the PRC complexes can be localized to discrete binding sites or spread through large regions of the mouse and human genomes. Current studies are focused on determining the site-specific factors that are involved in recruiting Suz12 to discrete sites vs. large chromosomal domains. Towards this goal, we have shown that some Suz12 target genes are bound by OCT4 in embryonal cells and suggest that OCT4 maintains stem cell self-renewal, in part, by interacting with PRC complexes.

28
Direct Visualization of Glucocorticoid Receptor and RNA Polymerase II Supports Formation of Chromatin Loops in the Interphase Nucleus of Living Mammalian Cells
H. Hsu, R. S. Singh, W. J. Dixon, T. Lee, C. Langer, Y. K. Lee; Ob-Gyn and Molecular & Medical Pharmacology, David Geffen School of Medicine at UCLA, Los Angeles, CA
To understand dynamic changes in gene expression mediated by steroid receptors, our laboratory has taken a direct visualization approach to analyze steroid hormone action. Using GFP-labeled steroid receptors, we previously showed that both estrogen and glucocorticoid receptors undergo subcellular changes in their organization in response to activation by steroid hormones. As the ligand-bound receptor functions to regulate steroid hormone-responsive gene transcription, we have analyzed the ability of the glucocorticoid receptor to recruit steroid receptor co-activators, basal transcription factors, and RNA polymerase II to an amplified array of a specific target gene. While different fluorescently labeled factors are recruited at varying efficiencies following hormone treatment, two different types of localization are observed—diffuse or highly localized. For a basal transcription factor, hormone treatment results in its recruitment to the amplified array, giving rise to a diffuse fluorescent signal that surrounds and encases a highly localized RNA polymerase II signal. Such strikingly different localization patterns most likely reflect intrinsic differences in the mechanism of factor concentration at the amplified array. The glucocorticoid receptor also shows a highly localized pattern, which varies in its overlap with that of RNA polymerase II. A “candy cane”-like structure is observed in cases of limited overlap, whereas, a single RNA polymerase II track, approximately 2-micron in length, is sandwiched between two glucocorticoid receptor tracks. The proximal end of the polymerase track contacts the proximal end of one receptor track, while the distal end contacts the distal end of the other receptor track. The central segment of the polymerase track shows no overlap with the receptor site. The segregation of fluorescent signals suggests a model of receptor and polymerase binding at different segments of a repeated chromatin loop, providing direct visual evidence for the presence of chromatin loops in the interphase nucleus of living mammalian cells.

Targeting Heterochromatin Formation in Drosophila melanogaster
S. C. R. Elgin,1 K. A. Haynes, S. D. Findley, B. Brower-Toland, A. A. Caudy, H. Lin; 1Biology, Washington University, St. Louis, MO, 2Cell Biology, Duke University Medical School, Durham, NC, 3Lewis-Sigler Institute for Integrative Genomics, Princeton University, Princeton, NJ
Drosophila melanogaster is an excellent system for studying the potential chromatin packaging that leads to heterochromatin formation and gene silencing. Using a P element reporter containing an hsp70-driven copy of the white gene, we observe a variegating phenotype when the reporter has inserted into the pericentric heterochromatin, the small fourth chromosome, or the telomeres. Detailed analysis of the fourth has indicated that the repetitious element 1360 can serve as a target for heterochromatin formation, insertion of a reporter within 10 kb of a 1360 element correlates with variegation. 1360 is derived from a DNA transposon, and incomplete copies are widely distributed in D. melanogaster heterochromatin. A Northern
blot shows short RNAs (21-23 nt) corresponding to 1360, indicating processing by the RNAi machinery. Using a P element construct carrying a single copy of 1360 upstream of the hsp70-white reporter, we find that this 1360 element contributes to HP1- and RNAi-dependent variegation at a pericentric insertion site, as demonstrated by a decrease in silencing after HLP-mediated removal of the 1360 element. These results suggest that heterochromatin formation at transposable element remnants is targeted by the RNAi system. We have found that PIWI, a protein broadly implicated in the RNAi system, interacts specifically with HP1 in a yeast two-hybrid screen, via interaction of a PIWI PeVXL motif with the HP1a chromo shadow domain dimer. PIWI is detected by immunofluorescent staining of polytene chromosomes both at sites in the euchromatic arms, and in a punctate pattern in the pericentric heterochromatin. The latter staining, not the former, is sensitive to RNase H, suggesting association through an RNA-DNA hybrid. The direct interaction between PIWI and HP1a provides a link between the RNAi machinery and epigenetic regulation. Supported by NIH grants GM073190 and GM068388 to SCRE and HD33760 to HL.

Asymmetric Cell Divisions in the Epidermis
T. Lechler, E. Fuchs; 1Cell Biology, Duke University Medical Center, Durham, NC, 2Laboratory of Mammalian Cell Biology and Development, Rockefeller University, New York, NY

The epidermis is a stratified squamous epithelium which forms the barrier that excludes harmful microbes and retains body fluids. To perform these functions, proliferative basal cells in the innermost layer periodically detach from an underlying basement membrane of extracellular matrix, move outward and eventually die. Once suprabasal, cells stop dividing and enter a differentiation program to form a barrier. The mechanism of stratification is poorly understood. Although in vitro studies have led to the view that stratification occurs through delamination and subsequent movement of epidermal cells, most culture conditions favor keratinocytes that lack the polarity and cuboidal morphology of basal keratinocytes in tissue. Such features could be important in considering an alternative mechanism, that stratification occurs through asymmetric cell divisions in which the mitotic spindle orients perpendicular to the basement membrane. We have found that basal epidermal cells use their polarity to divide asymmetrically, generating a committed suprabasal cell and a proliferative basal cell. We further demonstrate that integrins and cadherins are essential for apical localization of PKC, the Par3/LGN/Inscuteable complex and NuMA/dynactin to align the spindle.

31

The Agrin/Perlecan-related Protein Eyes Shut Is Essential for Epithelial Lumen Formation in the Drosophila Retina
N. Husain, 1 M. Pelikika, 1 H. Hong, 1 T. Klimentova, 1 K. Choc, 1 T. R. Clandinin, 1 U. Tepass 1; 1Department of Cell and Systems Biology, University of Toronto, Toronto, ON, Canada, 2Department of Neurobiology, Stanford University, Stanford, CA

The formation of epithelial lumina is a fundamental process in animal development. Each ommatidium of the Drosophila retina forms an epithelial lumen, the interrhabdomeral space, which has a critical function in vision as it optically isolates individual photoreceptor cells. Ommatidia containing an interrhabdomeral space have evolved from ancestral insect eyes that lack this lumen as seen, for example, in bees. In a genetic screen we identified eyes shut (eys) as a gene that is essential for the formation of interrhabdomeral space. Eys is a predicted proteoglycan related to agrin and perlecan and a component of the apical extracellular matrix secreted by photoreceptor cells. The honeybee orthologue of eys is not expressed in photoreceptors, suggesting that recruitment of eys expression may have made an important contribution to insect eye evolution. Our findings indicate the deposition of an apical extracellular matrix is critical for the formation of a luminal cavity.

The Role of Merlin and the ERM Proteins in Membrane Organization
M. Curot, 1 B. Cole, 1 C. Liu, 1 L. Saotome, 1 A. W. Chan, 1 A. I. McClatchey 1, 2; 1Massachusetts General Hospital Center for Cancer Research, Charlestown, MA, 2Department of Pathology, Harvard Medical School, Boston, MA

The neurofibromatosis type 2 tumor suppressor, Merlin and related ERM (Ezrin, Radixin, Moesin) proteins are thought to provide regulated linkage between the membrane and actin cytoskeleton, thereby organizing cortical domains that interface with the extracellular environment. Through mouse modeling, we have found that both Merlin and Ezrin play an important role in remodeling cell-cell contacts during tissue morphogenesis and tumorigenesis. We found that Ezrin is critically required for proper assembly of apical membranes and dynamic regulation of intercellular contacts during villus morphogenesis in the developing mouse intestinal epithelium. Both Ezrin overexpression and Merlin loss-of-expression have been linked to metastatic progression. At the membrane:cytoskeleton interface, Merlin is poised to modulate the transmission of mitogenic signals from the extracellular environment, in contrast to other tumor suppressors that function intracellularly to control the cell division cycle. We previously demonstrated that Merlin mediates contact-dependent inhibition of proliferation by organizing or stabilizing cell-cell junctions. In subsequent work we found that upon cell-cell contact Merlin coordinates the process of adherens junction stabilization with concomitant negative regulation the Epidermal Growth Factor Receptor (EGFR) by restraining the EGFR into a membrane compartment from which it can neither signal nor be internalized. This activity requires precise compartmentalization of Merlin itself into a defined membrane compartment. As a consequence, physiologic EGFR activation persists in confluent N2-/- cells, driving their continued proliferation. Our results suggest that excess EGFR signaling is critical for the hyperproliferation of N2-/- cells and tumors and reveal a novel mechanism of tumor suppressor action. Indeed, specific EGFR inhibitors such as Gefitinib (Iressa) block the proliferation of N2-/- cells, suggesting a therapeutic strategy for N2-mutant tumors. Our studies indicate that this model of Merlin function applies to several different cell types, including Schwann cells.

33

Tissue Architecture Sculpts Inhibitory Gradient(s) to Determine Sites of Mammary Branching Morphogenesis
C. M. Nelson, 1 M. van Duijn, 1 J. L. Inman, 1 D. A. Fletcher, 1 M. J. Bissell 1; 1Life Sciences Division, Lawrence Berkeley National Laboratory, Berkeley, CA, 2Department of Bioengineering, University of California, Berkeley, CA

The tree-like structures of many organs, including the mammary gland, are generated by branching morphogenesis, a reiterative process of branch initiation and invasion from a pre-existing epithelium. Using a micropatterning approach to control the initial three-dimensional architecture of mammary epithelial tubules, combined with an algorithm to quantify the extent of branching, we find that the geometry of tubules dictates the position of branch site initiation. We predict numerically and confirm experimentally that branch initiation occurs at sites with a characteristic geometry of tubules. Time-lapse confocal analysis verifies that branch site initiation is determined rather than stochastic, and shows that cells within the engineered tubules behave in a dynamic, coordinated manner. These results reveal that tissue architecture defines the local cellular microenvironment to control organ morphogenesis.

34

The C. elegans Tropomodulin Homolog, TMD-1, Regulates Adherens Junctions during Epidermal Morphogenesis
E. A. Cox, J. Hardin; Zoology, University of Wisconsin, Madison, WI

Association between the cadherin-catenin complex and the actin cytoskeleton is essential for epithelial development, but how this is accomplished and regulated is poorly understood. C. elegans is an excellent model system for exploring this issue, since its adherens junctions contain a highly conserved cadherin-catenin complex that is essential for epithelial morphogenesis. To identify proteins that regulate the cadherin-catenin complex during embryonic development we have performed a screen to look for enhancers of α-catenin loss-of-function allele, hmp-1(fe4). In this screen, we identified a tropomodulin homolog, tmd-1. Tropomodulins cap the slow growing, pointed ends of actin filaments. In vertebrates, tropomodulins regulate various actin networks, including those present in muscle sarcomeres, lamellipodia, and the cortical actin-spectrin cytoskeleton (reviewed in Fisher and Fowler, 2003, Trends. Cell Biol., 13, 593-601). Our work on TMD-1 indicates a new role for tropomodulins as regulators of adherens junctions during morphogenesis. RNA interference (RNAi) directed against tmd-1 does not yield lethality on its own, however, it enhances the embryonic lethality of hmp-1(fe4) homozygotes. We find that hmp-1(fe4);tmd-1(RNAi) embryos fail to properly undergo epidermal elongation, a process by which contraction of the exterior epidermis helps to squeeze the embryo into a worm-like shape. This involves the junctional anchorage and contraction of an ordered array of actin bundles. Interestingly, the adherens junctions of hmp-1(fe4);tmd-1(RNAi) embryos do not maintain their strict apical-lateral position, and develop a frayed appearance as the embryos attempt to elongate. These areas of perturbed cadherin-catenin complex localization correlate with areas of perturbed actin morphology, which likely accounts for the failed elongation of these embryos. Together, these results suggest that TMD-1/tropomodulin acts with HMP-1/tropomodulin to promote junctional integrity during epidermal morphogenesis.
A Requirement for Crumbs-dependent Cell Polarity during Epithelial Morphogenesis

K. A. Campbell, H. Skaer; Department of Zoology, University of Cambridge, Cambridge, United Kingdom

Many epithelial tissues undergo dramatic morphogenetic changes, yet maintain their apicobasal polarity. This occurs during the development of the epithelial renal tubules in Drosophila melanogaster. Organogenesis of these tubes involves both cellular rearrangement by convergent extension movements and integration of an additional cell population into the epithelium from the surrounding mesoderm. Thus the tubules face two challenges: 1) They have to maintain their polarity during these potentially destabilising events 2) The integrating cells must polarise with respect to their new position within the tube. To understand how they do this we have analysed the molecular basis for cell polarity in both cell types throughout tubule development. We find two stages in the maintenance of polarity in the tubules, the first is independent of the apical protein complex, Crumbs, whereas the second phase requires its activity. In contrast, the other major protein complexes, Bazooka and Scribble are required for polarity during tubule development. In the absence of Crumbs, the tubules localise polarity markers during early development and form Zonula Adherens (ZA) junctions. However, at the onset of cell integration and rearrangement, the cells lose polarity and the ZA junctions disperse. In the epidermis Crumbs is required at the onset of germband extension. We suggest that the temporal difference in the requirement for Crumbs between tissues underlines its role in maintaining polarity during the remodelling of cell-cell contacts. Maintaining cell polarity during cell rearrangement is also critical for the correct integration of the second cell population. When the apical protein Crumbs or the non-ECRGA PRC are overexpressed in tubule cells, integrated with their new neighbours they invade the lumen. We are examining this further using real time imaging in both mutant embryos and in embryos where polarity is selectively disrupted in either tubule or integrating cells.

The Function and Regulation of Podosomes in Dendritic Cells

M. A. West, H. Svensson, R. Zarra, A. R. Prescott, C. Watts; Division of Cell Biology and Immunology, University of Dundee, Dundee, United Kingdom

Podosomes are dynamic adhesive structures expressed in monocyte derived cells (macrophages, dendritic cells & osteoclasts) and some transformed cells. They are thought to play a role in cell migration and tissue invasiveness. We have been investigating the possible functions and control of podosome formation in murine dendritic cells. Our earlier studies showed that TLR signalling in dendritic cells (DC) triggers a reversible disassembly of podosomes that is mirrored by a reversible supramolecular complex formed by talin and RIAM. Finally, thrombin receptor stimulation of human platelets resulted in endogenous talin co-immunoprecipitating with RIAM. Thus, we have ordered a pathway from Rap1. In addition, shRNA-mediated knockdown of RIAM blocked complex assembly and integrin activation. By subcellular fractionation and immunofluorescence imaging, Rap1A(G12V) bypassed the requirement for PKC, establishing that Rap1 is downstream of PKC. Talin binding to integrins mediates Rap1-induced activation because Rap1A(G12V) failed to activate αIIbβ3 in cells expressing the integrin binding-defective talin(W59A). Over-expression of the Rap effector, RIAM, activated αIIBβ3 and bypassed the requirement for PKCα and Rap1. In addition, shRNA-mediated knockdown of RIM blocked complex assembly and integrin activation. By subcellular fractionation and immunofluorescence imaging, Rap1A(G12V) expression led to redistribution of talin to the plasma membrane and increased association with αIIbβ3. Furthermore, activated Rap1A increased the abundance of an ‘activation complex’ containing Talin and RIAM. Finally, thrombin receptor stimulation of human platelets resulted in endogenous talin co-immunoprecipitating with RIAM. Thus, we have ordered a pathway from agonist stimulation to integrin activation and established the Rap1-induced formation of an ‘integrin activation complex’, containing RIAM and talin, that binds to and activates the integrin.

Distinct Mechanism of Lytic Granule Release by Gα12/13-Cytotoxic T Lymphocytes

A. M. Beauvais, N. M. Simc, R. Varzi, V. P. Thomas, M. L. Dustin, Y. Sykulev; 1Thomas Jefferson University, Philadelphia, PA, 2Skirball Institute of Biomolecular Medicine, New York, NY, 3Blood System Research Institute, San Francisco, CA

Cytotoxic T lymphocytes (CTL) are capable of killing virus-infected and transformed cells with extreme selectivity and sensitivity by releasing cytolysins that deliver a lethal hit to target cells. Growing evidence suggests that mechanisms of granule release may vary for different cytotoxic lymphocytes and may influence the sensitivity of specific lysis. We have previously shown that sensitivity of lysis by CD8+ CTL is dependent on the peripheral adhesion ring (pSMAC) of the immunological synapse (IS) which functions as a gasket to focus the granules to the target cell membrane. We have also observed that the granules are directed to the central supramolecular cluster (cSMAC) and that disruption of pSMAC formation abrogates effective lysis. We now show that the CD4+ CTL are less efficient lytic effectors than CD8+ CTL despite similar expression levels of lytic granules. Nevertheless, granules isolated from CD4+ CTL can lyse target cells comparable to granules isolated from CD8+ CTL suggesting that CD4+ CTL have a distinct mechanism for targeting of cytolysins. To compare granule release by CD8+ and CD4+ CTL, we visualised IS formation and granule redistribution by CD4+ and CD8+ CTL using glass-supported lipid bilayers to mimic target cells. Analysis of lytic granule redistribution revealed that CD4+ CTL polarize granules towards the interface similar to CD8+ CTL. However, we show that the IS of CD8+ CTL is unlike that of CD4+ CTL in cSMAC granule localization. Further, using TIRFM we have found that CD4+ CTL demonstrate accumulation of secretory lysosomal membrane proteins mostly in the pSMAC while the CD8+ CTL have central accumulation in the cSMAC surrounded by the pSMAC ring. Our data show that CD4+ CTL utilize a distinct pathway of granule release to the periphery of the IS resulting in less effective granule delivery to the target cell.

Vav Proteins Control Integrin- and Adhesion-dependent ROI Production in Phagocytes

D. B. Graham, A. V. Milelic, V. Montgrain, K. Fujikawa, J. S. Brugg, R. Xavier, W. Swa; 1Department of Pathology & Immunology, Washington University School of Medicine and Siteman Cancer Center, St. Louis, MO, 2Department of Biochemistry, Hokkaido University School of Medicine, Sapporo, Japan, 3Department of Cell Biology, Harvard Medical School, Boston, MA, 4Department of Medicine, Harvard Medical School, Boston, MA

Reactive oxygen intermediates (ROI) generated by phagocytes possess potent antimicrobial properties, and patients bearing mutations in NADPH oxidase subunits develop chronic granulomatous disease (CGD) associated with recurrent, life-threatening infections. On the other hand, excessive ROI generation can contribute to tissue pathology in diverse settings, including sepsis and rheumatoid arthritis. More recently, ROI have also been implicated in intracellular signal transduction as second messengers which potentiate tyrosine kinase cascades by reversible oxidation of active site cysteine residues in protein tyrosine phosphatases. In phagocytes, the primary source of ROI produced during inflammatory responses is the NOX2 (gp91phox) NADPH oxidase complex. Unlike NOX1, NOX3 and NOX4 (which are constitutively active and regulated primarily by expression levels), or NOX5 and DUOX (which are activated by Ca2+), NOX2 is inactive in unstimulated phagocytes and becomes activated after exposure to inflammatory mediators as a result of assembly of cytosolic subunits with transmembrane gp91phox. Although the inductible assembly and function of the NOX2 is relatively well understood and involves translocation of regulatory subunits (p40, p47, p67, and Rac2) from the cytosol to plasma membrane-associated catalytic subunits (p91 and p22), the signaling pathways regulating NOX2 activation remain to be elucidated. A particular issue is the identification of GEF(s) responsible for the activation of Rac2 downstream of integrin or Toll-like receptors (TLRs). Herein, we identify the Vav family of Raf-related GEFs as critical regulators of integrin- and TLR-dependent ROI induction. We present data showing that Vav proteins exert global control over oxidant dependent ROI generation by regulating integrin-mediated “priming” of cytoxic NOX2 components and promoting GTP exchange on Rac2 in response to adhesion- or TLR-dependent ROI-generation in phagocytes. Strikingly, we demonstrate that Vav is specifically required for integrin-, but not TNFα- or GPCR-induced priming of NOX2, and that Vav-dependent ROI production is essential for neutrophil firm adhesion and spreading, and activation of several signaling effectors including the G protein-coupled receptors (GPR37A) that are important for the production of ROI.

39

A Roadmap to Integrin Activation

C. J. Lim, J. Han, N. Watana, A. Soriani, B. Ramikov, D. A. Calderwood, W. Puron-McLaughlin, E. M. Lafuente, V. A. Boussiotis, J. S. Shattil, M. H. Ginsberg; 1University of California, San Diego, La Jolla, CA, 2Pharmacology, Yale University School of Medicine, New Haven, CT, 3Division of Hematology and Oncology and Transplantation Biology, Massachusetts General Hospital, Boston, MA

Agonist stimulation of integrin receptors, composed of transmembrane α and β subunits, leads cells to regulate integrins’ affinity (“activation”) thus controlling cell adhesion and migration, extracellular matrix assembly, and contributing to angiogenesis, tumor cell metastasis, inflammation, the immune response, and hemostasis. A final step in integrin activation is the binding of the cytoskeleton to integrins to form integrin-activated cytoskeleton complexes. Various lines of evidence that regulate integrin affinity have been described, yet a pathway connecting agonist stimulation to talin binding and activation has not been mapped. We used forward, reverse, and synthetic genes to engineer and order an integrin activation pathway in a model CHO cell system expressing a prototype activating integrin, platelet αIIbβ3. Phorbol myristate acetate (PMA) activated αIIbβ3 only after the increased expression of both recombiant protein kinase Cz (PKCz) and talin to levels approximating those in platelets. Inhibition of Rap1 GTPase by Rap1GAP overexpression reduced αIIbβ3 activation while expression of the constitutively active Rap1A(G12V) bypassed the requirement for PKCz, establishing that Rap1 is downstream of PKCz. Talin binding to integrins mediates Rap1-induced activation because Rap1A(G12V) failed to activate αIIbβ3 in cells expressing the integrin binding-defective talin(W59A). Over-expression of the Rap effector, RIAM, activated αIIBβ3 and bypassed the requirement for PKCz and Rap1. In addition, shRNA-mediated knockdown of RIM blocked complex assembly and integrin activation. By subcellular fractionation and immunofluorescence imaging, Rap1A(G12V) expression led to redistribution of talin to the plasma membrane and increased association with αIIbβ3. Furthermore, activated Rap1A increased the abundance of an ‘activation complex’ containing Talin and RIAM. Finally, thrombin receptor stimulation of human platelets resulted in endogenous talin co-immunoprecipitating with RIAM. Thus, we have ordered a pathway from agonist stimulation to integrin activation and established the Rap1-induced formation of an “integrin activation complex”, containing RIAM and talin, that binds to and activates the integrin.
40

CD2-CD58 Interaction Activates Microdomain Formation and Signaling in the Absence of T-Cell Receptor Activation in Jurkat T Cells

Y. Kaizu, A. D. Douglass, R. D. Vale; Cellular and Molecular Pharmacology, University of California, San Francisco, San Francisco, CA

Activation of T-cell by antigen presenting cells (APC) is thought to involve the ligation of the T-cell receptor (TCR) and a subsequent tyrosine phosphorylation cascade, which includes activation of a critical scaffold protein called CD2. Another T cell surface protein called CD2, which interacts with human CD58 on the APC, also has been implicated in signaling but its role and requirement has been controversial and poorly understood. Through real time imaging in a reconstituted system consisting of Jurkat T-cells and a planar lipid bilayer (as a mimic of an APC), we found that activated TCR and CD2 separate into distinct microdomains and LAT tends to colocalize with the CD2 domains. In addition, CD58 alone, in the absence of TCR activation, caused co-clustering of CD2 and LAT into microdomains. The ACD8/D2 microdomains displayed robust phosphotyrosine staining, indicating a signaling function. These results suggest an important role of CD2 in T-cell activation, through the organization and activation of signaling molecules in the T-cell membrane.

41

E-cadherin/β-catenin Signaling Defines a Distinct Pathway of Dendritic Cell Maturation

A. Jiang, S. Ono, J. Untermaier, S. Jiang, J. A. Whitney, J. Connolly, J. Banchereau, M. Mellman; 1Department of Cell Biology and Section of Immunobiology, Ludwig Institute for Cancer Research, Yale University School of Medicine, New Haven, CT, 3Genzyme, Framingham, MA, 4Baylor Institute for Immunological Research, Dallas, TX

The maturation of dendritic cells (DCs) following exposure to microbial products, immune modulators, or inflammatory cytokines plays a critical role in initiating the immune response. We now find that maturation can also occur under non-inflammatory conditions, triggered by alterations in E-cadherin-mediated cell adhesion. Disruption of E-cadherin-mediated interactions results in all of the morphological correlates of DC maturation, including upregulation of MHC class II, costimulatory molecules, and CCR7, a chemokine receptor important for migration of DCs from sites of residence in peripheral tissue to draining lymph nodes. These events apparently occur at least in part through activation of the β-catenin signaling pathway, based on activation of TCP-1/EFT-LEF-dependent transcription and maturation induced by transfection of β-catenin. Inhibition of GSK3β, which normally suppresses β-catenin signaling by phosphorylation, also induces DC maturation. Remarkably, however, E-cadherin/β-catenin-stimulated DCs exhibit an overall transcriptional profile highly distinct from DCs matured by microbial products (Toll-like receptor [TLR] ligands). Notably, they fail to produce any inflammatory cytokines (e.g. IL-6, IL-12 and TNF-α), suggesting that these DCs are unable to initiate immune responses. Although E-cadherin-matured DCs are as effective as TLR-stimulated cells in presenting antigen to T cells in vitro, in vivo, immunization with E-cadherin-stimulated vs TLR-stimulated DCs produced entirely distinct T cell responses. E-cadherin-stimulated DCs generated IL-10-producing CD4+CD25+ T cells (possibly regulatory T cells that suppress immune responses), while LPS-matured DCs generated INF-γ-producing effector T cells that mediate immune responses. Thus, DCs matured in an E-cadherin-like manner may represent the elusive "tolerogenic DCs" present in vivo under steady state conditions. We propose that the steady state migration of DCs from peripheral tissues to lymph nodes may generate the E-cadherin-stimulated mature phenotype as peripheral DCs break E-cadherin contacts with their neighbors upon emigration from resident epithelia.

Regulation of Axonal Dynein Activity by a Calmodulin and Radial Spoke Associated Complex (CRC)

E. E. Dynes, F. E. Smith; Department of Biological Sciences, Dartmouth College, Hanover, NH

Calcium-induced modulation of ciliary motility involves regulation of dynein-driven microtubule sliding. Numerous studies indicate that calmodulin localizes to the axoneme and is a key calcium sensor. To understand the role of calmodulin in modulating dynein activity, we first used an immunoprecipitation approach to identify calmodulin interactors. In addition to the radial spokes and calmodulin, nine polypeptides were specifically precipitated using anti-calmodulin antibodies. These nine polypeptides form two distinct complexes, one of which localizes to the C1a projection of the central apparatus (Wargo et al., 2005). Three polypeptides (CAMP-IP2, -3, and -4) form a second complex that is precipitated from both central pairless and radial spokeless mutants. Using mass spectrometry we determined that IP2 is the Chlamydomonas homologue of AAT-1, a protein first identified in testis that forms a complex with an A-kinase anchor protein (AKAP) (Yukitake et al. 2002). Using several biochemical approaches we determined that CAMP-IP2 interacts with the radial spoke protein RSP3, an AKAP that links the spoke to the doublet microtubule. These results indicate that the CalmIP2, -3, -4 complex most likely localizes to the base of the radial spokes near the dynein regulatory complex. We then tested whether this complex is involved in regulating dynein activity using isolated axonemes in a microtubule sliding assay. Addition of CaM-IP2 antibodies to mutant axonemes with reduced dynein activity which lack either the radial spokes (pf14) or central apparatus (pf18) restores dynein activity to wild-type levels. Importantly, addition of CaM-IP2 antibodies also reduces dynein activity in axonemes lacking both the central apparatus and the inner arm dynein heavy chains (pf16a/b) but not inner arm dynein (pf16a/b). Based on these combined results, the calmodulin and spoke associated complex (CRC) most likely mediates regulatory signals between the central apparatus/ radial spokes and inner arm dynein.

43

Chlamydomonas Hydin Is a Central Pair Protein Required for Flagellar Motility

K. F. Lechtreck, G. B. Witman; University of Massachusetts Medical School, Worcester, MA

Mutations in HYDIN cause lethal congenital hydrocephalus in mice, and HYDIN is a strong candidate for causing hydrocephalus in humans. In mice, expression is high in spermatozoa and in ciliated epithelia of ovary, lung and brain, suggesting a role for hydin in the development or function of motile cilia. The gene is well conserved in many ciliated and flagellated species, including the green alga Chlamydomonas. An antibody raised against a portion of Chlamydomonas hydin was specific for a protein of ~540 kD in western blots. In immunofluorescence and electron microscopy, the antibody specifically decorated the central pair apparatus of Chlamydomonas. Hydin was strongly reduced in axonemes of pf15 and pf18, which lack the central pair apparatus. An 80% knock-down of HYDIN resulted in short and paralyzed flagella. Residual motility was often limited to one of the two flagella, and the two flagella of a given cell were frequently arrested asymmetrically, with one flagellum in the 'hands up' and one in the 'hands down' position. Electron microscopy of HYDIN knock-down strains revealed defects in the central pair apparatus, ranging from missing projections to the loss of microtubules. The central pair Kinesin-like protein 1 was strongly reduced in axonemes from HYDIN knock-down cells, suggesting that its localization to the central pair requires hydin. A combination of biochemical and immunocytochemical analyses showed that hydin is anchored on both central microtubules and partially encompasses the central pair. In conclusion, Chlamydomonas hydin is a central pair protein required for flagellar motility. Hydrocephalus caused by mutations in HYDIN likely involve malfunctioning of brain cilia due to a defect in the central pair. Currently, we are analyzing the effect of a HYDIN mutation on central pair structure and flagellar motility in the mouse.

IFT46 Transports Outer Arm Dynein into Flagella

Y. Hou, H. Qin, J. Follit, G. Pazour, J. Rosenbaum, G. Witman; 1Cell Biology, UMASS Medical School, Worcester, MA, 2Biological Sciences, Texas A&M University, College Station, TX, 3Program in Molecular Medicine, UMASS Medical School, Worcester, MA, 4Department of Molecular, Cellular, and Developmental Biology, Yale University, New Haven, CT

Intraflagellar transport (IFT) is responsible for transporting outer arm dynein into flagella. We isolated flagellae from three different strains of Chlamydomonas, with deletions of RRF46, MRC161, and MRC163, respectively. The IFT46 mutant showed defects in outer arm dynein localization. Immunofluorescence microscopy revealed that complex A and complex B proteins occurred in distinct but overlapping compartments in the peribasal body region; in the absence of IFT46, complex B protein IFT172 no longer overlaps with complex A, indicating that it does not interact directly with complex A in the cell body. Biochemical and MS analysis showed that IFT46 is phosphorylated at three sites. However, when the three sites were mutated to alanines or aspartic acids, the mutant constructs rescued IFT46 to wild-type swimming. Deflagellation experiments on the rescued cells showed that these phosphorylations are not critical for IFT46's function in flagellar assembly.

A Core Complex of BBS Proteins Promotes Ciliary Membrane Biogenesis

M. V. Nachury,1 A. V. Loktev,2 F. Bazan,3 V. C. Sheffield,4 P. K. Jackson1,2; 1Department of Tumor Biology and Angiogenesis, Genentech, South San Francisco, CA, 2Department of Pathology, Stanford University School of Medicine, Stanford, CA, 3Department of Protein Engineering, Genentech, South San Francisco, CA, 4Department of Pediatrics and Howard Hughes Medical Institute, University of Iowa, Iowa City, IA

The Primary Cilia Play an Essential Role in Cell Migration through PDGFR-α Signaling

L. Schneider,1 A. Schwab,2 C. Stock,2 G. Pazour,3 E. Hoffmann,1 P. Satir,4 S. Christensen1; 1Department of Biochemistry, The August Krogh Institute, University of Copenhagen, Copenhagen, entrance are inhibited. In 1977 Albrecht-Buhler observed that primary cilia predominantly oriented parallel to the direction of movement in migrating 3T3 fibroblasts and hypothesized that Specific (gas) protein PDGFR-alpha localizes to the primary cilium and its signaling is regulated through the cilium in quiescent cells. Wt MEFs re-enter cell cycle upon incubation with Primary cilia are essential in PDGFR-alpha signaling during growth arrest in mouse embryonic fibroblasts (MEFs) (Schneider et. al. 2005 Curr Biol. 25;15(20):1861-6). The Growth Arrest network. Finally, the dense network seals to form a double lipid bilayer. Our data suggest that NE formation does not involve vesicle fusion but rather tethering, branching and fusion of tubules interact with DNA and eventually tubules align with the chromatin surface. In a second step, immobilized membrane tubules expand by branching and fuse to form a dense tubular plane above a flat chromatin by 4D-confocal microscopy. High-resolution time lapse imaging of NE reorganization events suggest that the NE forms by at least three steps. First, the tips of ER method for imaging nuclear envelope formation in real time. We immobilized dsDNA on a glass surface and transformed the spotted DNA into chromatin by the addition of Xenopus egg experiments will test for BBSome-dependent transport of known and novel ciliary signaling factors. As predicted, αRNA-mediated depletion of PCM1 disintegrates centriolar satellites and prevents the assembly of primary cilia. Conversely, loss of the BBSome subunit BBS1 keeps centriolar satellites functionally intact while still preventing ciliogenesis. These results place PCM1 upstream of the BBSome and imply that the BBSome is a critical ciliogenic cargo of centriolar satellites. To further understand the ciliogenic function of the BBSome, we performed structural modeling on the most conserved subunit and uncovered two Pleckstrin Homology (PH) folds. PH domains usually recognize phosphatidylinositol phosphate and protein-lipid interaction assays confirmed that this subunit recognize specific phospholipids. In vivo, BBSome-lipid interactions appear to take place at the ciliary membrane since detergents selectively extract the ciliary BBSome pool. In conclusion, we propose that centriolar satellites deliver the BBSome to the basal body where it is transferred onto the ciliary membrane and may coordinate the intrflagellar transport of signaling factors involved in weight regulation, phototransduction and kidney homeostasis. Future experiments will test for BBSome-dependent transport of known and novel ciliary signaling factors.

The Roles of Cilia in Mouse Developmental Signaling Pathways

K. Anderson, D. Huangfu, T. Caspary, J. Oshima; Developmental Biology, Memorial Sloan-Kettering Cancer Center, New York, NY

Although the core of the Hedgehog signal transduction pathway is conserved between Drosophila and vertebrates, recent studies have identified at least a dozen proteins that are required for Hedgehog signaling in the mouse, but not in Drosophila. Among these vertebrate-specific components of the pathway are the Intraflagellar Transport (IFT) proteins, which are known to be required for the assembly and maintenance of cilia. Mouse mutants that lack any one of several different IFT proteins fail to specify ventral neural cell types, which depend on Sonic hedgehog signaling. Genetic analysis shows that the IFT proteins are required for cells to respond to Hedgehog and that they control the activity of the Gli transcription factors that mediate Hedgehog responses. The data indicate that IFT proteins are required for Hedgehog signaling because Hedgehog signal transduction components are localized to non-motile primary cilia. Evidence from our lab and other labs has suggested that cilia are required for other signaling pathways as well. We are testing whether cilia are required for canonical and noncanonical Wnt signaling, as well as other developmental signaling pathways.

The Primary Cilia Play an Essential Role in Cell Migration through PDGFR-α Signaling

L. Schneider,1 A. Schwab,2 C. Stock,2 G. Pazour,3 E. Hoffmann,1 P. Satir,4 S. Christensen1; 1Department of Biochemistry, The August Krogh Institute, University of Copenhagen, Copenhagen, Denmark, 2Institut für Physiologie, Muenster, Germany, 3Molecular Medicine, University of Massachusetts, Worcester, MA, 4Department Anatomy and Structural Biology, Albert Einstein College of Medicine Yeshiva University, Bronx, NY

Primary cilia are essential in PDGFR-alpha signaling during growth arrest in mouse embryonic fibroblasts (MEFs) (Schneider et. al. 2005 Curr Biol. 25;15(20):1861-6). The Growth Arrest Specific (gas) protein PDGFR-alpha localizes to the primary cilium and its signaling is regulated through the cilium in quiescent cells. Wt MEFs re-enter cell cycle upon incubation with PDGFR-AA, which is a specific ligand for PDGFR-alpha. In growth arrested Tg3774E mutant MEFs, which have defects in cilary assembly PDGFR-alpha cascades leading to cell cycle entrance are inhibited. In 1977 Albrecht-Buhler observed that primary cilium predominantly oriented parallel to the direction of movement in migrating 3T3 fibroblasts and hypothesized that they are involved in directional control of these cells. Benzing and Walz (2006) hypothesized that the primary cilium in acts as a cellular GPS. Here we investigated a possible role of the primary cilium in PDGFR-alpha-mediated regulation of cell migration in fibroblasts. Initially we used wound healing assays to show that the primary cilium in growth arrested wt MEFs orient parallel to one another and perpendicular to a wound within 30-60 minutes after wounding. Migration speed is lowered during quiescence compared to cells in interphase growth. PDGFR-AA incubation increases the migration speed and translocation directionality of wt cells during cell growth arrest. Growth arrested Tg3774E MEFs have significantly higher migration speed compared to wt MEFs, and migration speed is unaffected by PDGFR-AA incubation. Further Tg3774E MEFs have decreased translocation directionality. Using micro-pipettes to inject small amounts of PDGFR-AA creating a gradient, we show that growth arrested wt MEFs respond immediately to PDGFR-AA and migrate towards the pipette. Tg3774Epcp cells do not react to gradients of PDGFR- AA. These results strongly indicated that the primary cilium is necessary for PDGFR-alpha-influenced cell migration and control of directional movement, which is essential in developmental processes and wound-healing.

Role of Mmr1p and Cortical ER in Retention of Mitochondria at the Cell Poles during Inheritance in Budding Yeast

T. Swayne,1 I. Boldogh, 1 S. Thoms, 2 R. Erdmann, 2 L. A. Pon 1; 1Department of Anatomy/Cell Biology, Columbia University College of Physicians & Surgeons, New York, NY, 2Institute of Physiological Chemistry, University of Bochum, Bochum, Germany

During cell division, yeast mitochondria move to and are anchored at opposite cellular poles, the bud tip and mother cell tip. These processes contribute to equal segregation of the organelle during inheritance. We find that two proteins implicated in mitochondrial inheritance, a type V myosin (Myo2p) and a mitochondrial protein that binds to Myo2p (Mmr1p), are not required for poleward mitochondrial movement leading to inheritance or for normal mitochondrial membrane organization detected by EM. In contrast, mutation of these proteins results in reduced retention of mitochondria in the bud tip, and enhanced retention of mitochondria in the mother tip. Mislocalization of Myo2p from the bud tip does not result in release of accumulated mitochondria from that site. Thus, Myo2p does not interact directly with mitochondria in the bud tip. Rather, ultrastructural analysis indicates that mitochondria interact with cortical ER (cER), flattened sacs of ER that underlie the yeast cell cortex, during retention of mitochondria at the poles. Mitochondria-associated microsomes (MAM), ER-derived membranes that co-fractionate with yeast mitochondria and are released from the organelle by low pH, have been implicated in phospholipid delivery from ER to mitochondria. We find that 1) Mmr1p is recovered with mitochondria and MAM during subcellular fractionation, 2) Mmr1p and MAM are released from the mitochondrial fraction by low pH, and 3) deletion of MMR1 results in a decrease in the amount of MAM recovered with mitochondria during subcellular fractionation. Deletion of MMR1 has no obvious effect on cER localization or morphology. Rather, our findings support a role for ER-mitochondrial interactions in anchorage of mitochondria at the poles during cell division and inheritance, and for Mmr1p in this process. Finally, Myo2p may contribute to Mmr1p function as a motor to drive movement of Mmr1p from the mother cell tip to the bud tip.

Real Time Imaging of Nuclear Envelope Formation

M. W. Hetzer, D. J. Anderson; Molecular and Cell Biology Laboratory, Salk Institute for Biological Studies, La Jolla, CA

Nuclear envelope (NE) reformation on the surface of chromatin is a massive membrane-restructuring event that occurs at the end of mitosis in metazoans. Two models have been proposed to explain this poorly understood process. Electron and fluorescence microscopy studies on fixed nuclear assembly intermediates supported the idea that NE formation involves the fusion of chromatin-bound nuclear vesicles. In contrast, in vivo data suggest that the NE re-emerges from the tubular ER network. To discriminate between these possibilities we have developed a novel method for imaging nuclear envelope formation in real time. We immobilized dsDNA on a glass surface and transformed the spotted DNA into chromatin by the addition of Xenopus egg extracts. In the presence of fluorescently-labeled membranes a NE containing nuclear pore complexes formed specifically on the chromatin spot. NE formation was monitored in a single x-y plane above a flat chromatin by 4D-confocal microscopy. High-resolution time lapse imaging of NE reorganization events suggest that the NE forms by at least three steps. First, the tips of ER tubules interact with DNA and eventually tubules align with the chromatin surface. In a second step, immobilized membrane tubules expand by branching and fuse to form a dense tubular network. Finally, the dense network seals to form a double lipid bilayer. Our data suggest that NE formation does not involve vesicle fusion but rather tethering, branching and fusion of membrane tubules.
A Novel Mitotic Function for Rab5 in Structural Reorganization of the Endoplasmic Reticulum and Nuclear Envelope Disassembly

A. Audhya, A. Desai, K. Oegema; Cellular and Molecular Medicine, Ludwig Institute for Cancer Research, La Jolla, CA

Membranes of the endoplasmic reticulum (ER) typically exist in two morphologically unique forms, either a tubular network that extends toward the cell periphery or as sheets that encircle the nucleus. This fundamental property relies on a number of factors that are enriched on either the peripheral or nuclear ER. However, when the nuclear envelope disassembles during mitosis, the ER must transiently reorganize and lose this distinction. Inner nuclear membrane proteins are redistributed to the peripheral ER, where they reside until nuclear envelope reformation. How this transition is regulated remains unclear. Here we identify two pathways required for ER remodeling that involve a class of integral membrane ER proteins, DJ1/NogoA and Reticulon, and the Rab-type GTPase Rab5. We show that disruption of either pathway perturbs ER morphology in a phenotypically similar fashion, which is most pronounced during mitosis when the ER is normally restructured and compacted. Importantly, in the absence of ER remodeling, nuclear envelope disassembly fails. Our results argue that ER reorganization is a necessary step essential for complete nuclear envelope disassembly, and indicate a novel role for Rab5 in ER reorganization that is independent of its previously characterized functions during endocytosis.

The Mother Centriole Plays an Instructive Role in Defining Cell Geometry

J. L. Feldman, S. Geimer, W. F. Marshall; 1Biochemistry, University of California, San Francisco, San Francisco, CA, 2Biologie/Elektronenmikroskopie, Universität Bayreuth, Bayreuth, Germany

A fundamental question in cell biology is how cell geometry is established and maintained. Precise organelle positioning is critical for signaling, growth, division, and in establishing cell polarity. The centriole provides an ideal case for investigating the problem of organelle positioning. Unlike more complex organelles, centriole position can be easily measured and described. Moreover, centriole position is known to respond to cell polarity and developmental cues, and is thought to link such signals to the arrangement of the cytoskeleton. Currently, little is known about the mechanism by which centrioles are properly positioned within the cell. Using a computer-aided screen in the unicellular green alga Chlamydomonas reinhardtii, we identified thirteen mutants, which we term askev (ask), with defective centriole positioning. Combining genetic analysis, three-dimensional imaging, and a novel algorithm for quantifying cellular geometry, we demonstrate that the mother centriole guides the daughter centriole to the proper subcellular location. Specifically, in mutants where mother and daughter centrioles are separated, only mother centrioles localize properly. We further show that in mutants in which the centrioles are detached from the nucleus, the nucleus becomes randomly positioned while the mother centrioles retain correct positioning, indicating that the nucleus depends on the mother centriole for proper positioning within the cell and not vice-versa. Classic experiments in ciliates have demonstrated that local cell geometry is controlled by a stable structure with defined orientation that can propagate positional information over many generations. Our data indicate that the mother centriole serves this purpose, acting as a node to coordinate the positioning of many subcellular structures. We have identified flanking sequence to the insertion site in ask1, ask2, and ask7 and will present our progress towards identifying the affected loci in these mutants.

The P21-activated Kinases Cla4 and Ste20 Regulate Vacuole Inheritance in the Budding Yeast S. cerevisiae

C. R. Bartholomew, C. F. J. Hardy; Cell and Developmental Biology, Vanderbilt University School of Medicine, Nashville, TN

The vacuole (lysosome) in budding yeast is partitioned along actin cables, using the type V myosin, Myo2, via a tubular segregation structure that enters the bud and fuses to the daughter vacuole. The vacuole-specific Myo2 receptor, Vac17 is degraded in the bud during mitosis, preventing vacuole movement to the bud neck later in the cell cycle. The P21-activated kinases (PAKs) Cla4 and Ste20 accumulate specifically in the bud site of polarized bud growth. Here we show that Cla4 also accumulates in the bud at a perivacuolar site associated with the segregation structure. Cla4 does not interact with vacuoles in the mother or with vacuoles in mutants defective for segregation structure formation and vacuole inheritance. In support of a role for PAKs in regulating vacuole inheritance, cells over expressing CLA4, and to a lesser extent STE20, fail to form segregation structures. Interestingly, over expression of CLA4 results in Vac17 degradation an event which prevents segregation structure formation and vacuole inheritance. Strikingly, these defects are suppressed in cells expressing a non-degradable form of Vac17 (Vac17APEST). In addition, we find that PAK activity is required for the degradation of Vac17 during mitosis. These results suggest that segregation of negative regulators of vacuole movement to the bud positions the cell to inactivate the organelle partitioning machinery after, but not before, the vacuole has been partitioned to the bud.

Pex11β Functions as a Peroxisomal Scaffold Protein Involved in Membrane Elongation of Pre-Existing Peroxisomes Prior to Organellar Fission

B. Agricola, H. K. Dellel, G. H. Luers, M. Schrader; 1Department of Cytobiology, University of Marburg, Marburg, Germany, 2Department of Anatomy and Cell Biology, University of Marburg, Marburg, Germany

Members of the Pex1 family of peroxisomal membrane proteins have been implicated in the regulation of peroxisome abundance, division and proliferation, but their biochemical properties are still a matter of debate. We have shown recently that Pex1p, one of the three mammalian isoforms, is primarily involved in membrane elongation of peroxosomes instead of directly mediating peroxisome division. To further elucidate its function, and to manipulate peroxisomal division at different steps, we have examined N- and C-terminally modified versions of Pex1p. Removal of the C-terminal transmembrane domain or the cytoplasmic tail did not interfere with targeting but inhibited elongation of peroxisomes. Addition of a fluorescent tag to the C-terminal (but not to the N-terminus) led to the formation of tubular peroxisomal aggregates (TPAs), which had lost their ability to constrict or divide. The number of peroxisomes was drastically reduced, often leaving the cell with only one large peroxisomal structure. Ultrastructural and fluorescence studies revealed that the TPAs were composed out of highly ordered elongated peroxisomal membranes which each originated from a pre-existing peroxisome. Pex11β localized predominantly to the tail-like membrane compartment, whereas matrix proteins and PMP70 were exclusively targeted to the connected mature peroxisome. ER marker proteins were absent from these membrane structures. Time course experiments revealed that Pex1p early on localized to the membranes of pre-existing, spherical peroxisomes, where it was observed to concentrate at the side of tubule formation. These observations imply that Pex11β is a peroxisomal scaffold protein required for the deformation and elongation of the peroxisomal membrane. Our data further demonstrate that peroxisomal growth and division is a complex multistep process where the consecutive steps are linked to each other, and may be triggered by an assembly of distinct machineries at the peroxisomal membrane.

Kinetics of Morphogen Gradient Formation

M. González-Gaitán1,2; 1Max Planck Institute of Molecular Cell Biology and Genetics, Dresden, Germany, 2Department of Biochemistry, University of California, San Francisco, San Francisco, CA, 2Biochemistry, CNRS UMR 6061, Rennes, France, 3Biologie, CNRS UMR 8542, Ecole Normale Supérieure, Paris, France

During the larval development of Drosophila the morphogen Decapentaplegic (Dpp), a TGF-beta homolog, provides cells with information about their position along the anterior-posterior axis of the developing wing. Dpp is expressed in a restricted source of cells from where it spreads to form a gradient of concentration in the target tissue. How the morphogen molecules move and form graded profiles of concentration is not fully understood. It has been proposed that two different modes of transport through the wing epithelium play a role in Dpp gradient formation - extracellular diffusion and intracellular trafficking (transcytosis). To determine the relative contribution of each of these modes of transport to the establishment of a stable and robust gradient, high-resolution quantitative data about the kinetics of morphogen spreading are necessary. We have approached the kinetic analysis of Dpp gradient formation at the tissue level by employing FRAP (Fluorescence Recovery After Photobleaching). Using this method, we have been able to determine the effective diffusion coefficient, degradation rate, production rate and mobile fraction of Dpp and other morphogens. These crucial kinetic parameters provide a full quantitative description of the morphogen gradient formation. In addition, by applying FRAP in different conditions, we have gained insight on the cell biological processes that are involved in Dpp transport, as well as in maintaining the stability and robustness of the gradient.

Activation of Notch Signalling by Transcytosis

R. Le Borgne, F. Schweiguth; 1Genétique et Développement, CNRS UMR 6061, Rennes, France, 2Biologie, CNRS UMR 8542, Ecole Normale Supérieure, Paris, France

Cell-cell signalling is an essential process in the formation of multicellular organisms. Notch is the receptor of an evolutionarily conserved signalling pathway regulating numerous developmental decisions. Notch and its transmembrane ligands are distributed widely throughout development, yet Notch activity is tightly controlled and restricted in time and space. In Drosophila, Notch signalling regulates binary fate decisions at each asymmetric cell division in sensory organ lineages. Following division of the sensory precursor cell (pI), Notch is activated in one daughter cell (pI1a) and inhibited in the other (pIb). The E3 ubiquitin ligase Neuralized segregates unequally in the pIb cell. Neuralized upregulates endocytosis of the Notch ligand Delta in the pIb cell and acts in the pIb cell to promote the activation of Notch in the pIa cell by a yet unknown mechanism. We observed that in the pIb cell, Delta mostly resides in endosomal structures at steady state. By contrast, in the pIa cell, Delta localizes predominantly at the basal-lateral cortex and is physically separated from Notch that resides at the apical cortex. In neuralized mutant cells, Delta accumulates at the basal-lateral cortex in both pl daughters preventing its interaction with apically localized Notch. We propose that in order to become
active. Delta has to be transported to the basal membrane towards the apical cortex by a transcytotic route, and that Neuralized promotes the first step in this intracellular transport event. Regulating the sorting of the receptor and its ligands along the apico-basal axis could be an efficient mechanism to control the activation Notch signalling in a spatio-temporal manner.

FGF Mediates Asymmetric Heart Specification in the Primitive Chordate Ciona intestinalis
B. Davidson, M. Levine; UC Berkeley, Berkeley, CA
Asymmetric cell divisions are often crucial for specification of embryonic cell lineages. However, no such role has been demonstrated during vertebrate cardiac specification. Here we employ the simple chordate, Ciona intestinalis, to investigate the role of asymmetric cell divisions in chordate heart development. Midway through embryogenesis the four cells of the Ciona heart lineage undergo an asymmetric division, generating four small rostral heart precursor cells and four large caudal tail muscle precursors. We demonstrate that this division is associated with an FGF driven specification event. Targeted expression of a dominant negative FGF receptor blocks the asymmetric division and heart specification. Specification is also blocked by inhibition of MAPK signaling, or targeted expression of a constitutive repressor form of the downstream transcriptional effector Ets1/2 (Ets-WRPW). Conversely, application of bFGF to isolated heart lineage cells or targeted expression of a constitutively active form of Ets1/2, Ets-VP16, doubles the number of heart progenitor cells. Intriguingly, blocking the MAPK pathway or Ets activation does not appear to inhibit asymmetric cell division. We are currently investigating this apparent uncoupling of specification and asymmetry downstream of FGF. We are also exploring the functional importance of asymmetric cell division in Ciona cardiogenesis and whether this role is conserved in the vertebrates.

Retinoic Acid Signaling Limits Atrial and Ventricular Cells through Different Cellular Mechanisms
J. S. Waxman, B. R. Keegan, D. Yelon; Developmental Genetics, Skirball Institute of Biomolecular Medicine/NYU School of Medicine, New York, NY
All vertebrate hearts begin as a simple, linear tube composed of a single atrium and ventricle. The proper proportion of atrial and ventricular cells needs to be determined in order to establish a normal, functional heart. Work from chicks and mice has suggested that retinoic acid (RA) signaling determines the relative proportions of the atrial and ventricular chambers through instilling atrial identity. Here, we use loss and gain of function experiments to test the hypothesis that RA signaling is necessary and sufficient for determining atrial cell identity in the zebrafish heart. To our surprise, loss of function experiments indicate that RA signaling is not required to create atrial cells in zebrafish. Instead, loss of RA signaling results in increased numbers of both atrial and ventricular cells. Using fate mapping to examine the cellular mechanisms underlying these increases, we find that the increase in atrial and ventricular cells occur through different mechanisms. Loss of RA signaling causes increased numbers of progeny from atrial progenitors and also causes increased specification of ventricular progenitors. In complementary gain of function experiments, we find that high RA signaling can eliminate all atrial and ventricular cells. However, modest increases in RA signaling can increase the number of atrial cells without affecting the number of ventricular cells, also suggesting there may not be a tradeoff between atrial and ventricular cells. Therefore, our results indicate that the relative proportions of cardiac chambers in the zebrafish heart is determined through independent effects of RA signaling upon atrial and ventricular cells.

Functional Roles of Wnt and Slug Target Genes during Avian Neural Crest Development
L. A. Tanyhill, M. Bronner-Fraser; Biology, California Institute of Technology, Pasadena, CA
The vertebrate neural crest is a population of migratory cells that arises, in part, via an inductive interaction between neural plate and ectoderm. Previous work in our lab has demonstrated that Wnt signals are necessary and sufficient for induction. However, the molecular nature of downstream targets of Wnt signaling are unknown, and few quantitative studies have examined the expression of candidate genes involved in this process. To this end, we screened the Affymetrix microarray to identify novel targets of Wnt signaling during neural crest development, employing intermediate neural plate tissue cultured in collagen in the presence of either Wingless or control conditioned medium as the starting material. Secondary in situ hybridization analysis of those genes that are induced by Wnt signaling > 2-fold reveals many novel markers of the neural crest. One Wnt target gene is the transcriptional repressor, Slug, known to regulate various genes in the pre-migratory neural crest and be involved in epithelial-to-mesenchymal transitions. We find that depletion of Slug using morpholino antisense oligonucleotides results in the up-regulation of many dorsal neural tube genes, as assessed by QPCR. Moreover, the cell adhesion molecule cadherin6B is de-repressed by 30 minutes after blocking Slug translation. Examination of the chick cadherin6B genomic sequence revealed the presence of three pairs of clustered E boxes, representing putative Slug binding sites. Furthermore, in vivo and in vitro biochemical analyses demonstrate that Slug directly binds to these sites and regulates cadherin6B transcription. These results are the first to describe a direct target of Slug repression in vivo and in the context of the epithelial-to-mesenchymal transition that characterizes neural crest development. Collectively, these experiments have enabled us to generate a molecular description of genes activated by Wnt signaling that facilitate the transformation of a non-motile precursor cell into a migratory neural crest cell.

Lipoproteins in Hedgehog Signaling
S. Eaton, D. Panavoko, C. Eugster; Max Planck Institute of Molecular Cell Biology and Genetics, Dresden, Germany
Mechanisms controlling the spread and signaling activity of morphogens are critical for growth and pattern formation. Morphogens of the Wnt and Hedgehog families are covalently linked to lipids, which are essential for normal trafficking and signaling of these proteins. While the lipid anchors confer a strong affinity for membranes, we have shown that Wingless and Hedgehog can be released from the cell membrane on the Drosophila lipoprotein Lipophorin. This association is necessary for normal long-range signaling. Our recent data show that Lipophorin does not just affect Hedgehog transport, but has an integral role in the Hedgehog signaling pathway. Lipophorin particles themselves are required for the degradation of Cubitus interruptus that occurs in the absence of Hedgehog. Lipophorin may stabilize CI, at least in part, by binding to Lipophorin and altering its signaling activity. Furthermore, binding of the glypicanc Dally to Lipophorin increases Hedgehog signaling efficiency without affecting its spread. Thus, Lipophorin is a multicomponent signaling particle - our data raise the possibility that lipoprotein association may just affect Hedgehog transport, but has an integral role in the Hedghog signaling pathway. Lipophorin particles themselves are required for the degradation of Cubitus interruptus that occurs in the absence of Hedgehog. Lipophorin may stabilize CI, at least in part, by binding to Lipophorin and altering its signaling activity. Furthermore, binding of the glypicanc Dally to Lipophorin increases Hedgehog signaling efficiency without affecting its spread. Thus, Lipophorin is a multicomponent signaling particle - our data raise the possibility that lipoprotein association may increase the complexity of signals that can be generated by morphogens.

Intraflagellar Transport (IFT) and Flagellar Assembly: New Insights into the Role of Cilia/Flagella in Health and Disease
J. L. Rosenbaum; Department of Molecular Cellular/Developmental Biology, Yale University, New Haven, CT
Much of the new research interest in cilia and flagella has been derived from the discovery of the Intraflagellar Transport (IFT) process in 1993. The molecular basis of IFT, required for the assembly of almost all eukaryotic cilia and flagella, has led to the discovery of genes involved in a variety of human diseases in which the role of cilia was unsuspected. Among these is the most common life threatening inherited disease of humans, PKD (polycystic kidney disease) which has been shown to involve the absence or abnormal function of the primary cilium of kidney tubules. In the retina, the primary cilium gives rise to the rod outer segments, and it is now known that a defective IFT process within the connecting cilium is related to rod outer segment degeneration and blindness (RP, retinitis pigmentosum). In addition, all developmental condition, Situs Inversus, (organs misplaced on wrong side of body), has been related to the absence or abnormal function of cilia on the embryonic node. Recent genomic and proteomic analyses have led to the discovery that cilia are also involved in pathologies such as Bardet-Biedl Syndrome (BBBS) and Congenital Hydrocephalus. New work centers on the role of cilia in the control of the cell cycle. Almost all cells in the Go stage of the cell cycle have a primary cilium that is resorbed prior to cell division, when the ciliary basal bodies duplicate and become the poles of the mitotic apparatus. This resorption may be involved in the cell cycle, as recent results indicate that there are ciliary IFT proteins required for the completion of cell division. Finally, IFT may be directly involved in the sensory processes of primary cilia as IFT is required for the movement of channels and receptors in the plane of the ciliary membrane. (Support, NIH-GM-38135).

Preformed Homo- and Heterodimers of EGF/ErbB2 Receptors as Major Forms on the Cell Surface
T. Sudhaharan, P. Liu, R. Koh, L. C. Hwang, T. Wohland, I. Maruyama; Centre for Molecular Medicine, Singapore, 2Chemistry, National University of Singapore, Singapore, 3Institute of Molecular and Cell Biology, Singapore, 4Molecular Neuroscience Unit, Okinawa Institute of Science and Technology, Okinawa, Japan
The epidermal growth factor (EGF) /ErbB receptor family plays pivotal roles in the development of organisms ranging from worms to humans. Dysregulation of the receptor’s activity is frequently implicated in a variety of cancers. It is widely thought that ligand binds to the monomeric form of the receptor and induces its dimeric form for activation. Prior to ligand binding, however, it remains controversial whether the receptor has a monomeric or dimeric structure. We have recently found that the majority of the EGF receptor (EGFR) and ErbB2, another
member of the family also called HER2 or Neu, have preformed homo- and heterodimeric structures at physiological expression levels (<10^12 molecules per cell) on the cell surface. When EGF and ErbB2 fused with a fluorescent protein (FP) were expressed on the cell surface at physiological levels, fluorescence resonance energy transfer (FRET) was clearly observed between the donor and acceptor FPs. Furthermore, cross-correlation between FPs separately fused to EGF or ErbB2 was also observed by fluorescence cross-correlation spectroscopy (FCCS), indicating EGF and ErbB2 molecules diffuse together as homo- or heterodimers in the cell membrane. Our results demonstrate that the unactivated cell-surface receptors can form spontaneously homo- and heterodimers as major forms.

62 Interaction of EGF-R and COX-2 Signaling Pathways in Human Fetal Intestine
R. M. A. Kajumte, P. Lindkainen, S. Leppä, A. Ristimäki, P. Miettinen; Molecular and Cancer Research Program, University of Helsinki, Helsinki, Finland, 2Hospital for Children and Adolescents, Helsinki University Central Hospital, Helsinki, Finland, 3Department of Oncology, Helsinki University Central Hospital, Helsinki, Finland, 4Program for Developmental and Reproductive Biology, University of Helsinki, Helsinki, Finland

Hydrocortisone (HC) has been used in clinical trials to improve the outcome of preterm infants and indomethacin, an inhibitor of both cyclooxygenase-1 (COX-1) and -2 (COX-2), is used to treat patent ductus arteriosus (PDA). Side-effects related to NSAID treatment include gastric lesions in the mouse, necrotizing enterocolitis (NEC) and spontaneous intestinal perforation (SIP). The identification of the cellular pathways in the development of NEC and gastric lesions is critical. Data pertaining to the role of indomethacin and glucocorticidal drug treatment in the development of gastric lesions is scarce. The aim of this study was to elucidate the crosstalk between EGF-R, glucocorticoids and COX-2 expression during human intestinal development and the interplay between them in the intestine using 1) normal small intestine cell line 2) paraffine sections of human fetal intestine, wt and EGF-R null mice. We showed that HC, indomethacin or PGE_2 alone had no significant effect on cell proliferation. However, when HC was combined with EGF, they synergistically increased cell proliferation and migration but HC had no effect on MAPK (pERK) or PI3-K (pAK) pathway when combined to EGF. High doses of indomethacin also induced apoptosis. EGF upregulated COX-2 mRNA and this could be inhibited by EGF-R, MAPK and PI3-K inhibitors. EGF-induced COX-2 mRNA upregulation was suppressed by HC, but HC alone had no significant effect. Correlating with these results, also PGE_2 production was increased by EGF and blocked by EGF-R inhibitor. Furthermore, HC reduced EGF-induced PGE_2 production and indomethacin suppressed it to baseline. Also, COX-2 immunoreactivity was greatly reduced in the EGF-R (-/-) jejunal suggesting that EGF-R signalling is needed for COX-2 expression. These results suggest that EGF-R regulates COX-2 expression and activity in the intestine.

63 Spatial Localization of EGFRs Dictates Activation of Growth Versus Apoptotic Pathways
B. P. Ceresa, D. Hyatt; Cell Biology, University of Oklahoma Health Sciences Center, Oklahoma City, OK

The epidermal growth factor receptor (EGFR) plays physiological roles in regulating cell growth, proliferation, DNA and protein synthesis, and differentiation. Ligand binding to the EGFR induces the dimerization of two monomers, activation of the intrinsic kinase, and transphosphorylation of carboxyl terminal tyrosines on its receptor pair. These phosphoryrosines are docking sites for downstream signaling proteins that, when activated, integrate to produce receptor specific physiologies. In addition to signaling, ligand binding to the EGFR initiates the internalization of the receptor through clathrin-coated pits and into the endocytic pathway. Here the receptor is sorted for its proper fate, such as recycling to the plasma membrane or lysosomal degradation. Endocytic trafficking is known to be an important regulator of EGFR-mediated effector activation, but there is little data to indicate these changes have a biological consequence. Both the non-specific effects of the inhibitors of EGFR internalization, as well as the limited cell responses have restricted the interpretation of how endocytosis affects EGFR-mediated cell physiology. We have re-examined this important question using an approach that specifically inhibits EGFR internalization without perturbing other endocytic processes and used a cell line that robustly responds to EGFR stimulation. In order to determine the physiological consequence of limiting EGFR signaling to a single cellular location, we have used EGF covalently conjugated to 900 nm polystyrene beads (EGF-beads). EGF-beads can bind and stimulate the EGFR, but do not allow entry via clathrin-coated pits (~50-100 nm). EGF induced apoptosis has been well established in MDA-MB-468 cells. When these cells are treated with EGF-beads, despite comparable levels of EGFR phosphorylation, cell growth is enhanced as measured by 3H-thymidine incorporation. Further, intracellular EGFR can stimulate caspase-3 activity whereas cell surface EGFRs inhibit caspase-3 activity. These data demonstrate that EGFR internalization can convert signaling from an anti-apoptotic to a pro-apoptotic phenotype.

64 Tenascin-C EGF-like Repeats - Novel Matrix Kinesin Ligands for EGFR
A. Iyer, K. Tran, L. Richardson, C. Borysenko, C. Camacho, H. Blair, I. Bahar, A. Wells; 1Molecular Pathology, University of Pittsburgh, Pittsburgh, PA, 2Chemical Engineering, Massachusetts Institute of Technology, Cambridge, MA, 3Molecular Genetics & Biochemistry, University of Pittsburgh, Pittsburgh, PA, 4Computational Biology, University of Pittsburgh, Pittsburgh, PA

Recently, EGF-like (EGFL) repeats of matrix proteins have been shown to signal via the EGFR receptor (EGFR), though only at concentrations higher than those for classical soluble ligands such as EGF. The molecular nature of these interactions between EGFR repeats and EGFR has not yet been elucidated. We modeled the 14th repeat of tenascin-C (Ten14) using structure prediction servers to produce a tight molecule with truncated loops, and generated two bound conformations with EGFR. Analysis of the generated bound structures using the Gaussian Network Model and FastContact suggested that Ten14 is much more labile in the ligand-binding pocket of EGFR compared to prototypical ligands EGF/TGFα, implying both low affinity and flexibility enabling ligandation even when embedded within the ECM. Such low-affinity binding should result in distinct biochemical/biophysical and cellular responses as compared to EGF/TGFα. Radio-ligand binding assays showed that recombinant Ten14 did not bind stably to EGFR, with no significant internalization of Ten14 over either the short or long term, both in contrast to EGF. Immunofluorescence and flow cytometry analysis confirmed Ten14-mediated restriction of activated EGFR at the cell surface. Surface plasmon resonance analysis yielded a K_d of 74 µM for Ten14, three logs higher than EGF. Surface-compartmentalization of EGF due to matrix-constrained presentation of EGFR ligands should result in predominant activation of the membrane-restricted PLCγ1, resulting in enhanced cell migration. Indeed, sustained migration over 2D surfaces was observed at levels of Ten14 that failed to stimulate proliferation, concomitant with potent peri-plasma membrane PLCγ1 and m-caspin signaling, but weak activation of intracellular ERK/MAPK, p90Rsk and Elk1 signaling. Thus, with this study, we present a comprehensive analysis of a novel ligand for EGFR in a matrix-constrained environment, and how its signaling impacts overall cellular behavior. This has implications for cell responses during normal tissue regeneration, a situation in which tenascin-C is upregulated.

65 The Effect of PTHrP on EGFR Activation in Co-cultures of Mouse Mammary Epithelial and Stromal Cells
T. T. Nguyen, W. J. Shive, M. E. Dunbar; Biology, Penn State University-Berks Campus, Reading, PA

Parathyroid hormone related protein (PTHrP) is a normal product of mammary epithelial cells where it plays a role during both embryonic and post natal mammary development. We have previously shown that PTHrP overexpression during puberty results in defects in estrogen induced epithelial cell growth during puberty. It is our hypothesis that PTHrP regulates estrogen induced growth by modulating the effects of estrogen in the mammary stroma. To explore the effects of PTHrP on estrogen induced growth of mammary epithelial cells, we developed a cell culture system to recapitulate the effects of PTHrP on estrogen stimulation of cell proliferation in vitro. Co-cultures of mouse mammary epithelial and stromal cells respond to 17β-estradiol with an increase in cell proliferation. This increase in cellular proliferation is blocked by pre-treatment with PTHrP. Therefore, this cell culture system mimics the situation in vivo. Much prior work has implicated stromal epidermal growth factor receptor (EGFR) in estrogen induced ductal elongation during puberty. Therefore, we examined the effects of PTHrP on estrogen induced expression/activation of EGFR in our co-culture system. Co-cultures were treated with either 17β-estradiol or epidermal growth factor (EGF) in the presence or absence of PTHrP. Western blot analysis was performed to determine the levels of expression and/or activation of EGFR. Treatment of co-cultures with either estrogen or EGF did not result in an increase in expression of EGFR. However, there was a marked increase in the level of activated EGF in co-cultures treated with either 17β-estradiol or EGF. Pre-treatment with PTHrP blocked EGFR activation in co-cultures treated with estrogen. Together, these results suggest that PTHrP inhibits estrogen induced proliferation of mammary epithelial cells by inhibiting the activation of EGFR in the mammary gland.

66 TGFβ Role on the Gastric Epithelium: From Signaling to Cell Cycle Control
E. R. De Andrade Sá, B. Bitencourt, E. P. Alves, P. Gama; Cell and Developmental Biology, University of Sao Paulo, Sao Paulo, Brazil

The growth of the gastric mucosa is coordinated by a complex interaction of hormones, growth factors, milk- borne molecules and genetic program. We have shown that epithelial cell proliferation can be stimulated by fasting specifically during suckling phase, suggesting that milk potentially regulates the process. In addition, when milk-borne hormones are administered
concomitant with fasting, the stimulatory response is reversed. The inhibitory role of transforming growth factor beta (TGFβ) on gastrointestinal cell proliferation has been mostly studied in vitro. Our aim was to identify the mechanisms of TGFβ function in the gastric epithelium in vivo. We evaluated the activation of signaling cascade, DNA synthesis and cell cycle control in stomach of suckling rats. TGFβ1 was administered by gavage (1 ng/g body weight) to 14-ldl old rats during fasting. The stomach was collected in time-course experiments to evaluate signaling by immunohistochemistry, as well as cyclin E, Cdk2 and p27 levels by western blotting and immunoprecipitation. To estimate DNA synthesis index, pups were injected with BrDU. Active TGFβ1 increased in the gastric mucosa concomitant with constant levels of TJRII. The labeling index (LI) for Smad2/3 increased more rapidly at 30 min (P<0.05). Smad7 was restricted to surface epithelial cell. Next, we observed that TGFβ1 inhibited DNA synthesis by 20% (P<0.05). Although Cdk2 level increased after 2 h, cyclin E was unchanged and the complex cyclin E-Cdk2 was not altered. The concentration of p27 also increased after 2 h and exceeded cyclin E-Cdk2. TGFβ1 triggered Smad pathway and inhibited DNA synthesis, possibly through the modification of p27/cyclin E-Cdk2 levels. We suggest that the potential of TGFβ1 to regulate a hyperproliferative process should be more explored in the progression of gastric diseases during the stages when cells are still responsive.

67 Anti-inflammatory Effect of TGF-beta Is Mediated by Smad6 in Primary Peritoneal Macrophages

Y. Lee, S. Kim, S. Park; In Ha University, Incheon, Republic of Korea, NIH, Bethesda, MD

The transforming growth factor-beta (TGF-beta) is a potent anti-inflammatory cytokine. We here demonstrated that the increased expression of Smad6, upon treatment of TGF-beta, inhibited the expression of pro-inflammatory genes in primary peritoneal macrophages. The reduced expressions of pro-inflammatory genes were due to the disruption of Myd88-IRAK-Pellino-1-TRAF6 signaling complexes via direct binding of Smad6 to Pellino-1. The blockade of IRAK-mediated signaling complexes by Smad6 decreased the DNA binding activity of NF-kB transcription factor, resulting in the decreased expressions of pro-inflammatory genes in primary macrophages. These results strongly indicate that the anti-inflammatory effect of TGF-beta is mediated by Smad6.

68 Phosphorylation of p66Shc by TGF-β Type I Receptors Attenuates Its Subsequent Phosphorylation by EGF Receptors

M. K. Lee, S. M. Smith; Center for Craniofacial Molecular Biology, University of Southern California, Los Angeles, CA

Shc adapter proteins participate in multiple signaling pathways. Canonically, Shc isoforms are phosphorylated by receptor tyrosine kinases at two sites in the CH1 domain to initiate the Erk MAP kinase signaling cascade. Shc proteins are also directly phosphorylated by activated TGF-β receptors. TGF-β stimulation induces strong Shc serine phosphorylation and weak tyrosine phosphorylation, resulting in low-level Erk MAP kinase activation. Because they are substrates of two different receptors with different specificities, Shc proteins may represent a point at which EGF and TGF-β pathways regulate one another. We hypothesize that TGF-β-mediated Shc phosphorylation attenuates its subsequent phosphorylation by EGF receptors. To evaluate this postulate, bacterially-produced p66Shc was phosphorylated in vitro by either wild-type or T 204D constitutively active TGF-β Type I Receptors. We speculate that the activation of Erk MAP kinases by Shc signaling is dependent on the order of receptor activation.

69 Pro- and Anti-Angiogenic Cytokines Modulate FGFR-1 Isoform Splicing in an Opposing Manner

S. S. Kelpke, J. A. Thompson; Surgery, University of Alabama at Birmingham, Birmingham, AL

Inflammation and angiogenesis are co-dependent processes, wherein several cell types, cytokines, and growth factors interact to promote repair and maintenance of vascular integrity. During inflammation, activated T helper (Th) cells control angiogenesis by polarizing to different phenotypes (Th1/Th2) and producing specific Th1- or Th2-like cytokines that promote or antagonize angiogenesis in a manner analogous to their classification as pro- or anti-inflammatory. The coordination of angiogenesis in vivo includes the responsibility of the fibroblast growth factor (FGF) family and interactions with their high affinity cell surface receptors. Structural variants of FGF receptors (FGFR-1) are generated by alternative splicing, resulting in major FGFR-1 isoforms containing either three (FGFR-1α) or two (FGFR-1β) Ig-like extracellular domains. In the adult, vascular structures primarily express FGFR-1α, whereas during angiogenesis and wound healing, isoforms switching to FGFR-1β is observed. FGF ligand activation of these FGFR-1 isoforms induces distinct signal transduction cascades that differentially modulate vascular cell morphology, growth, migration, and responses to oxidative stress. To examine the ability of inflammatory-angiogenic cytokines to modulate alternative splicing of FGFR-1, primary rat carotid adventitial fibroblasts (AFs) were treated (24hrs) with 1.0 ng/ml of either IFN-γ (Th1; antiangiogenic) or IL-6 (Th2; proangiogenic). IFN-γ treatment resulted in a 15-fold increase in FGFR-1α mRNA (qRT-PCR) and protein (Western) that was accompanied by a 22-fold increase in Srp55 mRNA and protein. In contrast, IL-6 treatment resulted in a 10-fold increase in FGFR-1β mRNA and protein that was accompanied by a 50% decrease in Srp55 mRNA and protein. Transfection of siRNA recognizing Srp55 confirmed that normal expression of FGFR-1α required this splicing factor, which appears to be differentially modulated by Th1 and Th2 cytokines. Following individual cytokine treatments, AFs demonstrated FGF-dependent responses consistent with distinct signal transduction cascades. These results provide insights into new mechanisms potentially regulating the resolution of inflammation and angiogenesis.

70 RhoA-Mediated Cell Death Promoted by Fibroblast Growth Factor-2 (FGF2) in Mouse Tumor Cells Transformed by ras Oncogenes

F. L. Forti, H. A. Armelin; Biochemistry, Institute of Chemistry, University of Sao Paulo, Sao Paulo, Brazil

The Rho-GTPases family (Rho, Rac and Cdc42) regulates architecture and activity of the actin cytoskeleton to control important cellular functions like adhesion, migration, cell cycle progression and proliferation. Several growth factors were reported to activate RhoA in many cell types, promoting cell migration and proliferation. Here we show for the first time that recombinant FGF2 (18kDa) causes a RhoA-dependent drastic morphological modification, leading to death of two mouse tumor cell lines (Y1 adrenal cortical cells carrying overexpressed K-Ras-GTP and Balb3T3 fibroblasts, B61, transformed by the H-ras-V12 oncogene), but not of normal Balb3T3 fibroblasts. In both tumor cell lines, RhoA-GTP is undetectable in G0/G1-arrested cells maintained in SFM (serum-free medium); serum addition elicits RhoA activation, cell migration, cell cycle progression and proliferation. FGF2 also causes RhoA activation and cell migration, but leads to cell death, irrespective of serum presence. In addition, Y1 tumor cells treated with FGF2 display activation of caspase-3, -7 and PARP. Overexpression of the dominant negative mutant RhoA-N19, but not of the constitutively activated RhoA-V14, renders both tumor cell lines resistant to cell death induced by FGF2. Stable transfectant clonal sub-lines Y1 and B61-RhoA-N19 are unable to migrate but grow well in serum supplemented medium and respond to FGF2 with growth stimulation. Altogether, these novel results demonstrate that FGF2 can trigger a RhoA-dependent death in tumor cells in sharp opposition to the largely accepted notion that FGF2 is a bona fide oncogenic factor.

71 Identification of Novel Gab1-Interacting Proteins Downstream from the Met Receptor Tyrosine Kinase

G. N. Palouras, M. Park; Experimental Medicine, McGill University, Montreal, PQ, Canada

The Met receptor tyrosine kinases (RTK) is frequently dysregulated in human cancer and plays a significant role in its development and progression. Growth factor-stimulated cell growth is dependent on the activation of multiple structural and enzymatic proteins. Stimulation of the Met receptor by its ligand HGF (hepatocyte growth factor) results in a remodeling of the actin cytoskeleton of epithelial cells that is essential for cell morphogenesis, cell migration and invasion. This process downstream from the Met receptor requires the scaffold protein Gab1, which we have shown to be a critical modulator of the morphogenic response induced by Met and is important for tumorigenesis. Gab1 is a member of a family of Gab family of adaptor/scaffold proteins linking a broad range of growth factor, cytokine, and antigen signals to intracellular signaling pathways. Gab1 has been found to recruit and activate proteins, including Shp2, the p85 subunit of PI3K, Phospholipase Cγ and Crk which have been found to be involved in cellular migration, invasion, adhesion, apoptosis and proliferation. To identify novel Gab1-protein complexes following Met receptor activation, we have generated a Gab1-TAP-tag fusion protein and have used this in a proteomic screen to identify novel Gab1 protein-protein interactions. Preliminary proteins identified by mass spectrometry of Gab1-associated proteins ranged from cytoskeletal assembly proteins, to proteins that regulate cell migration. Understanding the molecular events that regulate Gab1 signaling will identify the Gab-dependent signaling pathways required for epithelial cell tumorigenesis and invasion and new Gab protein interactions will be presented.
72

**VEGF Is Critical in Resolution of Inflammation during Wound Healing**

M. L. Petreaca, M. Yao, M. Martins-Green; Cell Biology and Neuroscience, University of California, Riverside, Riverside, CA

Wound healing processes show a sequential series of events, including inflammation, granulation tissue formation, and remodeling. Appropriate resolution of inflammation is essential for normal healing, as alterations in the extent and/or duration of inflammation are responsible for many pathological healing conditions. However, little is known about resolution of inflammation and the factors important in regulating this process. Here, we present evidence that Vascular Endothelial Growth Factor (VEGF), a key angiogenic molecule known to function in the development of the granulation tissue, may play an important role in resolution of inflammation during wound healing. Inhibition of VEGF or its receptors during the healing of rabbit wounds markedly increased the number of macrophages at the wound site. As macrophages normally disappear from the wound site via apoptosis, we investigated a possible role for VEGF in stimulating macrophage apoptosis. We found that VEGF can induce apoptosis in cultured macrophages, as shown by a decreased number of cells remaining in culture after treatment and by an increased macrophage annexin V staining. This apoptosis is accompanied by increases in the activation of caspases 3 and 9, as shown by immunostaining and immunoblot analysis, and does not occur immediately after treatment. Therefore, we hypothesized that VEGF-mediated macrophage apoptosis occurs via the stimulation of pro-apoptotic molecules rather than proceeding from VEGF stimulation directly. Microarray and RT-PCR data reveal that VEGF strongly induces the expression of at least one pro-apoptotic gene that belongs to the Tumor Necrosis Factor ligand superfamily; we are currently investigating the possibility that this molecule is important in VEGF-mediated macrophage apoptosis. Taken together, our results identify a novel role for VEGF in the induction of macrophage apoptosis during wound healing, and thus in the resolution of inflammation.

73

**VEGF-related Protein Isolated from Vipera Palestinae Venom, Promotes Angiogenesis**

M. Higgins,1 I. Staniszewska,1 I. Oliva,1 J. Calveci,1 P. Lazarovici,1 C. Marcinkiewicz;1 1Department of Neuroscience, Temple University, Philadelphia, PA, 2C.S.I.C., Instituto de Biomedicina, Valencia, Spain, 3Department of Pharmacology, Hebrew University, Jerusalem, Israel

Vascular endothelial growth factor (VEGF) plays a crucial role in promotion of angiogenesis. The mechanism of this promotion includes induction of endothelial cell migration and proliferation. We isolated a new protein, vpVEGF, from *Vipera palestinae* venom that structurally shows high homology with human VEGF but is analogous to human VEGF, however, vpVEGF is missing the heparin binding domain. The effect of vpVEGF on angiogenesis-related activity of endothelial cells was assessed using dermal vascular endothelial growth factor (VEGF). boyden assay. The effect of vpVEGF on DmVEC migration was performed in two assays, in Boyden chamber and radial migration in collagen gel. In both assays we observed vpVEGF-induced migration of endothelial cells. The analysis of signal transduction induced by vpVEGF showed phosphorylation of MAPK Erk1/2, which is characteristic for VEGF interaction with endothelial cells. This signaling process has been blocked by a specific inhibitor of VEGFR2 (Flk-1), k525a, suggesting that vpVEGF is a ligand for this cell surface receptor. This finding was confirmed using siRNA technique by silencing a Flk-1 gene in DmVEC. The “knockout” cells lost the ability to induce proliferation and cell signaling following treatment with vpVEGF. The pro-angiogenic activity of vpVEGF was confirmed in vivo using CAM assay of the embryonic quail system. In this assay, vpVEGF increased the ratio of vascularization to the same level as human microvascular endothelial cells (dHMVEC), which are important in several pathologies of skin, including melanoma. vpVEGF significantly induced proliferation of dHMVEC in the BrdU assay. The effect of vpVEGF on DmVEC migration was performed in two assays, in Boyden chamber and radial migration in collagen gel. In both assays we observed vpVEGF-induced migration of endothelial cells. The analysis of signal transduction induced by vpVEGF showed phosphorylation of MAPK Erk1/2, which is characteristic for VEGF interaction with endothelial cells. This signaling process has been blocked by a specific inhibitor of VEGFR2 (Flk-1), k525a, suggesting that vpVEGF is a ligand for this cell surface receptor. This finding was confirmed using siRNA technique by silencing a Flk-1 gene in DmVEC. The “knockout” cells lost the ability to induce proliferation and cell signaling following treatment with vpVEGF. The pro-angiogenic activity of vpVEGF was confirmed in vivo using CAM assay of the embryonic quail system. In this assay, vpVEGF increased the ratio of vascularization to the same level as human recombinant VEGF. However, addition of k525a completely abolished vpVEGF-induced angiogenesis, confirming that Flk-1 is a receptor for vpVEGF.

74

**Insulin and Cell Medicine: Leading to Acceleration of Wound Healing**

Y. Liu, M. Yao, M. Martins-Green; Cell Biology & Neuroscience, University of California Riverside, Riverside, CA

Wound healing is a complex process that involves an inflammatory response, re-epithelialization and angiogenesis and, is governed by the local production of cytokines and growth factors. Our recent studies have shown that the topical application of insulin significantly enhances the wound healing process in vivo. To determine the cell and molecular basis of insulin acceleration of wound healing, we studied the effects of insulin on keratinocytes (important in re-epithelialization) and endothelial cells (important in angiogenesis). Insulin stimulates keratinocyte proliferation and migration in a dose- and time-dependent manner and stimulation is dependent on activation of Akt, PI3-K and steroid regulatory element binding proteins (SREBPs) but not on EGFR and its receptor. Our studies on the effects of insulin on microvascular endothelial cell proliferation and migration, show that this protein stimulates endothelial cell migration but not proliferation and that this is independent of VEGF. In microvascular endothelial cells, insulin stimulates Src-phosphorylation very rapidly and this stimulation is followed by phosphorylation/activation of Akt and ERK1/2 which is inhibited by the Src inhibitor SU6656. Furthermore, SREBPs are also involved in the effects of insulin on endothelial cell migration, in particular the precursor and mature form of SREBP1. Our results show that insulin stimulates keratinocytes and endothelial cells to migrate and that in both cases Src-Pi3K-Akt-SREBP are critical molecules. Taken together these results show that insulin is another factor that accelerates wound healing and hence it should be considered as potential treatment for impaired wounds.

75

**Prokineticin Receptors Localize to Caveolae Membranes**

E. L. Bradshaw,1 E. J. Smart2 1Physiology, University of Kentucky, Lexington, KY, 2Pediatrics, University of Kentucky, Lexington, KY

Hyposia-induced angiogenesis is a compensatory mechanism to supply blood to ischemic tissues. In the peripheral vasculature, ischemia-initiated angiogenesis is controlled by a variety of growth factors, which allow for endothelial permeability, proliferation, and migration. LeCouter et al. recently described a new angiogenic factor, endocrine gland-derived vascular endothelial growth factor (EG-VEGF). EG-VEGF causes proliferation, migration, and fenestration of the endothelium causing massive vascularization. To date, prokineticin receptor (EG-VEGF receptor) localization within the plasma membrane and protein-protein interactions have not been elucidated. Caveolae are cholesterol and sphingolipid rich invaginations of the plasma membrane, which are characterized by caveolin-1. Caveolae are recognized as centers for signal transduction, and caveolin modulates cellular signaling cascades. Immunofluorescence data shows caveolin-1 and prokineticin receptors colocalize, suggesting that prokineticin receptors localize in caveolae. As a complementary method, subcellular fractionation studies show that prokineticin receptor-1 and -2 are enriched in the caveolae membrane fraction along with caveolin-1. Furthermore, immunoprecipitation data from CHO cells as well as murine tissues shows that prokineticin receptors-1 and -2 immunoprecipitate caveolin-1. This potentially has interesting implications for prokineticin receptor function because caveolin-1 has been shown to negatively regulate and inhibit signaling of G-protein coupled receptors as well as tyrosine kinase receptors. Overall, caveolae-localization of prokineticin receptors allows for close proximity to many signaling molecules, which may facilitate its robust angiogenic response.

76

**Ephedra sinica Friction Inhibits Hepatocyte Growth Factor (HGF)/c-Met Signaling and HGF-induced Tumor Cell Migration and Invasion**

C. Hyun-Young1, L. Ming Hong2, K. Inhae,1 K. Myeongdeok,1 R. Jae-Ha,1 L. Jae-Ho; 1Department of Biochemistry and Molecular Biology, Ajou University, Suwon, Republic of Korea, 2College of Pharmacy, SooMyung Women’s University, Seoul, Republic of Korea

Aberrant hepatocyte growth factor (HGF) c-Met signaling has been known to be involved in many human cancer development and progression. During the search for an effective inhibitor of HGF/c-Met signaling with the herbal extracts, we have found that Ephedra sinica fraction (ESM) showed inhibition of HGF-induced MDCK-2 cell scattering. Studies were performed to address whether ESM inhibits HGF/c-Met signaling, to find the underlying mechanisms, and to evaluate its therapeutical potential. As mentioned, ESM effectively blocked HGF-induced scattering and uPA activation in MDCK-2 cells, with 50% inhibition at 2.5 μg/ml concentration and complete inhibition at around 12.5 μg/ml. Inhibition by ESM was accompanied by the decrease of HGF-induced tyrosine phosphorylation of Met as well as HGF-mediated activation of p44/42 mitogen-activated protein kinase, but not epithelial growth factor (EGF)-induced tyrosine phosphorylation of EGFR, suggesting the specificity of ESM to HGF/c-Met signaling. In addition, at high doses, ESM seemed to reduce the expression of c-Met protein. This inhibition leads to decrease in HGF-induced migration of B16F10 murine melanoma cells. Also, the decrease in HGF-induced invasion of SK-LMS-1 human leiomyosarcoma cells was also observed, showing the possible application of ESM for preventing HGF-induced cancer cell migration or invasion. In conclusion, ESM specifically inhibits c-Met phosphorylation induced by paracrine HGF stimulation which leads to decrease in cell migration and invasion in vitro. These data suggest the feasibility of selectively targeting c-Met with ESM to inhibit aberrant HGF/c-Met signaling in human cancer.
Activation of the C-jun NH2-terminal Kinase Determines Mitotic Entry and Paclitaxel Sensitivity in Human Hepatoma Cells

S. Chae,1,2 W. Lim,1 H. Cho1,2,1 Biochemistry and Molecular Biology, Ajou University School of Medicine, Suwon, Republic of Korea, 2Chronic Inflammatory Disease Research Center, Ajou University, Suwon, Republic of Korea, 3Department of Molecular Science and Technology, Ajou University, Suwon, Republic of Korea

Paclitaxel is a class of anti-microtubule agent and currently used in the chemotherapeutic treatment of patients with ovarian, breast and lung carcinomas. However, paclitaxel resistance in liver cancer often renders the drug ineffective. Here, we investigated the molecular mechanism underlying paclitaxel resistance in HCC cell lines. Human hepatoma cell lines, SNU series were used to investigate the mechanism of paclitaxel resistances. Two out of six HCC cell lines (type I) underwent active cell death upon paclitaxel treatment whereas four cell lines showed paclitaxel resistance (type II). We observed that type I cells tended to arrest at G2 phase upon paclitaxel treatment, whereas type II cells entered mitosis and died, which was accompanied with Bcl-2 phosphorylation. In type I cell paclitaxel treatment induced activation of the c-Jun NH2-terminal kinase (JNK) and paclitaxel-induced cell death in these cells was significantly inhibited by SP600125, a specific inhibitor of JNK, but not with inhibitors of Erk1/2 (U0126) or mTOR (rapamycin). In addition, treatment with SP600125 suppressed cells entering mitosis. On the contrast, in type II cells, caffeine, an ATM/ATR partially rescued paclitaxel resistance evidenced by increase of mitotic entry and cell death. These results suggest that activation of the JNK mainly determines mitotic entry and paclitaxel sensitivity in human hepatoma cells.

Activin Regulates Myofibroblast Proliferation and Differentiation Following Liver Injury

F. Kalantar2, J. Lebrun,1 E. Chevet1,2,3 H. Vail,4 P. Auguste1,2, Anatomy & Cell Biology, McGill University, Montreal, PQ, Canada, 2Surgery, McGill University, Montreal, PQ, Canada, 3Medicine, McGill University, Montreal, PQ, Canada, 4Inserm e362, Universite Bordeaux 2, Bordeaux, France

Transplantation remains the only viable treatment for end-stage liver diseases. Liver transplantation is often associated with numerous ischemia-reperfusion related complications including calcification. We have previously demonstrated that one major mechanism involved in this process is linked to the proliferation and differentiation of myofibroblasts. Here, we show that the expression of activin receptors is up-regulated in myofibroblasts near calcified regions of the liver. We also present that, activin-associated smad signal transducers are activated and co-localized with activin receptors. Since proliferating and differentiating myofibroblasts show activated activin signaling, we hypothesize that activin may stimulate myofibroblasts differentiation and/or proliferation leading to calcification of liver tissues. To assess the role of activin on myofibroblasts, we studied the impact of activin on the proliferation and differentiation of C3H/10T1/2 cells and compared these results with those obtained from TGFI experiments. Activin signaling was analyzed by measuring the activation of the Smad pathway after C3H/10T1/2 stimulation. The results of this experiment revealed an increase in p-Smads which was specifically correlated with an activin-mediated cell proliferation. These data were validated using dominant negative Smad2 and Smad3 stable cell lines where activin signaling is blocked. The same approach was used to evaluate cell proliferation and differentiation. In conclusion, our work demonstrates the involvement of activin as a critical regulator of myofibroblasts proliferation and differentiation and could represent a potential therapeutic target to reduce fibrosis in the liver. In addition, as both activin and TGFI play a role in bone formation, their possible involvement in liver calcification should be explored.

Novel Modification of the Ran Exchange Factor, RCC1, and Its Function in Mitosis

T. Chen1, T. Muratore,1 C. Schaner-Tooley,1 D. Hunt,1 F. Macara1, Microbiology, University of Virginia, Charlottesville, VA, 2Chemistry, University of Virginia, Charlottesville, VA

RCC1 is the only known guanine nucleotide exchange factor for the Ran GTPase, and plays pivotal roles in nucleocytoplasmic transport, mitosis, and nuclear envelope assembly. RCC1 can bind to chromatin through histones H2A and H2B, in a Ran-regulated manner. Mitotic phosphorylation of RCC1 can also modulate chromatin binding. We now report a unique modification on RCC1. An enzyme activity specific for this modification of RCC1 is present in soluble nuclear extracts from HeLa cells. Modification-defective mutants of RCC1 are unable to function in certain aspects as effectively as the wild type protein, which results in mitotic defects. These defects are additive to those caused by a mutation that disrupts exchange activity.

The Expression of Dvl2 Increases Frizzled-7 Dimers and Prevents Frizzled-7 C-terminus Cleavage at the Plasma Membrane

C. D. Mao, I. T. Strewing; GCNS, University of Kentucky, Lexington, KY

The frizzled (Fz) proteins are seven-transmembrane G-protein coupled receptors involved in the control of cell polarity and Wnt-signaling. Though there is increasing evidence that Wnt endocytosis with its receptors, Frizzled, and co-receptors, LDL-receptor like protein-5/6, is required for full activation of the downstream Wnt-signaling pathways, the role and mechanisms of Frizzled endocytosis and turnover at the plasma membrane have not been identified. We have recently shown that Fz7 receptors are subjected to a specific C-terminus cleavage at the plasma membrane that can be increased by PMA and calcium in endothelial cells and attenuated by both clathrin-dependent and caveolin-dependent endocytosis inhibitors. However, Wnt13A and Wnt5A, two putative endogenous ligands for Fz7 in endothelial cells, had no effect on the appearance of Fz7 C-terminus cleavage, suggesting that Fz7 is subjected to constitutive endocytosis and down-regulation. On the other hand, co-expression of Fz7 with the Wnt-downstream effector, dvl2, resulted in a decrease of Fz7 C-terminus cleavage and an increase of the formation and/or stabilization of Fz7 dimers. These data are also consistent with a constitutive Fz7 endocytosis and down-regulation modulated by the levels of dvl2, though it remains to determine whether dvl2 prevents Fz7 C-terminus cleavage and/or Fz7 endocytosis. For this purpose, we have identified the cleavage site within the 3rd intracytoplasmic loop and designed various mutations of the putative cleavage site. However all the Fz7 mutants identified so far that displayed a reduced C-terminus cleavage were also defective for inducing dvl2 translocation to the plasma membrane, which included the Fz7 receptor mutated within the conserved KTLXXW sequence in the cytoplasmic tail. Therefore, our results altogether emphasize the intricate link between Fz7 C-terminus cleavage and Fz7 signaling.

Differential Transmission of Actin Motion within Focal Adhesions

K. Hu, L. Ji, K. Thompson, G. Danuser, C. Waterman-Storer; Dept. of Cell Biology, Scripps Research Institute, La Jolla, CA

Cell motility requires transmission of forces generated in the actin filament cytoskeleton through molecularly complex integrin-based Focal Adhesions (FAs) to the extracellular environment. Although it is well-accepted that spatiotemporal coordination between FA and actin is required for the regulation of cell migration, the dynamics of molecules within these two arrays have not been analyzed simultaneously in living cells. In this study, we have successfully visualized the dynamics of molecules within individual FA in living cells, using TIR-FSM, an imaging technique that combines Total Internal Reflection fluorescence microscopy with Fluorescent Speckle Microscopy. To determine if FA molecules dynamically interact with actin filaments within living cells, we developed a novel technology, Correlative Fluorescent Speckle Microscopy. This new method allows quantitative analysis of the degree of correlation between the motions of two molecule population labeled with spectrally distinct fluorophores. Monte Carlo simulations have confirmed that a high degree of correlated speckle motion indicates an interaction between the molecules. We screened a cross-section of known FA proteins (ECM binding proteins: α1/β1 integrin; F-actin binding FA proteins: α-actinin, vinculin and talin; and FA “core” proteins, that do not bind F-actin or ECM directly, but include structural and signaling molecules: paxillin, zyxin, focal adhesion kinase (FAK)), using this technology to analyze their correlated motions with actin. Our results illustrate that different classes of FA proteins display different dynamic behaviors. We find that motion of the actin cytoskeleton is differentially transmitted through focal adhesions, with the efficiency of transmission gradually decreasing from actin-binding proteins to integrins, thus defining the FA as a hierarchical molecular friction clutch. Interestingly, the degree of this transmission is spatially and temporally regulated, and modulation of transmission correlates with specific events in the cell migration cycle. Therefore, FA internal molecular dynamics represents a key element in the mechanics of cell morphogenesis during migration.

Human Insulin Receptor (hIR) and Glucose Transporter (GLUT4) Trafficking in Transfected CHO Cells: Effects of the Inhibitors of PI-3 and MAP Kinases and That of the Actin-Microtubules

A. A. Sattar, P. Berhau; Endocrinology/Internal Medicine, Wayne State University School of Medicine, Detroit, MI

The binding of insulin to insulin receptor (IR) triggers intracellular insulin signaling and GLUT4 redistribution from the intracellular compartment to the plasma membrane, where it facilitates entry of glucose into the cell. We sought to determine insulin-induced IR and GLUT4 trafficking in transfected CHO cells as a function of time and with respect to the inhibitory effects of the inhibitors of PI3 and MAP kinases and that of the actin-cytoskeleton to better understand the dynamics of their trafficking by analyzing immunostained cells using confocal microscopy. Insulin (30 nM) -stimulated IR trafficking from cell periphery to perinuclear sites (up to 25% of the maximal) within 20 min, reached a maximum at 30 min and then declined to 42% of the maximal at 60 min. On the other hand, GLUT4 trafficking from perinuclear to peripheral sites (up to 73% of the maximal) within 10 min, gradually to a maximum at 30 min, and then declined to 85% at 60 min. Pretreatment of the cells either with 100 nM wortmannin or 100 µM PD98059 reduced insulin-mediated intracellular IR trafficking by ~60% and ~55%, respectively; whereas contrast, in type II cells, caffeine, an ATM/ATR partially rescued paclitaxel resistance evidenced by increase of mitotic entry and cell death. These results suggest that activation of the JNK mainly determines mitotic entry and paclitaxel sensitivity in human hepatoma cells.

2006 ASCB Annual Meeting Abstracts

15
GLUT4 trafficking decreased by ~95 and ~25%, respectively. Pretreatment of the cells with 1 μM latrunculin A reduced insulin-induced IR prenuclear localization by ~50%, and 13 μM nocodazole apparently had no consequence on IR trafficking. On the other hand, both latrunculin A and nocodazole disrupted insulin-mediated GLUT4 trafficking by ~95 and 55%, respectively. These results demonstrate: 1) a lack of time-dependent correlation between insulin induced IR and GLUT4 trafficking, 2) although PI-3 and MAP kinases regulate intracellular IR trafficking, GLUT4 trafficking is mostly regulated via PI-3 kinase, and 3) intact microtubule may not be essential for insulin-induced IR trafficking to the perinuclear region but microtubule and F-actin networks are required for GLUT4 trafficking to the cell periphery.

83 Interleukin 6 Up-regulates Angiogenin Secretion from Human Prostate Cancer Cells, LNCaP
M. Arakawa, M. Kawada, D. Ikeda; Drug Development Unit, Microbial Chemistry Research Center Numazu Bio-Medical Research Institute, Numazu, Japan
Objective: Androgen-dependent human prostate cancer LNCaP cells rarely form tumors without prostate stromal cells in SCID mice, and even if the tumor is formed, the tumor growth is very slow. In recent studies, we have established the cytokine-resistant LNCaP cells (LNCaP-CR) that acquired high tumorigenicity by the selection of survived cells on the co-culture with the normal fibroblast in the presence of IL-1 β (Kawada et al, 2006). LNCaP-CR exhibited not only higher tumorigenicity but also higher secretion of angiogenin (ANG), one of the angiogenesis factors, than the parental LNCaP. Methods: To examine effects of several cytokines (IL-1β, TNF-α, IL-6, IFN-γ) and signal transduction inhibitors (MEK inhibitors, JAK2 inhibitor, IP3K inhibitor) on ANG secretion in culture media of LNCaP-CR or LNCaP, we assessed ANG secretion using human ANG ELISA. Results: IL-6 (50 ng/ml) significantly increased ANG secretion from LNCaP-CR (345 ±47 pg/ml, 24h) compared with that of untreated-LNCaP (140 ±37 pg/ml, 24h), while it had a slight effect on LNCaP-CR. Moreover, IFN-γ (200 ng/ml) decreased the IL-6 (50 ng/ml)-induced ANG secretion from LNCaP-CR, but it had little effect on that of LNCaP-CR. In addition, JAK2 inhibitor, AG490 (50 μ M), significantly decreased ANG secretion from both LNCaP and LNCaP-CR. Conclusions: These results suggest that the production of ANG from IL-6-treated LNCaP may be regulated through the activation of JAK/STATs (Janus kinase/signal transducers and activators of transcription) pathways. Furthermore, the disruption of the JAKs/Stats pathways may be involved in the high secretion of ANG from the cytokine-resistant LNCaP-CR.

84 Anillin-mediated Targeting of Peanut to Pseudocleavage Furrows Is Regulated by the Ran Pathway
R. V. Silverman-Gavrilova, A. Wilde; Medical Genetics and Microbiology, University of Toronto, Toronto, ON, Canada
Pseudocleavage furrows are required to maintain the separation between microtubule spindles during nuclear divisions in the syncytial Drosophila embryo. The pseudocleavage furrow is analogous to the cytokinetic furrow in somatic cells and invagination of the membrane is similarly driven by the actin cytokinetic ring. Failure to form pseudocleavage furrows allows neighboring microtubule spindles to make contact and fuse, thereby disrupting chromosome segregation. We observed this phenotype during a screen to identify mitotic processes regulated by the GTPase, Ran. Further investigation found that whilst the septin Peanut failed to be targeted to the nascent cleavage furrow, other furrow components were correctly targeted, including Actin, Anillin and Sep2, another septin family member. Septins are thought to be targeted to furrows by interacting with the PH domain of Anillin. Indeed we found that both Peanut and Sep2 bind to the PH domain of Anillin. However, in the presence of nuclear transport receptors Peanut failed to bind to the PH domain of Anillin whereas Sep2 did. These data suggest a molecular mechanism by which the Ran pathway can regulate furrow ingress. Furthermore, these data suggest that the PH domain of Anillin contains at least 2 distinct septin binding sites that bind distinct classes of septins.

85 Physiological Role of the Oxidative Stress-sensitive TRPM2 Ca2+ Channel in Immune Cells
S. Yamamoto, S. Shimizu, T. Wajima, Y. Mori; Kyoto University, Kyoto, Japan, 3Showa University, Tokyo, Japan
TRPM2 is a Ca2+ permeable channel activated by redox status changes such as oxidative stress. Although it has been suggested that Ca2+ influx via TRPM2 mediate cell death, its physiological significance is still elusive. TRPM2 is expressed in immune cells such as monocytes and lymphocytes. In monocyteic cell line U937, although it is known that hydrogen peroxide (H2O2) induces chemotactic cytokine interleukin-8 (IL-8) production via Erk / NF-κB pathway and that IL-8 is produced via intracellular Ca2+ increases, the detail mechanism is not known. Here, we investigate if oxidative stress-sensitive TRPM2 Ca2+ channels participate in H2O2-induced IL-8 production in U937. Addition of H2O2 to U937 triggered Ca2+ influx, and both Ca2+ influx and TRPM2 expression were attenuated by the treatment of TRPM2 siRNA. H2O2-activated Erk was amplified by Ca2+ influx. The amplified Erk translocated NF-κB to the nucleus, which mediated IL-8 production. The amplification of Erk, nuclear translocation of NF-κB, and IL-8 production induced by H2O2 were inhibited by the treatment with TRPM2 siRNA. Thus, Ca2+ influx via TRPM2 is involved in IL-8 production via Erk / NF-κB pathway. Additionally, we investigated the physiological significance of the above role played by TRPM2 in vivo by utilizing TRPM2 knockout mice.

86 The Armadillo-protein P0071 Regulates Rho-signalling during Cytokinesis
A. Wolf, R. Keil, M. Hatzfeld; Division of Pathobiochemistry, Institute for Pathophysiology, Halle/Saale, Germany
Cytokinesis requires the spatio-temporal coordination of cell cycle control and cytokinetic reorganization. Members of the Rho-family of GTPases are crucial regulators of this process and assembly of the contractile ring depends on local activation of Rho-signalling. We show that p0071, a member of the armadillo-family of proteins previously implicated in regulation of cell cell adhesion, in addition plays an essential role in Rho-signalling during cytokinesis. In contrast to the closely related p120ctn, p0071 was localized at the centrosome throughout the cell cycle and at the midbody during cytokinesis. Both, knockdown and overexpression of p0071 interfered with normal cell growth and survival due to cytokinesis defects with formation of multinucleated cells and induction of apoptosis. This failure of cytokinesis apparently correlated with the deregulation of RhoA-activity in response to altered p0071 expression, as shown by FRET-measurements based on biosensors and by GST-chtoekin pull-down assays. To determine where in the molecular signalling cascade p0071 modulates Rho-activity we analyzed its interaction with RhoA itself as well as upstream regulatory proteins. We show a direct association of p0071 with RhoA with a preference for activated RhoA which occurs at the region of furrow ingression during mitosis. Moreover, we found a physical and functional interaction of p0071 with Ect2, the one Rho-guanine nucleotide exchange factor (GEF) essential for cytokinesis. Testing RhoA activation in an GDP-GTP-exchange assay revealed that p0071 stimulates RhoA exchange activity in conjunction with Ect2. These results suggest that both, p0071 and Ect2 are necessary for full activation of RhoA during cytokinesis. Our findings indicate that p0071 serves an essential role in regulating spatially restricted Rho-signalling during cytokinesis.

87 Phosphorylation Motif Clustering as a Signature for Protein Kinase Substrates
H. Aldaz, M. Joachimiak, P. Houshmand, G. Barnes, D. G. Drubin; Molecular and Cell Biology, UC Berkeley, Berkeley, CA
Protein phosphorylation is a widely used form of cellular regulation. The identification of new kinase substrates, however, has proven challenging. Though many protein kinases exhibit a preference to phosphorylate certain consensus motifs, use of these motifs in a guide to identifying new substrates is often impractical due to the common occurrence of such motifs. Here is reported the observation that phosphorylation consensus motifs are organized within the primary sequences of many protein kinase substrates in a manner best described as clusters. Substrates of the budding yeast protein kinase lpllp were determined to be quantitatively enriched with lpllp consensus motif clusters, relative to the rest of the yeast proteome. Quantitation of consensus motif clustering showed little correlation with the number of motifs in a given protein, supporting this as a novel metric with which to judge potential kinase substrates. Experimental validation of this approach is underway, with early studies supporting this as a method to predict the identities of novel lpllp substrates. A set of proteins previously assayed for their ability to be substrates of another kinase with a known consensus motif, Cdc28p, was subjected to a similar analysis. The results revealed a strong correlation between identified substrates and proteins enriched with Cdc28p minimal consensus motif clusters, suggesting that consensus motif clustering may be a signature for the substrates of many protein kinases. This approach should aid in the discovery of new kinase substrates when only a general consensus motif is known. These results also suggest the possible existence of a general strategy of phosphoregulation.

88 Motific Phosphorylation of Mis13 Is Required for Kinetochore Assembly and Proper Chromosome Segregation

Y. Yang,1 T. Ward,2 Z. Dou,3,4 F. Wang,5 Y. Ke,6 K. Jiang,3 N. Li,3 J. Yao,7 X. Yao;8 1Physiology, Morehouse School of Medicine, Atlanta, GA, 2Cellular Dynamics, Hefei National Laboratory, Hefei, China

Chromosome segregation in mitosis is orchestrated by dynamic interaction between spindle microtubules and the kinetochore, a multi-protein complex assembled onto centromeric DNA of the chromosome. Our previous studies show that kinetochore is composed of several interactive protein subcomplexes such as Zw10, Hecl and CENP-E. However, the mitotic regulation of these protein-protein interaction networks remains elusive. To identify the proteins that regulate Mis13 in mitosis, we carried out proteomic search for Mis13-interacting protein in mitotic cells. To this end, mitotic extracts from HeLa cells stably expressing FLA-Mis13 were purified using a FLAG antibody-affinity chromatography. Among various known Mis3-binding proteins identified, Aurora B was found to be retained on Mis13 affinity beads. The Aurora B-Mis13 interaction was then confirmed with recombinant Mis13 and Aurora B proteins in test tubes. Significantly, Aurora B co-localizes with and phosphorylates Mis13 in vivo. This Aurora B-mediated phosphorylation of Mis13 was confirmed in vitro using recombinant proteins. Interestingly, suppression of Aurora B kinase by siRNA or kinase activity inhibitors reduced the level of Mis13 associated with kinetochore. Expression of non-phosphorylatable Mis13 resulted in a delay in prometa-phase-meta-phase transition. Immunofluorescence analyses revealed that localization of the outer plate proteins such as CENP-E, CENP-F and Hecl was severely reduced in the kinetochore expressing non-phosphorylatable Mis13. Moreover, our studies show that the absence of Mis13 or inhibition of Mis13 phosphorylation reduces tension at kinetochores of bi-oriented chromosomes. These results indicate that Aurora B-mediated phosphorylation of Mis13 links mitotic kinetochore assembly to faithful kinetochore-microtubule attachment, which is essential for chromosome segregation.

89 An Allosteric Model of Circadian KaiC Phosphorylation

J. S. van Zon,1 P. Altena,1 D. K. Lubensky,6 P. ten Wolde1 1Centre for Integrative Systems Biology, Imperial College London, London, United Kingdom, 2FOM Institute for Atomic and Molecular Physics [AMOLF], Amsterdam, The Netherlands, 3Department of Physics, Vrije Universiteit Amsterdam, Amsterdam, The Netherlands

Cyanobacteria show 24 hour rhythms in gene expression. In the cyanobacterium Synechococcus elongatus three genes, kaiA, kaiB and kaiC are essential for this circadian rhythm. In higher organisms, it is known that these circadian oscillations are the result of transcriptional feedback loops. However, it was recently shown in vitro KaiC undergoes a stable circadian oscillation in its degree of phosphorylation when incubated with KaIA, KaiB and ATP. Here, we present a model of how the experimentally observed interactions between the Kai proteins together with allosteric transitions within KaiC proteins can give rise to such stable oscillations.

90 Bdm-1, a Phosphducin-like Protein Required for G-protein Signaling in the Filamentous Fungus Cynodon cymosa, Is a Phosphoprotein Targeted by Casein Kinase II

J. A. Salamon-Kozubowska, A. L. Dawe; Biology, New Mexico State University, Las Cruces, NM

In this study we have explored the nature of a post-translational modification to a protein that is required for functional G-protein signaling. G-protein signaling modulates many responses in fungi, including virulence of plant and animal pathogens. Previous studies with the filamentous fungal plant pathogen Cryptocapsa parasitica, the chestnut blight fungus, have identified components that include a phosphducin-like protein (BDM-1). Perturbation of the G-protein signaling pathways has been shown to affect virulence, pigmentation and sporulation. It has also been shown that deletion of the beta subunit CGBP-1 in BDM-1 affects these characteristics in an identical manner and caused similar alterations in transcriptional profile. Furthermore, G-proteins have also been shown to be reduced in accumulation by infection of C. parasitica with virulence-attenuating dsRNA viruses (hypoviruses). We have approached the study of BDM-1 by first showing that CGBP-1 protein levels are undetectable in the absence of BDM-1, thus explaining the identical phenotypes of the two null-mutants. Tagging BDM-1 with the FLAG epitope and transfection of the Bdm-1 strain demonstrated that the FLAG-tag does not affect BDM-1 function. Using this tool we show by treatment with phosphatase that BDM-1 exists in a phosphorylated form. Re-phosphorylation of BDM-1 can be accomplished in the presence of total protein lysates, but this activity is inhibited by the casein kinase II specific inhibitor DMAT, indicating that BDM-1 is substrate for this kinase. These tools are now possible to explore the effects of phosphorylation on BDM-1 function and determine if this modification is altered by the presence of hypoviruses, thereby providing a model for exploring the molecular events associated with viral-mediated changes of eukaryotic cell signaling pathways.

91 Autophosphorylation-deficient Mutant of Protein Kinase C delta Mutant Has Higher Kinase Activity and Apoptosis Activity Than Protein Kinase C delta Wild Type

J. Jang,1 H. Kwon,1 D. Park,1 J. U. Kazi,1 Y. Lee,1 Y. Lee,1 J. Soh;1 1Department of Chemistry, Inha University, Incheon, Republic of Korea, 2Korea Institute of Radiological and Medical Sciences, Seoul, Republic of Korea

PKC-delta is a protein kinase which is reported to mediate apoptosis. Upon activation, PKC-delta undergoes autophosphorylation and translocates to membrane and induces apoptosis. HSP25 (Heat Shock Protein 25) is known to bind to PKC-delta and inhibit phosphorylation of PKC-delta, which leads to inhibition of apoptosis. Recent studies identified V5 region of PKC-delta as a binding site of HSP25. And there are several autophosphorylation sites in V5 region of PKC-delta. Therefore, we designed an experiment with PKC-delta-WT and PKC-delta-S662A mutant, an autophosphorylation-deficient mutant of PKC-delta. And we compared apoptosis activities and kinase activities between PKC-delta-WT and PKC-delta-S662A mutant. We found that the kinase activity and apoptosis activity of PKC-delta-S662A mutant was higher than PKC-delta-WT. We observed that PKC-delta-S662A mutant has more phosphorylation on tyrosine 311 than PKC-delta-WT. We also found that PKC-delta-S662A mutant translocates to membrane faster than PKC-delta-WT after PMA treatment. Detailed biochemical mechanisms by which autophosphorylation regulate kinase activity of PKC-delta is under investigation.

92 Mechanisms Underlying Rho GTPass Signaling Specificity in Mammalian Cells

A. B. Jaffe,1 A. Schmidt,1 A. J. Self,1 A. Hall1;1 Cell Biology, Memorial Sloan-Kettering Cancer Center, New York, NY, 2MRC Laboratory for Molecular Cell Biology, University College London, London, United Kingdom

The precise temporal and spatial regulation of signaling pathways is essential for a wide range of cellular processes, such as migration, proliferation, and morphogenesis. The Rho family of small GTPases are key players in these processes, through their ability to control the rearrangement of the actin and microtubule cytoskeletons, the activation of gene expression, and the various phases of the cell cycle. In response to extracellular cues, Rho GTPases switch from the inactive, GDP-bound form, to the active, GTP-bound form via guanine nucleotide exchange factors (GEFs). One active, Rho GTPases transduce their signals by interacting with target proteins, termed ‘effectors’. Two crucial questions in Rho GTPase signaling are how specificity downstream of the GTPasses is controlled, and how the Rho GTPass-dependent signaling pathways are coordinated during various cellular processes. We have found that the scaffold protein hCnK1 can associate with a subset of Rho-specific GEFs, as well as components of the JNK MAPK pathway, and that hCnK1 is specifically required for agonist-induced JNK activation downstream of Rho. We are currently investigating how the hCnK1 complex is spatially and temporally regulated in response to extracellular signals, and how its regulation affects Rho GTPase-dependent signaling pathways.

93 Identification of Activation Mechanism and Signaling Pathway for Orphan Tyrosine Kinase Receptor 2 (Ror2)

Y. Liu,1 J. F. Ross,1 P. Bodine,1 J. Billiard1 1Women’s Health & Musculoskeletal Biology, Wyeth R&D, Collegeville, PA, 2Biological Technologies, Wyeth R&D, Cambridge, MA

Ror2 is an orphan receptor tyrosine kinase important for developmental morphogenesis, particularly of the skeleton. To investigate the Ror2 activation mechanism, we tested if the Ror2 receptor can form homo-dimers and whether this can lead to receptor activation similar to other receptor tyrosine kinases. Using an interaction assay between flag-tagged and his-tagged Ror2 over-expressed in U2OS cells, we demonstrated that Ror2 does form homo-dimers and that the extent of dimerization can be greatly enhanced by treatment with a bivalent Ror2 antibody. The antibody-induced dimerization leads to activation of the Ror2 tyrosine kinase, as measured by Ror2 autophosphorylation. We next investigated potential Ror2 binding partners. Ror2 was immunoprecipitated from Ror2-over-expressing U2OS cells lysates and Ror2 binding proteins were analyzed by mass spectrometry (MS). This analysis identified a scaffold protein 14-3-3β as a potential target. The interaction between Ror2 and 14-3-3β was confirmed by co-immunoprecipitation from cell lysates and by in-vitro binding assay using purified GST-Ror2 and 14-3-3β. We also found that Ror2 phosphorylates tyrosine residue(s) on 14-3-3β in both the cell and in vitro and that treatment with Ror2 antibody potentiates this effect. Furthermore, we performed MS analysis of 14-3-3β interactors in absence or presence of Ror2. We found several proteins that interacted with 14-3-3β in Ror2-dependent manner suggesting that interaction with Ror2 may have functional consequences on 14-3-3β signaling. Previously, we demonstrated that Ror2 stimulates osteoblast commitment and differentiation. Here, we found that treatment with a bivalent Ror2 antibody dose-dependently enhanced osteogenesis of human mesenchymal stem cells. Furthermore, treatment of neonatal mouse calvarial bones with the Ror2 antibody ex-vivo increased...
the rate of bone formation by 50% compared to IgG control. In conclusion, this work shows that antibody-induced dimerization of Rock2 leads to receptor activation and identifies 14-3-3β scaffold protein as the first substrate for Rock2 tyrosine kinase.

94  Strech-induced Tyrosine Phosphorylation of PECAM-1 in a Detergent-extracted Cell Model

Y. Chiu,1,2 E. McBeath,1 K. Fujimura1; Cardiovascular Research Institute, University of Rochester, Rochester, NY, 1Department of Biochemistry and Biophysics, University of Rochester, Rochester, NY

PECAM-1 (Platelet, Endothelial Cell Adhesion Molecule-1) is concentrated at interendothelial cell adhesions and interacts homophilically between neighboring cells. When a monolayer of endothelial cells is exposed to fluid shear stress, hypertonic shock, or cyclic stretch, PECAM-1 is rapidly tyrosine phosphorylated. Furthermore, we have shown that directly pulling on cell surface PECAM-1 will tyrosine phosphorylate the molecule and proposed that PECAM-1 is a mechanoresponsive protein of endothelial cells. To further investigate the mechanism of mechanical force-induced PECAM-1 phosphorylation, we made an extracted cytoskeletal model that could be mechanically activated. A confluent monolayer of bovine arterial endothelial cells cultured on an elastic silicon membrane was briefly treated with a Triton X-100 containing buffer to permeabilize the plasma membrane and release soluble cellular components. Immunofluorescence imaging showed that the resulting PECAM-1-actin complexes were able to undergo 2-fold increases in filamentous actin (F-actin) content, and we also identified three other mutant Actins whose ectopic expression favored F-Actin formation, nuclear accumulation of MAL and activation of SRF in the absence of external signals. The activation had similar or even shorter kinetics compared to control cells, whereas nuclear Elk-1 activation was decreased. Thus, the spatial organization of endosomes contributes to the cell cycle progression of human melanoma cells. We have demonstrated that the endosomal compartment provides spatial resolution of signal transduction which has implications for the understanding of cell cycle regulation.

95  TULA: A Novel Protein That Affects Protein Tyrosine Kinases’ Activation and Degradation

R. Agrawal, A. Tsyanov; Microbiology and Immunology, Temple University, Philadelphia, PA

TULA (T-cell Ubiquitin Ligand) is a novel protein of a family of 2 proteins. The proteins consist of UBA and SH3 domains; and the C-terminal half contains homologies to PhosphoGlycerate Mutase catalytic domain and also nuclear localization signal. TULA is the first protein described to contain both the UBA and SH3 domains. TULA is a primarily lymphoid protein, although the second protein of the family is ubiquitously present. TULA was shown to bind c-Cbl, ubiquitin and ubiquitylated proteins. As c-Cbl is an E3 ubiquitin ligase and is known to downregulate activated protein tyrosine kinases (PTKs) by ubiquitination, involvement of TULA in this process was studied. It was found that TULA protects receptor PTKs from c-Cbl mediated ubiquitilation. Double knockout mice for the two proteins of this family were viable and normal. The double knockout T cells had enhanced proliferative ability. Further analysis showed that in the double knockout T cells, p70, a S6 kinase kinase, was activated. Therefore, TULA protects an effect on PTKs but its molecular mechanism is not known. Hence, to understand these cellular mechanisms we chose to study the effect of TULA on Syk, a non-receptor PTK. Syk is found in both B and T cells, binds to c-Cbl and is ubiquitylated by c-Cbl. Our studies have shown that TULA activates Syk. However, the effect of the second protein is opposite to TULA’s effect on Syk. Therefore, in contrast to knockout data, which suggest both the members of this family have similar/overlapping effects, our studies show that these proteins may have different effects and act through different functional mechanisms. The details of the differential effects and mechanisms of the TULA proteins will be discussed.

96  Regulation of SRF-mediated Transcription by Monomeric Actin and MAL/MRTF

G. Posern, M. Bode, S. Fiehn; Dept. of Molecular Biology, Max-Planck-Institute of Biochemistry, Munich, Germany

Signal-induced activation of the transcription factor Serum Response Factor (SRF) requires Rho-mediated alterations in Actin dynamics. Direct evidence demonstrates that monomeric G-Actin itself participates specifically in SRF regulation. The molecular link between G-Actin and SRF was identified as the MAL protein, which serves as a Rho-regulated transcriptional coactivator for SRF. MAL was first described in the leukemic fusion protein OTT-MAL, which is a potentially deregulated oncogene. MAL translocates from the cytoplasm to the nucleus upon stimulation. The translocation is blocked by β-ACTin or non-polymiserable Actin mutants. MAL directly associates with G-Actin via N-terminal RPEL motifs with high affinity. Stimuli which activate SRF resulted in dissociation of the MAL-Actin complex. This suggests a titration model in which monomeric Actin negatively regulates SRF via its interaction with MAL. However, we also identified three other mutant Actins whose ectopic expression favoured F-Actin formation, nuclear accumulation of MAL and activation of SRF in the absence of external signals. The three mutants share several biochemical properties, e.g. increased binding to profilin, reduced binding to Gelsolin (Segment 4-6), and stabilised F-Actin formation. Two of the mutants interact with MAL, but activate SRF in a Rho- and Actin-treadmilling independent manner. Thus, the spatial organization of endosomes contributes to the cell cycle progression of human melanoma cells. We have demonstrated that the endosomal compartment provides spatial resolution of signal transduction which has implications for the understanding of cell cycle regulation.

97  Phosphotyrosine-3 Kinase Regulatory Subunit P55γ Interacts with Rb and Regulates Cell Cycle

W. Wang, T. Deh, M. Johnson, R. Dickson; Oncology, Georgetown University Medical Center, Washington, DC

Phosphotyrosine-3 Kinase Regulatory Subunit P55γ (P55γ) plays an important role in regulating the proliferation of the cells of the mammary gland. P55γ is a regulatory subunit of PI3K. In contrast to the widely studied 85 kDa regulatory elementsubunits p85α and p85β, p55γ is encoded by a distinct gene, p55γ3, and is expressed mostly in the brain, testis, kidney, and fatty tissues. The role of p55γ in breast tissue has not been studied in detail. Western blot analysis confirmed that p55γ is expressed at various levels in cells of mammary origin, normal or malignant mammary epithelial cells. An earlier report demonstrated that the NH2-terminal of p55γ contains retinooblastoma protein (Rb) binding ability. In MCF7 cells, overexpression of the NH2-terminal amino acids leads to cell cycle arrest. We hypothesize that p55γ might regulate cell cycle progression through its interaction with Rb. The aim of this study was to test this hypothesis and to determine the role of p55γ in cell cycle progression in human cells. We generated wild-type and epitope-tagged expression constructs for p55γ to study its role in epithelial cells. The interaction between full-length p55γ and Rb was studied by co-immunoprecipitation and western blot analysis. Mammalian cells overexpressing p55γ as a result of stable or transient transfection were subjected to cell cycle analysis by FACS. Using the constructs we generated have confirmed the binding between Rb and full-length p55γ protein. Preliminary results also suggested that overexpression of p55γ alters cell proliferation primarily by shortening the time of S phase entry in cell cycle. This is the first report indicating cellular function of a full-length p55γ protein in cultured mammalian cells, based on its interaction with Rb, and we continue to examine the underlying mechanisms. Supported by individual DOD predoctoral traineeship award #W81XWH-04-1-0408 (YW).

98  The Late Endosomal Compartment Provides Spatial Information for MAPK Signaling Pathways

N. Taub, D. Ten, L. A. Huber; Division Cell Biology, Biocenter Innsbruck, Innsbruck, Austria

Signal transduction through the MAPK cascade is regulated by the assembly of different scaffold complexes at distinct subcellular locations like plasma membrane or endosomes. Thus it appears likely that spatial resolution of signal transduction is a critical parameter to define signaling specificity. Therefore, we investigated if the endosomal compartment provides spatial information for MAPK signaling. To study the crucial signaling parameter space we used the dynemin subunit p50 to change the intracellular position of endosomes. Overexpression of p50 mislocalized late endosomes, LAMP-1 and LIPA positive compartments, to the cell periphery, whereas the distribution of early endosomes, EEA1 positive structures, was unaffected. This dearrangement of the late endosomal compartment also dramatically affected the transport of the EGFR and resulted in a prolonged EGFR activation on peripherally mislocalised endosomes. Moreover, the endosomal compartment also alters the kinetics of EGFR phosphorylation on peripherally mislocalised endosomes. This indicates that the endosomal compartment provides spatial resolution of signal transduction which has implications for the understanding of cell cycle regulation.

99  Stretch-induced Tyrosine Phosphorylation of PECAM-1 in a Detergent-extracted Cell Model

Y. Chiu,1,2 E. McBeath,1 K. Fujimura1; Cardiovascular Research Institute, University of Rochester, Rochester, NY, 1Department of Biochemistry and Biophysics, University of Rochester, Rochester, NY

PECAM-1 (Platelet, Endothelial Cell Adhesion Molecule-1) is concentrated at interendothelial cell adhesions and interacts homophilically between neighboring cells. When a monolayer of endothelial cells is exposed to fluid shear stress, hypertonic shock, or cyclic stretch, PECAM-1 is rapidly tyrosine phosphorylated. Furthermore, we have shown that directly pulling on cell surface PECAM-1 will tyrosine phosphorylate the molecule and proposed that PECAM-1 is a mechanoresponsive protein of endothelial cells. To further investigate the mechanism of mechanical force-induced PECAM-1 phosphorylation, we made an extracted cytoskeletal model that could be mechanically activated. A confluent monolayer of bovine arterial endothelial cells cultured on an elastic silicon membrane was briefly treated with a Triton X-100 containing buffer to permeabilize the plasma membrane and release soluble cellular components. Immunofluorescence imaging showed that the resulting PECAM-1-actin complexes were able to undergo 2-fold increases in filamentous actin (F-actin) content, and we also identified three other mutant Actins whose ectopic expression favored F-Actin formation, nuclear accumulation of MAL and activation of SRF in the absence of external signals. The activation had similar or even shorter kinetics compared to control cells, whereas nuclear Elk-1 activation was decreased. Thus, the spatial organization of endosomes contributes to the cell cycle progression of human melanoma cells. We have demonstrated that the endosomal compartment provides spatial resolution of signal transduction which has implications for the understanding of cell cycle regulation.
99  Profiling of Signal Pathway Activation during In Vitro Lymphangiogenesis  
L. V. Leak,1 V. S. Calver,2 J. D. Walkshulte,3 E. F. Petricoin, III,1 L. A. Liotta1; Anatomy, Howard University, Washington, DC; 1Molecular and Microbiology, Center for Applied Proteomics and Molecular Medicine, George Mason University, Manassas, VA; 1George Mason University, Manassas, VA; 1Molecular and Microbiology, George Mason University, Manassas, VA

Results from our laboratory and others have shown that VEGF-C is a potent mitogen for the lymphatic endothelium and a key lymphangiogenic factor. However, the biochemical signaling pathways activated via VEGFR-3 upon stimulation by VEGF-C in the lymphatic endothelium (LEC) are not well characterized. Likewise, the molecular mechanisms that regulate the discrete phenotypic modulations of proliferation leading to the formation of new lymphatic vessels from existing vessels during the process of lymphangiogenesis have not been defined. To profile and map multiplexed protein phosphorylation and determine the linkage of signal transduction events during these various stages, we have employed an in vitro cell culture model of lymphangiogenesis exhibiting all four stages, coupled with reverse-phase protein microarrays and phosphor-specific antibodies. The goal is to examine the activation status of key molecular proteins and determine the roles played by others. By employing this high throughput technology for the analysis of signal pathway profiling in LEC during lymphangiogenesis it will be possible to gain further insight into the molecular mechanism of signals in the lymphatic endothelium during various physiological and pathological conditions.

100  Retinoylation: Formation of Retinoylated Protein from Retinyl-CoA  
Y. Kubo, T. Obha, M. Naito, N. Takahashi; Laboratory of Physiological Chemistry, Institute of Medicinal Chemistry, Hoshi University, Tokyo, Japan

Retinoylation (acylation of protein by retinoic acid) is considered as one mechanism of retinoic acid (RA) action occurring in cells in vitro and in vivo. Previously our studies have shown that in rat tissues the formation of retinoyl-CoA from RA, the first step of retinoylation required ATP, CoA and MgCl2. In the current study, we examined whether the transfer of retinoyl-CoA into protein, the second step of retinoylation, occurs in rat tissues. [3H]-Labelled-retinoyl-CoA bound covalently to proteins in rat liver, kidney, testis, and brain. The levels of incorporation of retinoyl-CoA into proteins were higher in vitrino than in vivo. A distinct peak of RA was detected in rat liver, and the formation of retinoylated protein depended on the incubation time and the concentrations of retinoyl-CoA and homogenate. The reaction was suppressed by fatty acyl-CoAs and palmitic acid, but not by arachidonic acid. Vmax and Km values for retinol-CoA in the formation of retinoylated protein using crude liver extract were estimated to be 2597.3 pmol/min/mg protein and 9.5 x 10^-5 M respectively. Retinoylated proteins formed from retinyl-CoA, including a 17 kDa protein with high radioactivity, disappeared in the presence of 2-mercaptoethanol, indicating that RA was linked to protein by thioester. These results demonstrate that retinoylation in rat tissues occurs via retinyl-CoA formed from RA. This process may play a significant physiological role in cells.

101  Essential Amino Acids Determine Lifespan in Yeast  
P. Gomes, B. Sampaio-Marques, P. Ludovico, F. Rodrigues, C. Leão; Life and Health Sciences Research Institute (ICVS), Braga, Portugal

In virtually every organism, nutrient sensing and caloric intake regulate aging and longevity. In yeast, interventions resembling caloric restriction, either by reduction of glucose or non-essential amino acids content in the medium, prolong lifespan and retard aging, suggesting that the energetic status of the cell is the main responsible for the lifespan extension. In addition, it has been shown that subtle, often unrecognized amino acid limitations lead to much lower final biomass concentration in cultures of different commonly used auxotrophic Saccharomyces cerevisiae strains. In this study, we have examined the role that essential amino acid supplementation of auxotrophic S. cerevisiae mutants plays in determining yeast lifespan and stress resistance. Our results performed in yeast cells cultured in regular amino acid content showed that this is insufficient amino acid supplementation, being accompanied by a reduced final biomass and phenotypes of premature aging. These included shorter lifespan and a decreased resistance to oxidative stress, without significant changes in heat or acid stress resistance. These results indicate that starvation for essential amino acids results in cell stress, which may finally trigger apoptosis. In conclusion, our findings point to the fact that subtle amino acid limitation has severe consequences on cell physiology, lifespan and stress resistance, therefore presenting a note of caution for studies using auxotrophic yeast strains.

102  Gene Expression of hrp2+ Gene Related to SNF2 Family in Yeast  
I. Choi; Life Science, Silla University, Pusan, Republic of Korea

The SNF2/SW12 family comprises proteins from a variety of species with in vivo functions, such as transcriptional regulation, maintenance of chromosome stability during mitosis, and various types of DNA repair. This study was aimed at the characterization of hrp2+ gene which was isolated by PCR amplification using the conserved domain of SNF2 motifs. Sequence analysis of hrp2+ gene showed striking evolutionary conservation among the SNF2 family of proteins. The transcript of hrp2+ gene was found to be a 4.7 kb as identified by Northern hybridization. In addition, to determine the transcription initiation site of hrp2+ gene, primer extension analysis was performed. This result showed the band of 64 bp. The transcriptional start point was mapped to a position of 47 base pair from the first ATG codon of translational initiation codon. In order to investigate the inducibility of hrp2+ gene, transcript levels were examined after treating the cells to various DNA damaging agents. The transcripts of hrp2+ were induced by UV-irradiation. But the transcripts were not induced by treatment of 0.25% Methylmethane sulfonate (MMS). These results implied that the effects of damaging agents are complex and different regulatory pathways exist for the induction of this gene.

103  Response of the HgI MAPK Pathway in S. cerevisiae Shows an Ability to Learn from Previous Stimulation  
T. Ursell, K. Yasutis, B. B. Kaufmann, A. van Oudenaarden; Physiology Course 2006, Marine Biological Laboratory, Woods Hole, MA

In order to survive a wide range of osmotic conditions the budding yeast S. cerevisiae has developed a combined signaling and genetic circuit that, under hypertonic shock, temporarily up-regulates glycerol synthesis. In response to hyperosmotic stress, the MAPK HgI translocates to the nucleus upon phosphorylation by its upstream kinase Hence, nuclear localization of HgI is a direct measurement of activation of this protein cascade. Using YFP labeled HgI and GFP labeled nuclear protein Nrd1, the nuclear amount of HgI was tracked as a function of time. Cells were subjected to 250 mM pulses of NaCl for various periods from 4 minutes to 80 minutes. Simultaneous tracking of cell size gave a readout of the end product of the circuit as glycerol production increased and osmotic pressure equalized. Upon osmotic shock, initial Hog1 nuclear localization is transient, but subsequent identical shocks yielded an amplified response, and the ability of such protein circuits to learn from previous stimuli may be an important evolutionary tool for survival in diverse environmental conditions.

104  Dissecting the Glucose Signaling Network in Saccharomyces cerevisiae  
S. Zaman1, L. Schnerer,1 X. Zhang,2 K. M. Shokat,2 J. R. Bresch3; 1Department of Molecular Biology, Princeton University, Princeton, NJ; 3Department of Cellular and Molecular Pharmacology, University of California, San Francisco, CA

Glucose is an important nutrient that is used as the primary source of energy in most organisms. Misregulation in glucose utilization can cause diseases in humans such as diabetes mellitus. Glucose signals transcriptional changes through a number of different pathways. Identification of the transcriptional targets of the pathways will contribute towards the understanding of how mutations in specific pathways perturb the system to cause diseases. Interestingly, the proteins that make up the glucose signaling pathways are highly conserved from humans to yeast. The budding yeast, Saccharomyces cerevisiae, is a genetically tractable organism and we have used it to dissect out how the glucose signal feeds through the different signaling pathways and
investigate how the pathways interconnect with each other. *Saccharomyces cerevisiae* has at least four pathways, Ras/PKA, Snf1, Rgt1 and Sch9 that have been implicated in signaling changes to glucose availability. By using inducible and repressible mutants in the Ras/PKA, Snf1, Rgt1 and Sch9 pathways and following the changes in the transcriptional profile of the cells with microarrays after activation/repression of these pathways, we have made several new discoveries. Our studies show that selective inhibition of Snf1, the yeast homolog of mammalian AMPK, changes expression of only a few genes involved in carbohydrate acid metabolism. On the other hand, the C-terminally truncated pathway and Sch9 protein kinase, homologue to mammalian Akt, redundantly mediates most of the transcriptional changes that occur in response to glucose addition. However, the Ras/PKA pathway plays a bigger role than the Sch9 pathway because selective inhibition of PKA reduces but does not eliminate the response of cells to glucose. Inhibition of Sch9 pathway does not affect the response of cells to glucose. This study contributes towards the understanding of how the cell processes the glucose signal and opens up novel routes for intervention for disease treatment.

105 Cell Cycle Regulation of MAP Kinase Cascade Signaling in a Yeast Differentiation Pathway

P. Pyciak, S. Strickfaden, M. Winters, R. Lamson; University of Massachusetts Medical School, Worcester, MA

Control of cell fate by external signals often occurs in the context of cell division. Thus, it may be generally important to coordinate the response to differentiation signals with cell cycle status. In budding yeast, mating pheromones arrest cells in the G1 phase of the cell cycle by preventing passage through Start. Conversely, when cells pass Start and commit to a new cell cycle, they become resistant to pheromone arrest. In particular, signal transduction through the pheromone-responsive MAP kinase pathway is actively inhibited by G1 CDKs. But the target, mechanism, and physiological role of this inhibition has remained enigmatic. Here, we show that the target of this inhibition is Ste5, the MAPK cascade scaffold protein. G1 CDK phosphorylation of Ste5 occurs at a cluster of sites surrounding a small, basic membrane-binding motif. The added phosphates disrupt the electrostatic interaction of this Ste5 domain with the plasma membrane, which is required for pheromone resistance. Effective inhibition of Ste5 signaling requires phosphorylation at multiple (8) sites and a substantial accumulation of negative charge, suggesting that Ste5 acts as a sensor for high G1 CDK activity. Thus, Ste5 is an integration point for signals from both external (pheromone) and internal (cell cycle) sources. When Ste5 cannot be phosphorylated, its activity is no longer tied to the cell cycle, and pheronome now triggers an aberrant arrest at inappropriate stages of the cell cycle. This ectopic arrest occurs either in the presence or absence of the CKD inhibitor protein Far1. Overall, these findings define a mechanism and physiological benefit of restricting antiproliferative signaling to G1. Furthermore, by requiring phosphorylation at multiple CDK sites in Ste5, this regulatory circuit demands high G1 CDK activity, providing the cell with a mechanism for decisively shutting off pheromone signaling only when conditions are appropriate for cell cycle entry.

106 ATG1 Regulates Filamentous Growth in *Saccharomyces cerevisiae* Independent of Autophagy

M. D. Seya, M. Snyder, S. P. Dinesh Kumar; MCDB, Yale University, New Haven, CT

In response to nitrogen limitation, diploid *Saccharomyces cerevisiae* utilizes distinct signaling mechanisms for survival including pseudohyphal growth and autophagy. Moderately low nitrogen concentrations trigger diploid cells to undergo pseudohyphal differentiation while extremely low nitrogen concentrations trigger cells to undergo bulk protein degradation via autophagy for cell survival. Although these distinct processes operate within a relatively narrow physiological range of nitrogen availability, they must be stringently controlled to prevent cross activation yet flexible enough to facilitate a rapid and fluid response during nitrogen consumption. Here we present evidence that ATG1, a serine/threonine kinase required for autophagy, is also needed for pseudohyphal formation. 

107 Identification of Short Membrane-Targeting Domains in Yeast Cdc42 Effectors

S. Takahashi, P. M. Pyciak; University of Massachusetts Medical School, Worcester, MA

Signaling proteins often contain multiple interaction modules, which in principle can collaborate to control protein function. The *S. cerevisiae* p21-activated kinase (PAK) Ste20 functions in multiple MAPK signaling pathways as well as in actin organization, cell polarity and cell cycle transitions. Ste20 kinase activity and localization are controlled by the GTPase Cdc42, which binds an autoinhibitory region in Ste20 called the CRIB motif. We have identified a new domain, adjacent to the Ste20 CRIB motif, that interacts directly with plasma membrane lipids and is critical for Ste20 function. This region, termed the basic-rich (BR) domain, is a short (~27 residue) motif that can target GTP to the plasma membrane in vivo and bindsPIP2-containing liposomes in vitro. Mutations in the BR domain severely disrupt the localization and function of Ste20. In addition, the Ste20 BR domain can be functionally replaced with foreign lipid-binding domains, such as the PH (pleckstrin homology) domain from mammalian PLCγ. Thus, both membrane and protein interactions act in concert to regulate membrane-localized activation of Ste20 by Cdc42. Consistent with this model, the BR domain becomes dispensable when Cdc42 binding is bypassed by disrupting the autoinhibitory conformation of Ste20 with separate mutations. This situation is analogous to a mammalian Cdc42 effector, N-WASP, whose activation requires both Cdc42 and a polybasic PIP2-binding motif. Furthermore, we find that two other Cdc42 effectors in yeast, Gic1 and Gic2, also have BR-like motifs that are critical for their localization and function. These observations suggest a common theme for Cdc42 effectors in which a membrane-binding domain is required to help target the protein to its activator. Interestingly, some BR-like domains have the additional capacity to confer nuclear localization, raising the possibility that BR-like motifs may be generally useful for targeting proteins to both nucleus and the plasma membrane.

108 Triad3A Interacts with RIP1 through a TIR Homologous Domain

C. Fears, Q. Pan, J. C. Mathisson, T. Chuang; Immunology, The Scripps Research Institute, La Jolla, CA

Triad3A is a RING finger E3 ubiquitin-protein ligase identified in a yeast two hybrid screening using the *TIR* domain of TLR9 as a bait. This E3 ligase promotes ubiquitination and proteolytic degradation of TLR4 and TLR9, and negatively regulates their activation by LPS and CpG-DNA, respectively. Given that Triad3A is capable of binding to the TIR domains of TLR4 and TLR9, we reasoned that Triad3A may also be able to regulate proteolytic degradation of TIR domain-containing adapter molecules. In the present study, we investigated its activity on adapter molecules downstream of TLRs and TNF-α receptor 1. Triad3A promoted down-regulation of two TIR domain-containing adapter proteins, TRAP and TRIF, as well as a RIP1, but had no effect on other adapter molecules in either the TLRs or TNF-α signaling pathways. RIP1 is essential for TNF-α induced NF-κB activation. This adapter protein contains an N-terminal kinase domain, a RHIM motif, and a C-terminal death domain, but does not contain a TIR domain. However, the interaction between Triad3A and RIP1 suggested to us that RIP1 may have a domain with some conserved motif homologous to a TIR domain that allows for interaction with Triad3A. We performed multiple sequences alignment analysis using amino acid sequences from the TIR domain of each of the MyD88 family members and RIP1. The results indicated that the C-terminal domain of RIP1 contains a TIR homologous domain, and mutation of amino acid residues in this domain identified three residues critical for its interaction with Triad3A. Moreover, reduction of Triad3A expression by siRNAs rendered cells hyperresponsive to TNF-α stimulation. Conversely, overexpression of Triad3A in cells blocked TNF-α induced cell activation. These results suggest that Triad3A interacts with RIP1 through a TIR homologous domain, and negatively regulates TNF-α activation.

109 Suppressing Plus-end Microtubule Dynamics Leads to Loss of MTOC Cohesion at the Onset of Mitosis

J. Hornick, E. H. Hinchcliffe; Biological Sciences, University of Notre Dame, Notre Dame, IN

Cells treated with Taxol are observed to assemble multiple mitotic asters, resulting in abnormal spindle assembly and defects in cell division. Taxol preferentially stabilizes the plus-ends of microtubules ([Rogov et al. 1999 MTCB 18:947]), and inhibits minus-end directed transport, which requires the recruitment of dynein/dynactin to the dynamic plus-ends of the microtubules. However, it remains unclear how stabilization of the plus end leads to the observed mitotic defects. We examined Taxol spindle assembly in vivo using BSC1-otubGFP cells. Live-cell video microscopy of Taxol-treated cells entering mitosis reveals that the majority of microtubules dissociate from the centrosome just before NEB, and intact microtubules rapidly migrate to the cell periphery, where they become embedded in the cortex. The cortical arrays of microtubules are then bundled into large sheets, which bud off the cortex and form large, 20
hollow asters. These asters migrate toward the mass of chromosomes, where they fuse together to form a multipolar spindle. While some small asters form on the nuclear envelope, asters are not observed appearing de novo in the cytoplasm, contrary to the results of in vitro experiments. To examine whether microtubule dissociation from the centrosome is a result of microtubule stabilization or inhibition of transport, we treated cells with Taxol for 5 min and then observed cells at NEB. This 5 min treatment is sufficient to suppress plus-end dynamics and block “tip-tracking”, but does not cause microtubule dissociation from the centrosome at the onset of mitosis. Our results suggest that suppression of plus-end microtubule dynamics during interphase results in the inhibition of microtubule-based transport, leading to the depletion of “key factors” necessary to maintain the cohesion of the microtubule network at the centrosome as the cell transitions into mitosis.

Proteasome Inhibition Leads to Centrosome Fragmentation and Loss of Chromosome Motility
B. K. Carney, B. Becker, L. Cassimere; Biological Sciences, Lehigh University, Bethlehem, PA
We are interested in how the mitotic spindle assemblies and maintains a bipolar shape. We find that treatment of Hela or LLCPK cells with the proteasome inhibitor MG132 disrupts centrosome integrity, leading to centrosome fragmentation within 2 - 3 hours. MG132-treated cells also assemble multipolar spindles, consistent with a previous report (Ehrhardt and Sluder, 2005. J. Cell Physiol. 204: 808). In MG132-treated Hela cells ubiquitin is localized to an aggregate at the centrosome, suggesting that proteasomes are localized there. Live cell imaging of Hela cells expressing GFP-CENPA demonstrated loss of kinetochore directional instability 2 - 3 hours after MG132 addition and relaxation of tension between sister kinetochores. These results demonstrate that MG132 treatment disrupts both normal spindle structure and chromosome motility and suggest that the proteasome may function in these processes.

Laser Ablation of Mitotic Spindle in Anaphase Can Prevent Progression to Cytokinesis
N. M. Baker,1 G. Wu,1 L. Shi,1 E. Botvinick,2 M. Berns;2 1University of California, San Diego, La Jolla, CA; 2Beckman Laser Institute, University of California, Irvine, Irvine, CA
In previous studies we have shown that the second harmonic (532 nm) from a picosecond frequency doubled Nd:YAG laser can be used to cleanly and selectively ablate and sever fiber microtubules in live cells (Botvinick et al 2004, biophys. J. 87:4303-4212). It was shown that ablating only one half spindle (severing microtubule connections between pole and chromosome at the metaphase plate) after the immediate onset of anaphase did not affect chromosome movement to the poles and subsequent cytokinesis. In this current study on PTK2 cells, we have observed that immediate complete ablation across both half spindles immediately after anaphase onset results in the prevention of cytokinesis even though the chromosomes still undergo normal anaphase movements from the metaphase plate to the poles. Cells of the rat kangaroo line (PTK2) were stably transfected with YFP-tubulin and Histone-CFP and imaged and ablated using the automated RoboLase microscope (Botvinick and Berns, 2005, Micros. Res. Tech 69/65-74). Fluorescent (in metaphase-anaphase transition were irradiated with 0.2447 nJ/micropulse, corresponding to an irradiance of 1.4496*10^7 W/m^2. The irradiated cells were followed for up 24 hours with no observed cytokinesis. Other cells were fixed and stained immediately after laser ablation in order to determine whether or not the prevention of cytokinesis was due to disruption of the microtubules or due to effects on key proteins that require microtubules as a ‘rail’ for transport. The laser microablating system and experimental observations could contribute significantly to elucidating the cellular dynamics of anaphase mitotic spindles.

Cell Division Defects Associated with Exposure to Bisphenol-A
O. L. George,1 C. Corona,2 J. Arterburn,2 C. B. Shuster;1 1Molecular Biology and Biology, New Mexico State University, Las Cruces, NM, 2Chemistry, New Mexico State University, Las Cruces, NM
There is an increasing concern that mammalian reproduction may be adversely affected by exposure to artificial compounds resembling endogenous hormones. In particular, the ubiquitous component of polycarbonate plastics, Bisphenol-A (BPA), has shown to have weakly estrogenic properties. Additionally, rodent colonies accidentally exposed to BPA resulted in increased meiotic aneuploidies (Current Biol 13:546-553), suggesting that BPA may also have profound effects on cell division. In an effort to characterize its effects on cell division at the cellular and molecular level, we examined BPA effects on sea urchin embryo development, whose rapid cell cycles and lowered checkpoint responsiveness make them more sensitive to environmental pollutants. Examination of Lytechinus pictus and Strongylocentrotus purpuratus eggs and embryos exposed to BPA displayed dose-dependent effects on microtubule organization and cytokinesis. Live cell analyses suggest that while a bipolar spindle formed in the presence of 500nM BPA, the spindle fails to correctly direct contractile ring formation, resulting in ectopic furrows in the polar and equatorial cell surfaces. However microtubule polymerization in Xenopus oocyte extracts was not affected by BPA at any dose, suggesting that BPA is not directly affecting microtubule polymerization. Morphological examination of BPA-treated embryos revealed several general classes of phenotypes, including ectopic cortical microtubules, multipolar spindles, cleavage failure, and delayed mitosis. Pulse treatment of blastula-stage embryos resulted in an increase of mitotic figures, suggesting that BPA was delaying mitotic progression. Lastly, fractionation of mitotic extracts with biotinylated BPA analogs has identified several candidate BPA-binding proteins, including the cohesin subunit, SMC1. Together, these results provide additional evidence that in addition to its properties as an estrogenic molecule, BPA may adversely affect normal development by interfering with embryonic cell divisions.

Using Single-Fluorophore Speckle Microscopy to Examine Microtubule Dynamics in Xenopus Extract Spindles
G. Yang,2 B. Houghteling,3 J. Gaetz,2 J. Liu,2 G. Damaser,1 T. Kapoor;1 1Laboratory for Computational Cell Biology, The Scripps Research Institute, La Jolla, CA, 2Laboratory of Chemistry and Cell Biology, Rockefeller University, New York, NY
Fluorescence speckle microscopy (FSM) is a powerful technique for quantitatively tracking polymerization and transport dynamics of cytoskeletal proteins in a range of different cellular structures. In metaphase spindles, FSM has provided insightful into the spatial and temporal organization of microtubule flux and revealed the co-existence of different populations of microtubules. Under commonly used labeled tubulin concentration (~50nM for Xenopus extract spindles), each speckle represents a cluster of 2-8 fluorophores. When the fraction of labeled tubulin is reduced by about two orders of magnitude, approximately 80% of the trackable speckles (i.e. those with trajectories lasting 4 frames) correspond to single fluorophores as confirmed by photobleaching and intensity analyses. We report a comprehensive comparison of microtubule flux measurement under conventional, ultra-low labeling ratios and preliminary results on using single-fluorophore imaging to probe the structure of microtubule network. Although the ultra-low labeling is accompanied by much lower speckle density and thus reduced spatial resolution, we found microtubule dynamics that are not detectable using standard FSM conditions. Analysis of single-fluorophore speckles revealed a population of fast moving (~4-6 micron/min) microtubules, up to 3-fold faster that the rate of microtubule poleward flux. We are combining single-fluorophore FSM with perturbations of dynin and mitotic kinesins to examine the molecular basis for this fast transport in the spindle. In general, these results show that FSM at ultra-low labeling ratio provides an important complement to existing methods in reporting microtubule flux dynamics and further insight into the spatial and temporal heterogeneity of microtubule dynamics in metaphase spindles.
DNA Repair Pathways Involved in Anaphase Bridge Formation

C. Acilan,1 D. M. Potter,2 W. S. Saunders1; 1Biological Sciences, University of Pittsburgh, Pittsburgh, PA, 2Biostatistics, University of Pittsburgh, Pittsburgh, PA
Cancer cells frequently exhibit gross chromosomal alterations such as translocations, deletions, or gene amplifications, an important source of chromosomal instability in malignant cells. One of the better-documented examples is the formation of anaphase bridges - chromosomes pulled in opposite directions by the spindle apparatus. Anaphase bridges are associated with DNA double strand breaks (DSBs). While the majority of DSBs are repaired correctly, to restore the original chromosome structure, incorrect fusion events also occur leading to bridging. To identify the cellular repair pathways used to form these aberrant structures, we tested a requirement for either of the two major DSB repair pathways in mammalian cells: homologous recombination (HR) and non-homologous end joining (NHEJ). Our observations show that neither pathway is essential, but NHEJ helps prevent bridges. When NHEJ is compromised, the cell appears to use HR to repair the break, resulting in increased anaphase bridge formation. Cancer cells with high NHEJ activity are less likely to form bridges. In addition, the level of the NHEJ component XRCC4 can be used to estimate the tendency of different cancer cell lines to form bridges from chromatid breaks.

The Contribution of Chk1-dependent Centrosome Amplification to Mitotic Catastrophe and DNA Damage-induced Cell Death

E. Bourke,1 H. Dodson,1 S. P. Wheatley,2 A. Merdes,1 L. Currie,1 G. Zachos,1 M. Walker,1 D. Gillespie,1 C. Morrison1; 1National University of Ireland, Galway, Galway, Ireland, 2Genome Damage and Stability Centre, University of Sussex, Brighton, United Kingdom, 3CNRS-Pierre Fabre, Toulouse, France, 4Beatoson Institute for Cancer Research, Glasgow, United Kingdom
Centrosomal abnormalities are frequently observed in cancers. We used light and electron microscopy to show that DNA damage induces centrosome amplification in human cells. Caffeine abrogated this amplification in both ATM- and ATR-defective cells, suggesting a complementary role for these DNA damage-responsive kinases in promoting centrosome amplification. Inhibition of CHK1 by RNAi or drug treatment suppressed DNA damage-induced centrosome amplification. Radiation-induced centrosome amplification was abrogated in Chk1−/− DT40 cells, but occurred at normal levels in Chk1+ cells transgenically expressing Chk1. Using hypothermia, we observed that G2 arrest without DNA damage was insufficient to potentiate centrosome amplification. Interestingly, overexpression of Cyclin E in Chk1−/− cells restored DNA-damaged centrosome amplification, suggesting that Chk1 control of Cdk2-Cyclin E activity contributes to DNA damage-induced centrosome aberrations. To determine the contribution of centrosome aberrations to mitotic catastrophe and to analyse the extent to which mitotic catastrophe is involved in cell death after irradiation, we performed timelapse microscopy on human cells that expressed GFP-centrin1 and histone H2B-GFP following irradiation. We found a radiation dose-dependent increase in the frequency of cells failing in M, with > 50% of cells failing to complete mitosis successfully after 10 Gy (N = 107). The cellular outcome of having multiple centrosomes also depended on the levels of DNA damage. After 5 Gy, < 20% of cells with multiple centrosomes entered M and only 20% of these cells failed in their first mitosis (N = 32). Following 10 Gy, < 20% of cells with multiple centrosomes entered M and some 60% of these cells failed in M phase (N = 44). These findings demonstrate that mitotic catastrophe is a significant contributor to radiation-induced lethality and that centrosome amplification is a potential source of mitotic failure.

Tumor Formation via Loss of a Molecular Motor Involved in Maintenance of Chromosome Structure

M. Mazumdar, J. Lee, K. Sengupta, T. Ried, S. Rane, T. Misteli; National Cancer Institute, NIH, Bethesda, MD
Microtubule-associated kinesins are a diverse group of molecular motors that have been implicated in transport of membranes, chromosomes and viruses. The chromosome-associated chromokinesin KIF4 plays multiple roles in mitosis and its loss leads to mitotic defects including aneuploidy and genomic instability characteristic of many human cancers (Mazumdar et al., ICB, 2004). We have now taken advantage of the direct formation of aneuploidy in the absence of KIF4 to ask whether loss of a molecular motor and generation of aneuploidy can trigger tumorigenesis. We find that embryonic stem cells genetically depleted of KIF4 support anchorage-independent growth and form tumors in nude mice. Down-regulation or loss of KIF4 is physiologically relevant since reduced KIF4 levels are present in many human cancers from several tissues. In cells lacking KIF4 mitotic spindle checkpoints and DNA damage response pathways are activated in similar patterns as observed in early cancer cells (Mazumdar et al., Curr. Biol., 2006). Although the detrimental role of KIF4 loss becomes most evident in mitosis, we find that KIF4 also plays a critical role in interphase chromatin structure. Our results suggest that KIF4 is unique amongst known molecular motors in that it maintains both interphase and mitotic chromosome structure. Its functional loss can trigger tumor formation, possibly via alteration of chromatin organization, and they support the notion that aneuploidy can act as a primary trigger of tumorigenesis.

Aurora B Is Enriched at Merotelic Attachment Sites Where It Regulates MCAK

A. L. Knowlton, W. Lan, T. Stukenberg; Biochemistry, UVA, Charlottesville, VA
Often kinetochores form merotelic attachments, in which a single kinetochore is attached to microtubules from both spindle poles. These attachments can result in improper chromosome segregation, and are a significant source of aneuploidy, a hallmark of cancer. Aurora B kinase and the kinesin-13 microtubule depolymerase Mitotic Centromere Associated Kinesin (MCAK) are required to release improper microtubule attachments. Aurora B regulates MCAK's activity and localization. We set out to understand why MCAK and Aurora B are more abundant at some metaphase aligned chromosomes, but are present at low amounts on most others. We find that members of the Aurora B complex are specifically enriched at merotelic attachment sites. We also find that Aurora B does not appear to become enriched at these sites, however, inhibition of Aurora B activity causes a significant increase in the number of merotelic attachments per cell. Aurora B activity enriches MCAK at merotelic attachments and phosphorylates MCAK on residues that regulate its microtubule depolymerase activity. These data demonstrate that proteins which resolve the defect are specifically localized to merotelic attachments, where their enzymatic activities are regulated.

Human Tumor Cells with Chromosome Instability and Aneuploidy Display Elevated Rates of Merotely during Mitosis

S. L. Thompson, D. A. Compton; Biochemistry, Dartmouth Medical School, Hanover, NH
Chromosomal instability (CIN) is a distinct phenotype of some tumor cells that is characterized by frequent loss and/or gain of whole chromosomes. CIN contributes to aneuploidy in tumor cells, but the underlying mechanism of chromosome mis-segregation in CIN is unknown. Here, we use fixed and live cell imaging to examine chromosome segregation in human cancer cell lines with CIN. Using fixed cell assays, we found a significant increase in the number of anaphase cells displaying lagging chromatids in tumor cell lines with CIN (HT29, Caco2, and MCF-7) compared to tumor cells without CIN (HCT116). These lagging chromatids frequently displayed microtubule attachments to both spindle poles consistent with merotic attachment. Using live cell assays, we directly monitored chromosome segregation with GFP-histone H2B. As expected, the cell line without CIN (HCT116) aligned and segregated chromosomes faithfully greater than 90% of the time. The tumor cell lines with CIN (HT29 and Caco2) also aligned all chromosomes prior to anaphase onset and no cells entered anaphase with mis-aligned chromosomes. This demonstrates that these tumor cells with CIN have an intact spindle checkpoint, and rule out chromosome mis-segregation due to failure in spindle attachment. However, 23% and 86% of HT29 and Caco2 cells, respectively, displayed lagging chromatids at anaphase consistent with our fixed cell analyses. These data demonstrate that human cancer cell lines with CIN have elevated rates of merotely that are likely to contribute to aneuploidy. Interestingly, most Caco2 cells underwent transient monopolar spindle formation prior to bipolarization raising the possibility that syntely may precede merotely. Consistent with this idea, significant increases in lagging chromatids at anaphase were observed in near-diploid cells following recovering from monopolar spindles (via monastathal washout). We are currently testing if persistent merotely is sufficient to induce CIN in an otherwise normal diploid cell.

Functional Genomic Analysis of Genes Required for Clustering Supernumerary Centrosomes: A Novel Strategy for the Development of Selective Anticancer Drugs

M. Kwon, S. A. Godinho, N. S. Chandhok, D. Pellman; Pediatric Oncology, Dana Farber Cancer Institute, Boston, MA
Effective cancer therapeutics must exploit biological differences between tumor cells and the normal cells from which they arose. One striking feature of many cancers is the presence of extra centrosomes but efficiently form bipolar spindles (~90%). Using automated microscopy and visual inspection for multipolar spindle phenotypes upon RNAi, our primary screen identified 696 genes corresponding to ~3% of genome that are required for centrosome clustering. Among those, 44% have mammalian homologues. Potentially interesting candidates include genes involved in the regulation of actin and microtubules, cell polarity and cell adhesion. To determine if the actin cytoskeleton plays a role in centrosome clustering in mammalians, we used drugs that depolymerize actin or disrupt myosin II-dependent contractility in three different human breast cancer cell lines: one with a relatively normal centrosome
content (MCF-7) and two with extra centrosomes (MDA-231 and T47D). The MDA-231 cells, but not T47D cells, showed efficient clustering of extra centrosomes (40% of the bipolar spindles). Actin disruption selectively induced an increase of multipolar mitosis in MDA-231 cells but not in other cells. Currently we are performing automated image analysis and quantitative morphometrics measuring centrosome number, spindle length, pole width, and chromosome area for ~350 genes of our special interest. This will potentially enable the identification of different functional groups defining different mechanisms that promote centrosome clustering.

Identification of Novel Proteins Involved in Mitotic Spindle Assembly

J. Torres, 1, 2 D. Anderson, 3 P. Jackson 1, 2, 3
Tumor Biology and Angiogenesis, Genentech, Inc., South San Francisco, CA, 3Pathology, Stanford University School of Medicine, Stanford, CA, 3Institute of Molecular Biology, University of Oregon, Portland, OR

Although recent identification of factors involved in mitotic spindle assembly has enriched our understanding of this enigmatic structure, much remains to be understood about the formation, stabilization and checkpoints that ensure fidelity of mitotic spindle assembly. To elucidate novel proteins involved in proper mitotic spindle formation, we undertook a mass spectrometry analysis of mitotic microtubule-associated proteins. Mitotic HeLa cell extracts were used for in vitro microtubule polymerization reactions and proteins co-pelleting with microtubules were identified through 2D LC/MS/MS. We identified a set of 556 microtubule-associated proteins. About 1/3 of these were previously characterized proteins involved in various aspects of spindle dynamics. The remaining 2/3 are unknown or have been described to have functions outside of mitotic spindle assembly. We have systematically knocked down the expression of this set of genes by SirNA in human HeLa cells and analyzed mitotic spindle defects through fluorescence microscopy. We have identified a set of 25 novel gene knockdowns displaying mitotic spindle defects. These defects range in severity, penetrance and mitotic stage. Currently we are analyzing the mechanisms that lead to these defects and we hypothesize that these novel genes have a role in mitotic spindle assembly and will lend insight into mitotic fidelity.

Identification of Proteins That Contribute to Spindle Bipolarity in C. elegans Oocytes

S. M. Wigmill, A. M. Villeneuve; Developmental Biology, Stanford University, Stanford, CA

During cell division in most cell types, duplicated centrosomes nucleate microtubules, move apart, and ultimately form the poles of the spindle. However, oocytes of many species lack centrosomes and therefore spindles form through a different mechanism, where microtubules are nucleated around the chromosomes and then sorted into a bipolar array. One motor that is essential for both types of spindle assembly is Eg5, which is required for spindle bipolarity. Surprisingly, in C. elegans it has been previously reported that a deletion strain of the Eg5 homolog bmk-1 is homozygous viable, and spindle morphology appears normal in both oocytes (lacking centrosomes) and embryos (with centrosomes). Therefore, bipolarity must be established by a different mechanism. We performed an RNAi-based screen designed to identify genes required for spindle formation in C. elegans oocytes. Intriguingly, we found two genes whose depletion resulted in a phenotype reminiscent of Eg5 inhibition in other organisms: microtubules formed a single aster with the chromosomes towards the outside. In order to determine the arrangement of microtubules within the asters, we obtained an antibody to the worm homolog of Asp, a Drosophila MAP that localizes to spindle poles. As predicted, C. elegans Asp concentrates at spindle poles in both oocytes and embryos of wild type worms. Interestingly, Asp also localizes at the center of the asters observed in our screen, suggesting that they are monopolar spindles. The two genes with this phenotype are klp-18 (a Klp2 family kinesin), and a novel gene that we named mesp-1 (meiotic spindle 1). In contrast to Eg5, neither of these proteins is required for spindle bipolarity when centrosomes are present: spindle morphology in embryos is normal. Therefore, we have identified new factors that promote acentriolar spindle bipolarity; ongoing studies of these proteins should shed light on the mechanisms by which bipolarity is established.

123

Monastrol Causes Inhibition of Shortening or Lengthening of K-fibers during Anaphase in Crane-fly Spermatocytes

J. R. LaFontaine, R. Oldenbourg; 1Biological Sciences, University at Buffalo, Buffalo, NY, 2Marine Biological Laboratory, Woods Hole, MA

Anaphase A in crane-fly spermatocytes is MT flux-based: kinetochore (k) MTs add subunits to their plus ends and lose subunits from minus ends, yet kinetochore (K-) fibers shorten and attached chromosomes move poleward because the off-rate at poleward ends of kMTs is greater than the on-rate at kinetochore. We employed monastrol, a kinesin-5 inhibitor, to investigate what drives anaphase in spermatocyte spindles. Monastrol inhibited anaphase: after 3 hrs in 100µM monastrol, anaphase segregation velocities were 0.5µm/min vs. 1.0µm/min in controls; attached chromosomes move poleward because the off-rate at poleward ends of kMTs is perturbed by monastrol. Thus, because of the partial or complete inhibitory effect of monastrol on subunit loss from minus ends and the stabilization and checkpoints that ensure fidelity of mitotic spindle assembly. To elucidate novel proteins involved in proper mitotic spindle formation, we undertook a mass spectrometry analysis of mitotic microtubule-associated proteins. Mitotic HeLa cell extracts were used for in vitro microtubule polymerization reactions and proteins co-pelleting with microtubules were identified through 2D LC/MS/MS. We identified a set of 556 microtubule-associated proteins. About 1/3 of these were previously characterized proteins involved in various aspects of spindle dynamics. The remaining 2/3 are unknown or have been described to have functions outside of mitotic spindle assembly. We have systematically knocked down the expression of this set of genes by SirNA in human HeLa cells and analyzed mitotic spindle defects through fluorescence microscopy. We have identified a set of 25 novel gene knockdowns displaying mitotic spindle defects. These defects range in severity, penetrance and mitotic stage. Currently we are analyzing the mechanisms that lead to these defects and we hypothesize that these novel genes have a role in mitotic spindle assembly and will lend insight into mitotic fidelity.

Microtubule Pulling at the CellTip Cortex Drives Meiotic Nuclear Oscillation in Schizosaccharomyces pombe

S. K. Vogel, I. Tolic-Norrelykke; MPI-CBG, Dresden, Germany

During meiotic prophase, the fission yeast Schizosaccharomyces pombe shows a striking phenotype where the nucleus continuously oscillates between the two ends of the zygote for a few hours prior to the meiotic divisions. We set out to determine which forces drive the nuclear oscillation and how the force generation is spatially and temporally regulated. The nuclear oscillation is dependent on astral microtubules (MTs) radiating from the spindle pole body (SPB) and on cytoplasmic dynein, a minus end directed MT motor. Based on the observation that dynein is localized at the SPB, along MTs, and at certain cortical sites, two main models of force generation can be proposed: In the “pulling model” dynein resides immobilized at the cell cortex and generates a pulling force by walking along the astral microtubules towards their minus-ends, which are at the SPB. In the “pushing model” dynein is localized at the SPB and produces a pushing force on the SPB by moving along rearward extending MTs. By cutting single MTs using laser nanosurgery, we can distinguish between these two models and identify a subset of MTs that generates nuclear oscillation. Our data provide direct evidence that the main forces contributing to the nuclear oscillation are pulling forces, which are typically generated at the zygote ends, and that the event of force generation is driven by the interaction of forward extending MTs with the cell cortex.

Chromosome-directed Cortical Actomyosin Contractile Ring Assembly During Polar Body Extrusion in Mouse Oocytes

M. Deng, P. Suraneni, R. Li; Stowers Institute for Medical Research, Kansas City, MO

It is well known that the microtubule-based spindle is responsible for the equatorial assembly of an anactinomyosin contractile ring after initiation of anaphase in mitotic cells. Astral microtubules or spindle midzone are well recognized cues for inducing a cleavage furrow during cytokinesis. However, mammalian oocytes lack astral microtubules and centrosomes. Our data show that close-range extrusion to completion. We find that microtubule-based actomyosin ring assembly during metaphase of meiosis, long before anaphase onset. Injection of DNA beads to egg cortex mimics the meiotic chromosomes in inducing the actomyosin ring formation even in the absence of microtubule assembly, suggesting that the signals responsible for actomyosin ring assembly come from chromatin but not any microtubule-based structures. The chromatin-induced actomyosin ring contracts and creates an initial cleavage furrow during the early phase of polar body extrusion. The initiation of this early furrow does not require the presence of a bipolar spindle, suggesting that both actomyosin contractile ring assembly and the initial furrow formation are independent of spindle microtubules. However, further construction and closure of the contractile ring requires chromosome segregation and the anaphase spindle positioned perpendicular to the cortex, with the midzone encircled by the contractile ring. When microtubules are disrupted with nocodazole, even though the chromatin-induced actomyosin ring contracts and generates the initial furrow, polar body extrusion never completes and the initial furrow gradually regresses. In the case when the anaphase-spindle is positioned in parallel to the cortex, an extra furrow is formed at the cap, resulting in abortive polar body extrusion, suggesting that the neither the chromatin-defined initial furrow nor the midzone-induced ectopic furrow alone is able to drive the polar body extrusion. We propose that corticospinal signals derived from chromatin and midzone are spatiotemporally coupled to accomplish the highly asymmetric cytokinesis during meiosis in mammalian oocytes.
Two Mutants with Novel Meiotic Phenotypes in \textit{C. elegans}

S. Sover-Gri, A. Dernburg, Department of Molecular and Cell Biology, University of California at Berkeley and Lawrence Berkeley National Laboratory, Berkeley, CA

Diploid cells undergo meiosis to produce haploid gametes. Before the first meiotic division occurs, homologous chromosomes must pair, synapse, and recombine. Homologous chromosomes separate in the first meiotic division, followed by the sister chromatids in the second meiotic division. The failure of chromosomes to properly segregate leads to aneuploidies and genomic instability. In \textit{C. elegans}, the missegregation of \textit{X} chromosomes during meiosis in hermaphrodites (XX) results in an elevated number of male progeny, relative to the 0.2% of males self-progeny produced by wild type animals. We are studying two genes that give rise to this male bias: \textit{Cib1} (germline-enhanced At-Hook protein-1) and \textit{plk-2}, which is one of three polo-like kinases in \textit{C. elegans}. Neither of these mutants dramatically perturbs pairing, synapsis, or recombination, and these genes therefore illuminate other mechanisms that are required for accurate meiotic chromosome segregation. We noted that both \textit{Cib1} and \textit{plk-2} males produce 20-25% male progeny, and 40% of the hermaphrodites are completely sterile. These mutants are proficient in crossover formation and usually display 6 bivalents. However, the normal deconstruction of the synaptonemal complex elements seems to be perturbed in these mutants. \textit{plk-2} (tm1359) hermaphrodites display a weaker \textit{His} phenotype, producing 5-7% of males. They show some chromosome asynapsis, an abnormal number of bivalents in diakinesis and mislocalization of synaptonemal complex elements along the chromosomes. We are currently working to understand how these defects arise and why they give rise to the high levels of nondisjunction. One possibility is that the \textit{gak-1} and \textit{plk-2} genes may be regulating the disassembly of the synaptonemal complex. Further characterization of these mutants will be presented.

CIB1 Is Essential for Mouse Spermatogenesis

W. Yuan, T. Leisner, A. McFadden, S. Clark, S. Huller, N. Maeda, D. A. O'Brien, L. V. Parise, Pharmacology, UNC at Chapel Hill, Chapel Hill, NC, 3Pathology and Laboratory Medicine, UNC at Chapel Hill, Chapel Hill, NC, 3Cell and Developmental Biology, UNC at Chapel Hill, Chapel Hill, NC

\textit{Cib1} is a 22 kDa calcium-binding, regulatory protein with ~50% homology to calmodulin and calcineurin B. \textit{CIB1} is widely expressed and binds to a number of effectors such as integrin α3β1, p21 activating kinase 1, DNA-dependent protein kinase and polo-like kinases in different tissues. However, the in vivo functions of \textit{CIB1} are not well understood. To elucidate the function of \textit{CIB1} in whole animals, we used homologous recombination in embryonic stem cells to generate \textit{Cib1−/−} mice. We found that although \textit{Cib1−/−} mice grow normally, the males are sterile due to a disruption of differentiation during the haploid phase of spermatogenesis. This is associated with reduced testis size and numbers of germ cells in seminiferous tubules, increased germ cell apoptosis, appearance of multinucleated cells and the loss of elongated spermatids and sperm in \textit{Cib1−/−} male seminiferous tubules. In contrast, male \textit{Cib1+++} and female \textit{Cib1−/−} mice exhibited no obvious impairment of growth, development or reproductive performance. We confirmed that \textit{CIB1} is expressed in isolated pachytene spermatocytes, round spermatocytes, sperm and cultured Sertoli cells.

Furthermore, we found that \textit{Cib1−/−} females display a significantly increased mRNA and protein expression of the cell cycle regulator Cdc2/CDk1 (cyclin dependent kinase 1) relative to \textit{Cib1+++} females. However, \textit{Cib1−/−} and \textit{Cib1+++} tests show comparable mRNA expression levels of other spermatogenesis stage-specific markers such as \textit{Sperm-1} (Pou-homeodomain domain), \textit{Cre} (CAMP-responsive element modulator), \textit{Trf2} (TRBP related factor 2), \textit{Pmn-2} (protease 2), \textit{Trp-1} (transition protein 1 and 2). In addition, mouse embryonic fibroblasts (MEFs) derived from \textit{Cib1−/−} mice exhibit a higher sensitivity to apoptosis when compared to \textit{Cib1+++} MEFs. Taken together, these results indicate that \textit{CIB1} is essential for the normal process of spermatogenesis and point to a role for \textit{CIB1} in regulating the cell cycle or differentiation of spermatogenic stem cells and/or the supporting Sertoli cells.

Translational Unmasking of Emi2 Directs Cytostatic Factor Arrest in Meiosis II

P. K. Jackson, J. S. Tong, K. Padmanabhan, J. D. Richter, Chemical Biology and Pathology, Stanford University School of Medicine, Palo Alto, CA, 3Genentech Inc., South San Francisco, CA, 3University of Massachusetts Medical School, Worcester, MA

Cytostatic Factor (CSF) arrests unfertilized vertebrate eggs in metaphase of meiosis II to prevent parthenogenesis. By inhibiting the Anaphase Promoting Complex/Cyclosome (APC/C) from targeting cyclin B for ubiquitin-mediated destruction, CSF activity sustains Maturation Promoting Factor (MPF), the biochemical engine of meiosis composed of cyclin B/Cdc2. The APC/C inhibitor Emi2/XErlp satisfies a number of historic criteria for the molecular identification of CSF: Emi2 is sufficient and necessary for CSF arrest, and is rapidly degraded by a calcium-dependent mechanism upon egg activation. How CSF is activated selectively in meiosis II is the remaining unresolved criterion. Here we show that Emi2 is expressed specifically in meiosis II through translational de-repression or “unmasking” of its mRNA, thus explaining how CSF activity appears during oocyte maturation and peaks in meiosis II. We find that Emi2 protein is absent in immature G2 oocytes and accumulates ~90 minutes after germinal vesicle breakdown (GVBD), in contrast to earlier work reporting that Emi2 is present at relatively constant levels throughout oocyte maturation. Furthermore, premature expression of ectopic Emi2 blocks the meiosis I to meiosis II transition (MI-MII), very likely through APC/C inhibition. This suggests that the APC/C is required for MI-MII in Xenopus oocytes contrary to previous findings and demonstrates the need to delay Emi2 accumulation until meiosis II. We show that the 3′ untranslated region (3′UTR) of Emi2 mRNA contains cytoplasmic polyadenylation elements (CPEs) that directly bind the CPE binding protein (CPEB) and confer temporal regulation of Emi2 polyadenylation and translational unmasking of a meiosis II-specific APC/C inhibitor directs CSF arrest.

The Paromycin Sensitive Aminopeptidase, PAM-I, Is Required for Meiotic Exit and Anterior-Posterior Polarization in the \textit{C. elegans} Embryo

R. Lycra, J. Zweier, C. Snyder, L. Kalovits, A. Beauty, B. Bowerman, Biology Department, Ursinus College, Collegeville, PA, 3Institute of Molecular Biology, University of Oregon, Eugene, OR

In the nematode \textit{Caenorhabditis elegans}, sperm entry into the oocyte triggers the completion of meiosis and the establishment of the embryonic anterior-posterior (A-P) axis. Axis establishment occurs in tight succession with completion of meiosis and the sperm donated centrosome coordinates this process through destabilization of the cortical actomyosin network. How the early embryo makes the transition from a meiotic cyclin to a mitotic zygote and coordinates cell cycle changes with axis formation remains unclear. We have discovered roles for the \textit{C. elegans} paromycin-sensitive aminopeptidase, PAM-I, in both cell cycle progression and A-P axis formation, further implicating proteolytic regulation in these processes. \textit{C. elegans} PAM-I is highly related to human PSA. \textit{pam-1} mutant embryos exhibit a delay in exit from meiosis; thus, this peptidease is required for progression to mitotic interphase. In addition, the centrosomes associated with the sperm pronucleus fail to closely associate with the posterior cortex in \textit{pam-1} mutants, and the A-P axis is not specified. The meiotic exit and polarity defects are separable, as inactivation of the B-type cyclin, CYB-3, in \textit{pam-1} mutants rescues the meiotic exit delay but not the polarity defects. Thus \textit{PAM-I} may target CYB-3 to regulate meiotic exit but presumably targets other protein(s) to regulate polarity most likely by ensuring cortical/centrosome association. The degradation of proteins through ubiquitin-mediated proteolysis has been previously shown to regulate the cell cycle and A-P axis formation in the \textit{C. elegans} zygote. Our analysis of \textit{PAM-I} requirements show that a paromycin sensitive peptidease also is required for proteolytic regulation of the oocyte to embryo transition.

Live Imaging Reveals That Chiasmata Ensure Timely Coorientation during \textit{Drosophila} Meiosis

J. L. Cottia, S. Hughes, W. Gilliland, R. S. Hawley; Stowers Institute for Medical Research, Kansas City, MO
Anillin and the Septins Break Symmetry within the Actomyosin Cytoskeleton to Promote Unilateral Furrowing during Cytokinesis

A. S. Maddox, L. K. Lewellyn, A. Desai, K. F. Oegema; Cell and Molecular Medicine, LICR / UCSD, La Jolla, CA

Anillin and the septins are widely conserved structural components of the cortical cytoskeleton. Septins heteroligomers are thought to polymerize to form a membrane-associated filament system. Anillins are cytoskeletal crosslinkers that can bundle actin filaments and bind active myosin II and septin filaments. Inhibition of anillin or septin function in C. elegans causes stochastic but strikingly similar defects in growth, maturation and tissue morphogenesis, suggesting that they function together during development. We have examined the cortical localization of anillin and septins during the first cytokinesis of the C. elegans early embryo, where anillin is required to position the septins in the contractile ring. The first mitotic cleavage furrow is highly asymmetric: initially, a smooth indentation deforms the entire cell equator, then the furrow dips in at one location and sweeps across the division plane unilaterally. Unilateral furrowing is prevalent among species and cell types, including marine invertebrate eggs, mammalian cultured cells, and C. elegans somatic cells. In other systems, the eccentric position of the mitotic spindle, the presence of cell-cell and cell-substrate adhesions, or other existing axes likely contribute to unilateral furrowing. Importantly, in the C. elegans one-cell embryo, none of these possible confounders appear to exist, suggesting the existence of an intrinsic mechanism for unilateral furrowing. A novel four-dimensional imaging regime yielding an end-on view revealed that during unilateral ingestion, cytoskeletal components of the contractile ring are asymmetrically distributed around the ring, with greatest accumulation at the fastest-increasing side. Depletion of anillin or the septins did not alter the kinetics of contractile ring closure, but caused both furrow ingestion and contractile ring structure to become symmetric. We conclude that in the contractile ring, anillin and the septins act together to break the symmetry of the actomyosin cytoskeleton, an activity that may be important for neuronal path finding or other developmental events.

Microtubules Negatively Regulate Cortical Actin during Cytokinesis of Adherent Cells

K. T. Murphy, C. J. Fagerstrom, P. Wadsworth; Biology Department, University of Massachusetts, Amherst, Amherst, MA

During anaphase, an F-actin and myosin II containing contractile ring is assembled at the equatorial cortex and functions in cytokinesis. Microtubules are responsible for signaling the cortex for contractile ring assembly, but the mechanism remains poorly understood. LLC-PK1 epithelial cells expressing GFP-actin were treated with nocodazole during anaphase to disassemble microtubules, and the organization and dynamics of actin were examined. Addition of nocodazole within 1 minute of anaphase onset results in complete microtubule disassembly and blocks cytokinesis. Addition of nocodazole >1 minute after anaphase onset eliminates astral, but not interzonal microtubules, and cytokinesis proceeds to completion, demonstrating that astral microtubules are dispensable once incoordination is initiated. In these cells, the contractile ring appeared wider than in control cells, and actin from distal regions of the cortex contributed to ring formation. In nocodazole treated cells, loss of microtubules resulted in novel wave-like behavior of cortical actin. Waves could be initiated at various sites and moved rapidly across the cortex (~25-60 μm/min). FRAP experiments on nocodazole treated cells showed that the half-time for recovery was decreased 2-fold. To determine if the changes in actin behavior following microtubule disassembly are mediated by Rho, we examined the distribution of RhoA in nocodazole treated cells. In nocodazole treated cells that divided, RhoA was localized to the ring as in controls, but was also mislocalized to other regions of the cortex. Similar results were obtained by imaging C. elegans GFP-RhoA in living cells. Our results demonstrate that loss of microtubules results in increased accumulation of actin in the contractile ring, abnormal cortical behavior, increased actin turnover, wave-like behavior of cortical actin and mislocalization of RhoA. We conclude that microtubules negatively regulate actin behavior in the cortex of cultured epithelial cells.

Imaging Recruitment of Myosin and Actin to the Cytokinetic Furrow by Total Internal Reflection Fluorescence Microscopy (TIRF-M)

M. Zhou, Y. Wang; Department of Physiology, University of Massachusetts Medical School, Worcester, MA

Cytokinesis involves the recruitment and organization of actin and myosin filaments along the equatorial cortex, likely as part of the contractile process to drive the separation of daughter cells. Although many studies have attempted to address the mechanism of equatorial recruitment of actin and myosin, there has been little direct information on the dynamic process, partially due to the limitation of imaging techniques and the high background from the abundance of myosin and actin in the cytoplasm. In this study, we used total internal reflection fluorescence microscope (TIRF-M) to image the dynamics of GFP-actin II and GFP-actin during the assembly of equatorial cortex in dividing NRK cells. TIRF-M effectively reduced the cytoplasmic fluorescence background and highlighted the cortical structure. We found that myosin and actin followed clearly different patterns of recruitment into the equatorial region. While there was a striking flux of actin filaments toward the equator, myosin structures showed no directed movement but appeared to assemble de novo along the equator, initiating slightly ahead of the onset of actin flux. Actin flux was abolished by blebbistatin, a myosin ATPase inhibitor, although this did not inhibit the concentration of equatorial actin, suggesting that there is a flux-independent process for actin recruitment. In contrast, the recruitment of equatorial myosin during early cytokinesis did not appear to require F-actin, as the process was unpainted in cells treated with latrunculin. Our results suggest distinct mechanisms for the equatorial organization of actin and myosin. In addition, the recruitment of actin may involve both a myosin-dependent flux mechanism, and a flux-independent, de novo mechanism.

Cytokinesis Requires the Regulation of Actin Cytoskeleton by α-actinin in Mammalian Cells

S. A. Mukhina, Y. Wang, M. Murata-Hori; 1Temasek Life Sciences Laboratory, Singapore, 2University of Massachusetts Medical School, Worcester, MA

Recent advances in the regulation of cytokinesis have implicated the modulation of actin cortex during cytokinesis, which likely involves a number of actin modulating proteins. Concentration of an actin cross-linking protein α-actinin to the cleavage furrow has been reported over the past decades. However, its function during cytokinesis remains poorly understood. We have analyzed the function of α-actinin during cytokinesis by a combination of time-lapse imaging and molecular manipulations. α-actinin accumulated along the equator underwent gradual dissipation from the cleavage furrow as cytokinesis progressed. FRAP analysis demonstrated that α-actinin along the cleavage furrow was highly dynamic (τ1c = 8.4 ± 0.4 s), while being relatively stable at the subequatorial region (τ1s = 23.1 ± 4.3 s). Overexpression of α-actinin caused decelerated cytokinesis and cytokinesis failure due to excessive bundling of actin filaments and precocious formation of focal adhesions. In addition, we observed abnormal rope-like structures of myosin II along the cleavage furrow in cells overexpressing α-actinin. Conversely, global depletion of α-actinin by siRNA caused a decrease in the density of actin filaments throughout the cell cortex, surprisingly inducing not only accelerated cytokinesis but also ectopic furrowing. Furthermore, local disruption of α-actinin by chromophore-assisted laser inactivation resulted in the formation of wider and slightly deeper furrow at the site of irradiation. These observations suggest that furrowing requires remodeling and solution of the actin filament network and that equatorial-specific modulation of actin filaments mediated by α-actinin ensures proper cytokinesis in mammalian cells.

The Cell End Factor Pomp1p Inhibits Mid1p in Specification of the Cell Division Plane

N. N. Padte, M. S. Martin, M. Howard, F. Chang; Microbiology Department, Columbia University College of Physicians and Surgeons, New York, NY, 3Mathematics Department, Imperial College London, London, United Kingdom

Intrinsically spatial cues ensure the proper placement of the cell division plane. In the fission yeast Schizosaccharomyces pombe, the position of the nucleus helps to direct the medial positioning of contractile ring assembly and subsequent cell division. An important factor in this process is mid1p (anillin-like protein), which is a peripheral membrane protein that forms a broad cortical band of dots overlaying the nucleus in interphase and recruits myosin in early mitosis. How mid1p localizes to this cortical band and tracks the nucleus is not clear, especially as its localization is independent, de novo mechanism. We provide evidence that pom1p, a Dyrk family protein kinase, forms an inhibitory concentration gradient emanating from the non-growing cell end. In pomp1 mutants, mid1p is distributed over the entire cell plane over the non-growing cell end. Pomp1 is a well characterized cell polarity factor. However, this phenotype is not due simply to altered cell polarity, since other mutants with similar polarity defects positioned mid1p normally at the medial cortex. The abnormal mid1p distribution is established in a dynamic manner in interphase and leads to misplaced or multiple contractile rings. In

2006 ASCB Annual Meeting Abstracts
addition, we provide evidence that pom1p works in conjunction with a second inhibitor at the growing cell tip. Our computational and experimental results support a new model in which both positive cues from the medial nucleus and negative cues from the cell tips specify the position of the division mechanism. Further understanding of this interplay promises to provide new insights into the global spatial regulation of cell division.

Characterization of Cytokinesis Mutants in Saccharomyces cerevisiae
E. A. Vallen,1 L. Tha,2 C. Palmer,2 M. Lippincott,1 H. Han,1 H. Bhattachar,1 J. Luo,2 C. Dravis,1 E. Bi,2 1Biology, Swarthmore College, Swarthmore, PA, 2Cell and Developmental Biology, University of Pennsylvania School of Medicine, Philadelphia, PA

Cytokinesis in Saccharomyces cerevisiae occurs via the coordinated action of the actomyosin contractile ring and the septum-formation process. The actomyosin contractile ring is not essential in some strain backgrounds. However, it is required for cytokinesis and viability in our strain in the presence of a deletion of HOFL, a gene important for coordinating the ring function and septum formation (Vallen, Caviston and Bi, 2000 Mol. Biol. Cell, 11:593-611). A screen for mutants synthetically lethal with ho1p was utilized to identify and characterize proteins required for the function of the actomyosin ring pathway. Approximately forty HOFL-independent mutants were identified by screening 33,000 mutagenized colonies using a sectoring assay and other genetic tests. Complementation testing, linkage analysis and plasmid-linked suppression indicate that mutations were isolated in RHO1, RHO2, CDC12, CYK3, ELM1, GNA1, MCL1, MYO1, and PSE1. Some mutants have yet to be characterized. A subset of the myo1p alleles has been characterized in more detail. A number of the isolated mutations are premature stop codons occurring in the C-terminal quarter of the protein. Preliminary data analyzing GFP-myo1p+ suggests these proteins localize to the bud neck and that at least some of the mutant strains have actin rings as visualized by staining with rhodamine-labeled phallolidin. This suggests that these mutations are not complete loss-of-function alleles.

Identification of Cytokinesis Proteins by Dosage-Suppressor Screens in S. cerevisiae
N. Ko,1 R. Nishihama,2 J. R. Pringle1 1Department of Genetics, Stanford University School of Medicine, Stanford, CA, 2Department of Biology, University of North Carolina, Chapel Hill, NC

In the yeast Saccharomyces cerevisiae, a ring of myosin II (Myo1p) forms in a septin-dependent manner at the presumptive budding site in late G1. At the onset of cytokinesis, actin is recruited to the Myo1p ring; the resulting actomyosin ring then contracts, and a septum of cell wall concurrently completes cytokinesis. Three other proteins involved in cytokinesis are Iqg1p, Cyk3p, and Ho1p. Iqg1p is the only S. cerevisiae IQGAP; it promotes actomyosin-ring formation and is required for primary-septum formation and hence for normal cytokinesis. Because the actomyosin ring itself is not essential for primary-septum formation, Iqg1p must have at least one other cytokinetic function. Cyk3p was identified previously on the basis of its ability to suppress iog1Δ growth defects without restoring the actomyosin ring; thus, Cyk3p may function downstream of Iqg1p, or an actomyosin-ring-independent pathway for cytokinesis. Previous studies suggest that Ho1p may function as an adapter linking the actomyosin ring to the machinery that synthesizes the primary septum. To identify additional proteins involved in the septin-dependent, actomyosin-ring-independent pathway of cytokinesis, we have conducted screens for dosage suppressors of the myo1Δ cyk3Δ and myo1Δ ho1Δ synthetic-lethal phenotypes.

We have isolated several genes including EG12 (which encodes a GTP-anchored cell-wall endoglucanase thought to be involved in cell separation), ECM3 (which encodes a GPI-anchored protein that may function in cell-wall organization), and a truncated CDC24 (which encodes the GEF for the Rho-type GTPase Cdc42p) that lacks the C-terminal PDB domain. Overexpression of Ecm3p or the truncated Cdc24p can also suppress iog1Δ growth defects and restore the formation of primary septa. Because overexpression of Cdc42p does not rescue the iog1Δ growth defects, Cdc24p may have a cytokinetic function that is independent of Cdc42p. Further studies of these and other genes identified in the screens will be presented.

The Cdc14/Cdc1p Phosphatase Regulates Phosphorylation and Dynamics of Fission Yeast Contractile Ring Components through a Midl-dependent Mechanism
D. M. Clifford Hart,2 B. A. Wolfe,1 R. H. Roberts,1 W. H. McDonald,2 J. R. Yates III,2 K. L. Gould1 1Cell and Developmental Biology, HHMI and Vanderbilt University Medical School, Nashville, TN, 2Department of Genetics, Stanford University School of Medicine, Stanford, CA

In eukaryotes, progression through the cell cycle is directed by the activity of cyclin-dependent kinases (cdks). Reversal of cdk-dependent phosphorylation events involves the highly conserved Cdc14-family of phosphatases. The fission yeast Cdc14 homolog, Cdc1p/Fpl1p, localizes to many subcellular compartments, such as kinetochores, the mitotic spindle and the division site where it is involved in several facets of cell cycle control. However, the mechanism by which Cdc1p/Fpl1p functions at these distinct sites is unclear. To investigate the role of Cdc1p at the division site, we used a proteomics approach to identify the mechanism of Clp1 recruitment to the CAR and describe the functional consequence of its recruitment by examining the phosphorylation status and dynamic properties of key CAR components. We present evidence that Clp1/Fpl1 association with Mid1, an anillin-related protein required for correct cytokinetic actin ring (CAR) positioning, is necessary for Cdc1p/Fpl1 localization to the ring. Once localized at the CAR, Cdc1p activity regulates the complete dephosphorylation of the essential CAR component Cdc15 and influences the dynamic properties of both Cdc15 and myo1p to provide stability to this structure. Our findings underscore the significance of Cdc14 catalytic activity in the regulation of CAR dynamics and offer an explanation for the requirement of Cdc1p to ensure the fidelity of S. pombe cytokinesis.

Adaptive Evolution of Cytokinesis Pathways in Budding Yeast
N. Pavelka, G. Rancati, R. Li, Stowers Institute for Medical Research, Kansas City, MO

As pathogens evolve elegant immune escape mechanisms and eventually develop antibiotic resistance, cancer cells evade immune responses and eventually develop resistance to chemotherapy. In fact, adaptability to perturbations is common to all biological systems. As an example, Saccharomyces cerevisiae cells lacking a functional copy of the MTO1 gene, whose product is essential for forming the contractile ring during cytokinesis, are able to evolve alternative mechanisms of cell division. We have used a combination of adaptive evolution experiments and computational methods to investigate how yeast cells rapidly evolve novel, myosin-independent strategies for cell division. 45 myo1Δ yeast strains were allowed to independently evolve over hundreds of generations until they either died out or stabilized their improved growth ability. Growth curves, cytokinesis proficiency, DNA content, cellular size and viability of 29 stable evolved strains have been analyzed by a combination of methods, including optical density, microscopy and flow cytometry. Principal Component Analysis of these viability data revealed the emergence of recurring phenotypic classes, suggesting convergent evolution to a limited number of solutions. Surprisingly, among the strains that best recovered the capacity to undergo cytokinesis, all showed a change in their ploidy. In fact, we found that six of the 29 evolved strains had become diploid, four were tetraploid, ten were aneuploid, and the nine most cytokinesis-deficient strains were still haploid. This is reminiscent of the genomic aberrations that are typically observed in cancer cells and may suggest a selective advantage, e.g. in terms of increased adaptability, for cells that increase their ploidy. In order to gain further molecular insights into the adaptation strategies that these strains have evolved, we are in the process of applying a combination of microarray, proteomics and computational analyses to identify the genes whose differential expression correlates with genomic rearrangement and phenotypic improvement.

Promotion of Cytokinesis by the Iqg1p (IQGAP)-Cyk3p Pathway in Yeast
R. Nishihama, N. Ko, J. T. D. Perdue, J. R. Pringle 1Department of Genetics, Stanford University School of Medicine, Stanford, CA, 2Department of Biology, University of North Carolina, Chapel Hill, NC

It is widely believed that the contraction of an actomyosin ring results in the membrane invagination that forms the cleavage furrow during cytokinesis in animal and fungal cells. Cytokinesis in Saccharomyces cerevisiae involves such a contractile ring, which functions in conjunction with the formation of a chitinous primary septum (PS) by the chitin synthase Chs2p to complete cytokinesis. Null mutations of MTO1 (the only myosin II gene) block actomyosin-ring formation but are nonetheless nonlethal. Electron microscopy revealed that myo1Δ cells form PS-like, chitin-containing septa, but not the membrane invagination that occurs in wild-type cells. In contrast, deletion of CHS2 causes complete loss of the PS. Thus, Chs2p-mediated PS formation may drive the membrane invagination. In a screen for dosage suppressors of myo1Δ phenotypes, we recovered IQG1 (encoding an IQGAP essential for actomyosin-ring formation) and CYK3 (overexpression of which can suppress iog1Δ growth defects). Both gene products form rings at the division site, and increased expression of either gene caused a proliferation of PS-like structures. Electron microscopy showed that cyk3Δ cells have simultaneous formation of PS and secondary septa; although a ring of Chs2p was assembled properly at the division site, its constriction, as well as that of the actomyosin ring, proceeded much more slowly than in wild-type cells. Iqg1p was also dispensable for Chs2p localization, but overexpression of Cyk3p could restore PS formation in such cells. These results suggest that Iqg1p and Cyk3p are components of a pathway that promotes membrane deformation, PS formation, or both.

Phosphorylated on Ser-19 Residue of Vps74p Is Involved in the Apical Growth

F. S. Lee, J. Jung, L. Chang, Y. Liu. Institute of Molecular Medicine, National Taiwan University, Taipei, Taiwan

In Saccharomyces cerevisiae, apical bud growth occurs for a brief period in G1 when the deposition of membrane and cell wall is restricted to the tip of the growing bud. Vps74p (product of YDR372C) was recently reported to alter the elongated bud morphology of cdc34-2 cells arrested in the apical growth phase. Here, we show that Vps74p is phosphorylated on serine-19 in a growth-phase-dependent manner. Cdc28 kinase is required for Vps74p phosphorylation. Both alanine and aspartate substitutions in serine-19 directly affect elongated bud morphology of cdc34-2 cells. The alanine substitution abolished Vps74p functional activity on apical growth. In contrast, the aspartate substitution stimulates cellular elongated buds formation. Localization of Vps74p at the Golgi is not dependent on the N-terminal phosphorylation, but on its C-terminal domain. Vps74p is involved in the transportation of GPI-anchored protein Gas1. In addition, deletion of C-terminus, but not N-terminus, of Vps74p affects cell wall integrity. Together, we infer that the distinct functional outcome from Ser-19 phosphorylation modulates Vps74p activity in apical growth, but not in cell wall integrity.

The SIN Signaling Pathway Acts to Inhibit Interphase Polarity Machinery until Cytokinesis Is Completed

S. Ray, J. Nordberg, D. Hirata, D. McCollum. Molecular Genetics and Microbiology, University of Massachusetts Medical School, Worcester, MA, 2Graduate School of Advanced Sciences of Matter, Hiroshima University, Higashihiroshima, Japan

Maintenance of genomic stability requires precise coordination of cell cycle events. We have found that cytokinesis is coordinated with cell cycle progression through a cytokinesis checkpoint in the fission yeast S. pombe. If cells have delays in completion of cytokinesis, the cytokinesis checkpoint arrests nuclear division, keeping cells in a binucleate state. In addition, the checkpoint acts to maintain the actomyosin ring and inhibit return to interphase polarity until cytokinesis is complete. The SIN signaling pathway and the Cdc14-like phosphatase Clp1p are essential for this checkpoint. We have investigated the relationship between the SIN and Clp1p further, in particular whether Clp1p is required for checkpoint functions if the SIN is constitutively activated in the absence of Clp1p. We show that the SIN can carry out checkpoint functions independently from Clp1p, and activation of the SIN in interphase can block cells in G2 phase with disrupted interphase polarity and inhibited growth. G2 arrest is only observed if the SIN is activated early in the cell cycle, when Clk1 activity is low, suggesting an antagonistic relationship between the SIN and Cdk1. Consistent with this, we observe Cdk1 phosphorylation of the SIN kinase Sid2p. The G2 arrest induced by SIN activation is not due to a cell size checkpoint. Inactivation of Wee1 overrides the G2 arrest, but cells still have disrupted interphase polarity. We also show that interphase SIN activation disrupts localization of several polarity markers located at cell tips, including the Cdc42 protein, which is part of the Orb1 kinase pathway. Together these results suggest that the SIN not only promotes cytokinesis, but also inhibits cell cycle progression and the interphase polarity machinery until cytokinesis is complete.

Chemical Inhibitor Studies of Polo Kinase Function during Anaphase and Cytokinesis in Mammalian Cells

I. M. Brennan, U. Peters, T. M. Kapoor, A. F. Straight. Department of Biochemistry, Stanford University, Stanford, CA, 2Laboratory of Chemistry and Cell Biology, Rockefeller University, New York, NY

Polo-like kinase 1 (Plk1) is a key regulator of mitosis and cytokinesis. Genetic and RNA interference studies have determined that Plk1 is required for multiple processes during cell division including mitotic entry, spindle pole maturation, bipolar spindle assembly, and the mitotic checkpoint. These studies have also demonstrated that deficiency in Plk1 activity induces failure in cytokinesis yielding binucleate cells. However, the specific function of Plk1 in cytokinesis has remained difficult to deduce with genetic experiments due to extensive defects early in mitosis. We are investigating the role of Plk1 during cytokinesis using a specific small molecule inhibitor of polo kinase function. The high degree of temporal control afforded by the use of a small molecule allows for rapid inhibition of Plk1 during cytokinesis without disrupting prior mitotic events. Here we show that suppression of Plk1 activity in mammalian cells by inhibitor treatment at anaphase onset causes defects in cytokinesis. Interestingly, Plk1 inhibition also disrupts anaphase-B spindles elongation, affecting chromosome movements to the spindle poles during anaphase-A. The activities of polo kinase during furrow ingression and anaphase-B are separable; when the small molecule is washed out after inducing a complete block of anaphase-B and furrow ingression, the cells complete cytokinesis without spindle pole separation. These data imply separate and critical roles for Plk1 in anaphase spindle elongation and cytokinesis in mammalian cells.

A Critical Role for Novel PKC Epsilon Phosphorylations during Cytokinesis

To identify proximal PKCε targets we undertook a yeast 2-hybrid screen of a cDNA library using the PKCε regulatory domain (V1-V3) as bait. Among the positive clones identified was the scaffold protein 14.3.3β. We have confirmed in mammalian cells that 14.3.3β binds to PKCε in a phosphorylation dependent manner. Specifically, we have shown that binding is mediated through two previously unidentified phosphorylation sites within the V3 hinge region of PKCε, Ser346 and Ser368. Moreover, we have characterised Ser368 as a PKCε autophosphorylation site in vitro and Ser346 as a GSK3β site that requires an initial priming phosphorylation by p38-MAPK kinase at Ser350. The acutely induced phosphorylation of these sites has been monitored in distinct cell types and under different growth conditions, revealing that occupation of these sites may be involved in multiple processes. Notably however, immunofluorescence studies have revealed that phosphorylation of these sites also occurs in cells undergoing mitosis. These phosphorylations and the subsequent association of 14-3-3 is critical for cytokinesis as evidenced by an increased degree of binucleation and an extended time to mitotic cell separation in PKCε knockout MEFs expressing GFP-PKCε mutants incapable of binding 14-3-3 when compared to wild type GFP-PKCε. A catalytic requirement for PKCε in this process is demonstrated by the inhibition of cytokinesis following expression of a kinase dead PKCε or by specific inhibition of PKCε. Furthermore, this inhibition of cytokinesis via inhibition of PKCε correlates with the accumulation of PKCε at the furrow during the final stages of telophase, suggesting that PKCε activity is required for furrow progression and exit from this compartment. These data show that a series of regulated PKCε phosphorylations and subsequent 14-3-3 association is critical for furrow progression and separation of the daughter cells at the end of cytokinesis.

Regulation of the Small G-proteins Rho1 and Cdc42 during Cytokinesis and Polarized Growth

S. Yoshida, K. Kono, D. Lowery, S. Bartolini, D. Pellman. Pediatric Oncology, Dana-Farber Cancer Institute, Boston, MA, 2University of Tokyo, Kashiwa, Japan, 3Laboratory of Chemistry and Cell Biology, Rockefeller University, New York, NY

Budding yeast is an important model for asymmetric cell division where polarized morphogenesis must be coordinated with cell division. In the early part of the cell cycle Rho-type GTPases and downstream targets such as formins promote the growth of the daughter cell (the bud). During mitosis, these proteins are redirected to the cell division site to enable cytokinesis. Although mitotic Cdk1 activity is implicated in activation of Rho-family GTPases, the molecular mechanisms remain poorly understood. Here we present evidence that Polo-like kinase Cdc5 controls cell polarity and cytokinesis by affecting the activity and/or localization of Rho1 and Cdc42. We found that Cdc5 phosphatases and targets Rho1 Guanine nucleotide exchange factors (GEFs) to the division site, which is a critical step for cytokinetic actin ring assembly. In addition, we find that Cdc5 phosphorylates a Cdc42 GTPase activating protein (GAP) Bem3. As Cdc42-GTP accumulates to the distal bud cortex and cells hyper-elongates in the cdc5 mutant, regulation of Cdc42 by Cdc5 may be important for cell morphogenesis. Our results suggest a coordinated regulation of Rho1, Cdc42 and mitotic exit by Polo-like kinase, revealing a novel mechanism for regulating the cortical cytoskeleton during cell division.

The Requirement for Rho Kinase in Recruitment of Myosin II to the Cleavage Furrow Is to Phosphorylate the Myosin Regulatory Light Chain

S. O. Dean, J. A. Spudich. Biochemistry, Stanford University, Stanford, CA

Myosin II is recruited to the cytokinetic furrow of Drosophila S2 cells independently of F-actin, but the small GTPase Rho1 and Rho Kinase (Rok) are essential for this recruitment. Rok has been shown to phosphorylate multiple proteins involved in cytokinesis including the myosin II Regulatory Light Chain (RLC), Pten, and ERM proteins. Using phosphorylation state mimic constructs expressed in Drosophila S2 cells we show that phosphorylation of the RLC is indeed required for myosin II recruitment to the furrow and, furthermore, the only essential role of Rok...
in cytokinesis is to phosphorylate the RLC. Phospho-mimic RLC is fully functional in these cells demonstrating that while the presence of phosphorylated RLC is essential for cytokinesis, the ability to regulate the phosphorylation state spatio-temporally is not. In addition, we demonstrate that the essential role of Citron kinase is not phosphorylation of the RLC despite its ability to do so in vitro.

The Evi5 Oncogene Binder Bab1 in a GTP-Dependent Manner, and Cooperates with Bab1 in Regulation of Cytokinesis

C. J. Westlake,1 J. R. Junutula,2 R. Prekeris,2 M. Pilli,1 R. H. Scheller,1 P. K. Jackson,2 A. G. Eldridge1; 1Genentech, South San Francisco, CA, 2Cellular and Developmental Biology, University of Colorado Health Sciences Center, Denver, CO

The Evi5 oncogene has recently been shown to serve as a stabilizing factor for Emi1, an inhibitor of the Anaphase-Promoting Complex/Cyclosome (APC/C) that controls cell cycle progression in mitosis and G1. Evi5 stabilizes Emi1 by binding Emi1 and preventing its phosphorylation by the Polo-like kinase Plk and its association with the SCFβTrCP ubiquitin ligase. Sequence analysis of Evi5 revealed a TBC domain, which has been shown to act as a GTPase-activating protein (GAP) domain for the Rab family of small Ras-like GTPases. Here we describe the identification of Bab1 as a candidate target of Evi5. Like other Rab GTPases, Bab1 has been shown to regulate intracellular transport and vesicle trafficking. In addition to mediating endosome recycling, Bab1 has also been shown to be required for the completion of cytokinesis. By immunoprecipitation and Bisacore analysis, we demonstrate that Evi5 binds to Bab1 in a GTP-dependent manner. Evi5 co-localizes with both Bab1a and Bab1b, but not Bab1, in vivo. Furthermore the Bab1b effector protein FIP3 was found to modulate Evi5 localization at the centrosome.

Interestingly, in vitro binding studies suggest that Bab1 effector proteins compete with Evi5 for binding to Bab1. Consequently we have investigated the potential for Evi5 to act as a Bab1 GAP. Finally, ablation of Evi5 through RNA interference causes a multimuculate phenotype, indicative of cytokinesis failure, similar to that previously seen following perturbation of Bab1 and FIP3 function. These data argue that Evi5 cooperates with Bab1 in the regulation of critical aspects of cytokinesis.

A Novel RhGAP Functions in the Regulation of Cytokinesis

A. V. Poth, A. Gromley, X. Pan, D. Lambright, S. Dessey; Molecular Medicine, University of Massachusetts Medical School, Worcester, MA

Cytokinesis is the final step in the cell cycle when two daughter cells are physically separated in a process known as abscission. We have previously identified centrinol as a protein necessary for the completion of cytokinesis. Centrinol localizes to the maternal centriole and to the midbody ring of telophase cells. Depletion of centrinol results in cytokinesis defects, most notably persistent intracellular bridges that remain between daughter cells. In an effort to determine how centrinol functions in cytokinesis, we performed a yeast two-hybrid screen using a centrinol domain homologous the S. cerevisiae protein, nud1. We identified, cloned, and sequenced a previously uncharacterized cDNA encoding an ~150kDa protein with homology to RhoGTPase activating proteins (GAPs). In an effort to identify the GTPase target of the GAP, we performed GAP assays which show specific activity of the GAP toward the RhoGTPase family (RhoA, cdc42 and Rac1) with the highest activity toward Rac1. This activity can be inhibited by expression of an arginine finger mutation in the GAP domain. To verify the interaction of centrinol and the GAP, we have performed coimmunoprecipitation assays demonstrating an interaction between endogenous centrinol and the GAP. Centrosomal localization of the GAP throughout the cell cycle suggests a role in cytokinesis both by antagonistic protein and transient overexpression of epitope-tagged protein. Functionally, we found that overexpression of the GAP results in an increased population of telophase cells. We are currently working to identify the mechanism of action of the GAP during cytokinesis.

GTPase Flux Maintains a Tightly Focused Zone of Rho Activity During Cytokinesis

A. L. Miller, W. M. Beam; Zoology, University of Wisconsin-Madison, Madison, WI

Microtubules of the mitotic spindle provide a signal that specifies the position where the actomyosin-based contractile ring should form during cytokinesis. The nature of this signal from microtubules remains mysterious, although emerging evidence implicates the small GTPase RhoA. We recently showed that a precisely-bounded, microtubule-dependent zone of high RhoA activity forms during cytokinesis in echinoderm and Xenopus embryos. Moreover, work from other labs has shown that Ect2 (a RacA GEF also known as LET-21 or Pbl), MgcRacGAP (a RacA GAP also known as CYK-4, RacGAP50c, or Tumbleweed), and MKLP (a kinesin also known as ZEN-4, Pavarotti, or CHO1) are localized at the furrow and are important regulators of cytokinesis. Taken together, these results suggest that microtubules may specify the position of the contractile ring by precisely localizing regulators of RhoA activity, which then direct formation of a localized RhoA activity zone. Therefore, we are currently examining the roles of the RhoA regulators Ect2 and MgcRacGAP in modulating the RhoA activity zone during cytokinesis in Xenopus embryos. Importantly, both Ect2 and MgcRacGAP are necessary for cytokinetic RhoA activity zone formation and maintenance. Specifically, disruption of MgcRacGAP’s GAP activity leads to RhoA activity zones with increased intensity and breadth compared to controls. Additionally, disruption of MgcRacGAP’s GAP activity promotes the accumulation of a downstream target of RhoA, myosin-2, at the furrow. We propose that Ect2 locally activates RhoA, while MgcRacGAP locally inactivates RhoA, resulting in the constant flux of RhoA through the GTPase cycle. In this way, cells can maintain a tightly focused zone of RhoA activity to drive furrow formation and contraction.

Intermolecular Interactions of B. subtilis MreB

J. A. Mayer,1 G. J. Bean,2 K. J. Amann1; 1Cell and Molecular Biology, UW-Madison, Madison, WI, 2Molecular Biology, UW-Madison, Madison, WI

The bacterial actin homolog MreB has been implicated in the regulation of cell shape changes including the establishment of cell polarity and the condensation and segregation of chromosomes. We hypothesize that MreB carries out these roles both through its own direct action and through interactions with other bacterial proteins; however few such molecular interactions have been confirmed biochemically. We have overexpressed in E. coli and purified Bacillus subtilis MreB. We have studied polymerization dynamics using light scattering and sedimentation assays showing significant pH-,ionic-,cationic-, and temperature-dependences. At present, we are using this purified MreB to identify interacting molecules that may mediate the proposed cellular roles for MreB. We have purified putative binding partners and are testing them for direct interactions with MreB polymers and monomers using light scattering, sedimentation and fluorometric assays. We will quantitatively determine the nature of interaction of each ligand with MreB, particularly any influence on the polymerization dynamics, nucleotide use or polymer structure. As the details of these interactions are revealed, they will form a more complete picture of the cellular functions of the bacterial actin homolog MreB and its similarities and differences to eukaryotic actin.

Interaction of Actin with Translation Factors and the Role of Actin in Translation Fidelity

P. L. Cathcart, K. A. Kandl; Biology, St. Olaf College, Northfield, MN

Previous work demonstrated that actin plays a role in translation fidelity, as yeast strains with a subset of actin mutations (for example, act1-122) show read through of nonsense codons and sensitivity to paromomycin, an inhibitor of translation elongation (Kandl et al., 2002. Mol Genet Genomics 268: 10-18). We are testing the hypothesis that the fidelity defects seen in yeast with actin mutations are caused by altered physical or functional interactions between actin and translation factors known to affect translation fidelity. A likely candidate is the elongation factor eEF1A. eEF1A delivers aminoacyl-tRNAs to the ribosome, ensuring the incorporation of the correct amino acid into the elongating polypeptide, and eEF1A has been shown to bind and bundle actin in vitro. A cosedimentation assay, in which actin bound by eEF1A pellets after low speed centrifugation, showed that the mutant actin purified from yeast expressing actin alleles with act1-122 severe in the assay with eEF1A and eEF1B, the mutant actin remained banded by eEF1A, suggesting that the act1-122 mutant actin has a higher affinity for eEF1A than the wild type actin does. This result could explain the translation fidelity defects seen in act1-122 yeast, and experiments will be done to study this. This result also suggests that the strongest interaction between actin and eEF1A is not necessarily optimal, and this may have implications for understanding actin cytoskeleton dynamics.
Nucleotide-mediated Conformational Changes of Monomeric Actin

X. Zheng, D. Sept; Department of Biomedical Engineering and Center for Computational Biology, Washington University in St. Louis, St. Louis, MO

The nucleotide state of actin is an important regulator within the cell since it not only affects the polymerization of actin, but also the interaction of actin monomers and filaments with other proteins. Recent crystal structures of actin indeed show some structural differences between the two forms, but in order to gain some idea of the dynamical differences between the two nucleotide states, we performed long molecular dynamics (MD) simulations. Our MD simulations reveal many significant secondary structure changes in the DNase binding loop in subdomain 2. Comparisons between the two simulations as well as implications for potential differences in actin filaments will be presented. The effect of the cation (Mg versus Ca) in the nucleotide binding cleft will also be discussed.

Active Micro rheology of Actin with Laser Tweezers

Nucleotide-mediated Conformational Changes of Monomeric Actin

P. Dalhaimer, B. Nolen, T. Pollard; Yale University, New Haven, CT

The conformation of monomeric actin depends on the bound nucleotide: ATP, ADP-P, or ADP. Most crystal structures of actin with bound ATP have the central cleft closed around the bound nucleotide and a disordered DNase-binding (DB) loop. A crystal structure of rhodamine actin with bound ADP also has a closed cleft but an n-helical DB loop. We used molecular dynamics simulations to study the conformations of monomeric actin with bound ATP or ADP without nucleotide (apo-actin) in solution with Ca2+. Assuming equilibrium formalisms, the fraction of time each complex is in an open versus closed conformation for ATP, ADP, and apo is 10^{-6}, 0.1, and 29Δapo ~ kBT. Assuming equilibrium formalisms, the fraction of time each complex is in an open versus closed conformation for ATP, ADP, and apo is 10^{-6}, 0.1, and 29Δapo ~ kBT.

Active Micro rheology of Actin with Laser Tweezers

A. Pomerance, E. Rericha, W. Losert; Institute for Research in Electronics and Applied Physics, University of Maryland, College Park, MD

A living cell’s actin network is capable of exerting and responding to forces of several pN. In order to understand and model cell processes which that exert forces, such as in a crawling cell, it is necessary to characterize the mechanical response of the cytoskeleton under load. We use laser tweezers to locally apply forces of tens of pN to beads embedded in a purified, in vitro actin network. We show that for imposed strains below 4 microns, the beads recoil to their equilibrium position, suggesting that the actin network is undamaged by the strain. When beads are pulled beyond 4 microns, however, the beads do not recoil to their initial positions. We find the strain threshold is independent of pulling speed. The characteristic recoil time of strained beads, however, is a function of the strain rate and the total strain and obeys a power law in the total strain time with an exponent ~ 2/5. Finally, pulling a bead less than the threshold and holding it at beyond 4 microns, however, the beads do not recoil to their initial positions. We find the strain threshold is independent of pulling speed. The characteristic recoil time of strained beads, however, is a function of the strain rate and the total strain and obeys a power law in the total strain time with an exponent ~ 2/5. Finally, pulling a bead less than the threshold and holding it at its destination changes the recoil dynamics. During the holding time, the network relaxes and the force required to hold the bead in place lessens. For waiting times greater than 50s, the network fully relaxes and the bead no longer recoils. The strain relaxation in the long wait time experiments is explained by diffusion of filaments, however this is not sufficient to explain the observed strain threshold for larger strains and another mechanism of remodeling the actin network may be at work.

Residue Size at Position 204 of the Pointed-End in Actin Controls Polymerization

S. Yates, J. Dawson; Molecular and Cellular Biology, University of Guelph, Guelph, ON, Canada

Previous work has shown that the double mutant, A204C/C374A (AC), in yeast actin lacks the ability to polymerize in vitro. To understand the importance of the 204 position, a series of actins with a single mutation at this position, with Cys-374 retained, were created. The attempted substitutions were Gly, Ser, Cys, Asp, Ile, Lys, Phe and Trp. Plasmid shuffling was used to introduce the mutant actin containing plasmids into yeast. No viable yeast were obtained containing the Asp, Ile, Lys, Phe and Trp substitutions, suggesting that these mutations are lethal. The viable strains were those expressing A204G, A204S or A204C-actin. The A204G and A204S strains were slightly sensitive to cold-temperature and hypersensitivity, while the A204C strain, like AC-actin, shows much larger effects on its growth under these conditions. Fluorescence microscopy of yeast stained with DAPI, Calcofluor or rhodamine-phalloloid revealed only slight differences between wild-type and the A204G- and A204S-AC1 expressing cells. Cells expressing A204C-AC1 showed the anomalies as were previously observed for AC-actin, including abnormal actin structures. The similarity of the A204C and AC-actin strains illustrates that the mutation at position 204 alone is responsible for polymerization-deficient actin. Light scattering was used to monitor polymerization of these actins in vitro. A204G and A204S have increased critical concentrations of 12 and 13-fold, respectively, relative to wild-type. An investigation into the lag phase showed that A204G and A204S, like wild-type, nucleates through a trimmer. All the mutations, viable or lethal, were modeled into the Holmes model of F-actin and energy
minimization was performed. A correlation between size of the residue and stability of the modeled filament was observed. Non-viable strains contained actin with larger, bulkier 204 residues that would severely impair filament formation, whereas smaller substitutions at 204 could still be accommodated within the actin polymer interface.

Actin Isoform Specific Conformational Differences Observed with H/D Exchange and Mass Spectrometry
E. Stokasimov, P. A. Rubenstein; Biochemistry, University of Iowa, Iowa City, IA

Yeast actin appears to be biochemically more conformationally dynamic than muscle actin. The difference could arise from a predisposition of muscle actin for a more closed state than yeast actin. We used amide proton hydrogen/deuterium exchange detected by mass spectrometry to analyze conformational differences between yeast and muscle actins. After short labeling times, G-actin subdomain 3 and 4 peptides have 20-40% of their amides protons exchanged for yeast and 0-20% for muscle actin. After 3 hours of labeling, the peptides with the most extensive exchange in both yeast and muscle G-actin (40-60%) are in subdomain 4, the area around the DNase I loop in subdomain 2, the linker region between subdomains 1 and 3, and near the C-terminus. However, muscle actin shows less uptake (0-20% vs. 20-40% for yeast) in an outer helix between subdomains 1 and 2, and two helices in subdomain 4, one of which is in the nucleotide binding cleft. These results indicate that yeast G-actin is conformationally more flexible than muscle. Yeast F-actin incorporates about 20 deuteriums less per monomer than G-actin, observed throughout the molecule for short labeling times. After 3 hours of labeling, peptides in subdomain 3, around the DNase I loop, and towards the C-terminus show 11-27% less exchange compared to G-actin. Similar results are observed for muscle actin. For F-actins after 6 minutes, regions in subdomain 4 and between subdomains 1 and 2 exchange more slowly in yeast than muscle actin. At 3 hours labeling there are no differences in exchange between yeast and muscle F-actins except for a helix and a peptide in subdomain 1 (residues 94-125). In this helix-loop region the helix exchanges more in yeast and the loop more in muscle actin. This technique allows regional assessment of actin behavior in response to imposed forces on the protein.

Polycation Induced Actin Polymerization
A. Muhlrad, D. Pavlović, E. Reisser; Institute of Dental Sciences, Hebrew University, Jerusalem, Israel, Dept. of Chemistry and Biochemistry and the Molecular Biology Institute, University of California, Los Angeles, CA

Polycations, including basic proteins as myelin basic protein, polymerize very efficiently actin. This polymerization was proposed to be initiated by formation of antiparallel actin dimers that nucleate filament assembly (Bubb et al., 2002. J. Biol. Chem. 277:20999). We studied the factors affecting polycation induced actin polymerization by using pyrene labeled G-actin and polycation as a polycation model. As shown by excimer formation, antiparallel dimers are formed at the onset of polycation polymerization, but not upon polymerization of actin by Mg. At low ionic strength the polymerization of actin by polycation is very fast, but becomes slower as the ionic strength increases. 100 mM KCl completely abolishes the acceleration of polymerization by polycation. Inorganic phosphate, independently of the ionic strength, significantly inhibits actin polymerization in the presence of polycation. Divalent cations, Mg or Ca, are necessary for efficient polycation induced polymerization, which is optimal in the presence of 0.2 mM Mg or 2 mM Ca. The speed of polymerization depends also on the actin-bound cation and nucleotide and it decreases in the order MgATP > CaATP > NaATP and NaADP. This reduces the critical concentration for actin polymerization by increasing the rate of association and decreasing the rate of dissociation of monomers from the actin filament. The polymerization by polycation is accompanied by bundling of actin filaments even at very low actin concentrations. These results indicate that polycations may significantly affect the dynamics of actin in the cell.

Biological Thermal Phase Separation in Living Cells
C. Cheng, P. Leduc; Carnegie Mellon University, Pittsburgh, PA

The cytoskeleton in living cells is critical as it strongly influences many cellular functions such as motility, organelle transport, mechanotransduction and mitosis. This structural network is also known to respond to a variety of factors including chemical, mechanical, and scaffolding environments. In our studies, we are interested in the effects of localized cytoskeleton organization, with a particular focus on the actin filaments and their response to the thermal environment as heat shock responses have been shown to be critical in cell behaviors such as the apoptosis. We found that this mode of stimulation produces distinct reversible phases as the cytoskeleton will reorganize its network under defined reproducible thermal conditions. We first globally controlled the thermal environment of NIH 3T3 fibroblasts and after applying an increase in temperature of 5 °C, we observed a change in the actin filament network as these single molecular polymers depolymerized. When we reversed the process and lowered the temperature back to 37 °C, the actin repolymerized indicating a reversible phase that is controlled by the thermal environment. However, when examining this stimulation with respect to microtubules and intermediate filaments, little or no alterations in these structures were found. We also characterized the presence of F-actin and G-actin for these phases through analyzing the associated intensities in immunofluorescence studies. We also probed localized thermally-induced response within living cells through creating a thermal gradient. These studies suggest that cells not only have distinct phases or patterns, but also maintain a reversible equilibrium with respect to the thermal environment. These results have implications in a variety of fields such as cellular organization, biopolymer dynamics, and biothermal environments.

In Vitro Reconstitution of DNA Segregation: The Modulation of ParM Dynamic Instability Drives Plasmid Segregation
E. Garner, C. Campbell, D. Mullins; Biochemistry, UCSC, San Francisco, CA

The R1 par operon constructs a minimal DNA-segregating spindle from three components, the centromeric DNA sequence parC, the DNA binding protein ParR, and the actin homolog ParM. In vitro, ParM filaments exhibit rapid spontaneous nucleation, symmetrical elongation, and dynamic instability. In vivo, the ParC complex is thought to couple ParM polymerization to plasmid segregation. To determine how these three components combine to form a bipolar spindle we reconstituted this system in vitro from purified components. We combined parC conjugated beads with ParR and fluorescently labeled ParM. Isolated parC-coated beads short, dynamic, and radial symmetrical asters of ParM. The size of these asters is determined the difference in kinetic polarity between the stabilized, ParR/C bound filaments and the unbound dynamically unstable filaments in solution provides the monomer differential that drives bead segregation. The direct attachment of ParR/C to the ParM filament occurs between pairs of parC-coated beads, suggesting that both filament ends are bound and stabilized by the ParR/C complex. We directly observe this bipolar attachment by electron microscopy.

Cytosplasmic γ-Actin Null Mice Are Viable but Deaf
K. J. Sonnemann, K. W. Prins, S. Ikeda, A. Ikeda, J. M. Ervasti; 1Department of Physiology, University of Wisconsin, Madison, WI, 2Department of Medical Genetics, University of Wisconsin, Madison, WI

The six mammalian actin isoforms comprise a family of highly conserved cytoskeletal proteins that play fundamental roles in all aspects of cell biology. The "non-muscle" β,- and γ-cyto-actin isoforms are abundantly expressed and sorted to distinct locations within a variety of polarized cell types despite differing at only 4 out of 375 amino acids. A ubiquitous expression pattern, the conservation of actin sequences across species, and the inherent importance of the actin cytoskeleton have led to the theory that both β-cyt- and γ-cyt-actin are essential for cell viability. In contrast to mouse models which identified β-cyt-actin as an essential gene (Shawlot et al., Transgenic Res., 1998; Schmerling et al., Genesis, 2005), we show here that a substantial fraction of γ-cyt-actin null mice (Actγ1-/-) were viable, fertile, and survived beyond 1 year of age. Consistent with skeletal muscle-specific ablation of β-cyt-actin (Sonnemann et al., Dev Cell, In Press), Actγ1-/- mice exhibited an overt skeletal myopathy characterized by hind limb contractures and progressive cell necrosis and regression. Actγ1-/- mice also presented with age- and frequency-dependent hearing loss, closely mimicking a form of human deafness caused by mutations in γ-cyt-actin. The progressive phenotype observed both in muscle and the inner ear implies that γ-cyt-actin is essential for the long-term maintenance, but not establishment, of polarized cell types in vivo. Surprisingly, we found a compensatory upregulation of muscle actins in several Actγ1-/- tissues, which novelty suggests that muscle and non-muscle actins may be partially redundant in vivo. These results challenge the idea that both β-cyt- and γ-cyt-actin are essential for the development of polarized cell types and suggest more functional overlap between muscle and non-muscle actins than previously thought. Actγ1-/- mice thus provide a valuable tool to investigate how actin isoforms regulate the cytoskeleton and how actin mutations lead to human disease.
Abil Gene Silencing by Short Hairpin RNA Impairs Bcr-Abl-induced Cell Adhesion In Vitro and Leukemogenesis In Vivo

W. Yu, N. Clough, X. Sun, Z. Dai; Department of Medicine, University of Colorado Health Sciences Center, Aurora, CO

Actin polymerization, a core process in cytoskeletal mechanics, is closely associated with cell shape, adhesion, and migration. This dynamic cellular process is spatially and temporally regulated in normal cells. Its dysregulation, however, is often associated with cellular transformation and tumorigenesis. The mechanism by which tumor cell overrides normal control of actin polymerization is not fully understood. In this study, we explored the role of Abi1 in actin polymerization, in Bcr-Abl-induced abnormal actin polymerization, cell adhesion, and leukemogenesis. We introduced Abil short hairpin RNA (shRNA) into Bcr-Abl-transformed Ba/F3 cells and monitored leukemia development in NOD/SCID mice which received these cells. The expression of Abi1 shRNA resulted in a stable reduction of Abi1 protein to undetectable level, as analyzed by Western blot. Abil gene silencing by shRNA does not affect Bcr-Abl-stimulated cell proliferation and IL-3 independent growth. However, it attenuates the Bcr-Abl-induced abnormal actin remodeling and cell adhesion to fibronectin. The mice injected with Bcr-Abl-transformed cells developed leukemia with an average of 15.7 +/-2.1 day survival time, whereas the mice injected with Bcr-Abl-transformed cells expressing Abil shRNA survived longer with an average of 25.9+/2.3 day survival time. In contrast to Bcr-Abl-transformed cells, which induced splenomegaly when injected into NOD/SCID mice, Bcr-Abl-transformed cells expressing Abil shRNA failed to induce splenomegaly. Thus, these data provide direct evidence that Abil pathway contributes to the pathogenesis of Bcr-Abl-induced leukemia.

166 Fibroblasts in Wound Healing: Transformation, Motility, and Proliferation Differences in Syndecan-1-deficient Mice

R. A. Jurjus, S. Pal-Ghosh, Y. Liu, G. Tadvalkar, A. Sekaran, M. Stepp; Anatomy and Cell Biology, George Washington University, Washington, DC

Activated fibroblasts have several important functions in wound healing and express α smooth muscle actin (αSMA). Syndecans are transmembrane proteoglycans that play a major role in cell adhesion. Syndecan-1 (sdc-1) is upregulated in epithelial cells in response to injury and sdc-1 deficient mice show delayed corneal and skin wound healing. In this study we determine whether loss of sdc-1 on primary dermal fibroblasts altered the proliferation, motility, and proliferation of fibroblasts to myofibroblasts. Primary sdc-1 null (-/-) and wild type (+/+) fibroblast cultures were monitored to day 8 for nSMA expression, motility, migration, and proliferation by calculating the mitotic index (MI). Results show that +/- fibroblasts begin to convert to the myofibroblasts (αSMA+/-ve) at day 1 while +/- fibroblasts take longer. In time lapse migration studies, the velocity of +/- fibroblasts was significantly higher than that of the +/-/+ (p<0.0001) between 2 days and 3 identical between day 3 and 4. The MI of +/-/+ fibroblasts was higher at day 3 and decreased by day 5 when compared to +/-/- and +/-/+ fibroblasts were also treated with TGF-β at 10 ng/ml and monitored up to day 8 by analysis of nSMA expression, cell motility, and MI index. TGF-β accelerated fibroblast to myofibroblast conversion at earlier timepoints but the effect was more pronounced in +/- cells. The velocity of +/-fibroblasts after treatment with TGF-β at day 3-4 remained similar to +/-/. The MI decreased for both +/-/+ and +/- but with the increase remaining for +/-/+ cells. In conclusion, the sdc-1/-/- fibroblasts migrated faster than +/-/+ and their MI was transiently increased compared to +/-/. When sdc-1/-/- fibroblasts were treated with TGFβ, both their migration rate and MI decreased and were similar to TGFβ treated +/-/+ cells.

A Functional Role for the Smooth Muscle Specific Isoform of Actin

N. D. Weymouth, D. C. Rockey; Internal Medicine, University of Texas Southwestern Medical Center, Dallas, TX

Smooth muscle α-actin is one of six highly conserved mammalian actin isoforms that appear to exhibit functional redundancy. Nonetheless, we have postulated a specific functional role for the smooth muscle α-actin specific isoform. Given smooth muscle α-actin’s implied role in myofibroblast contraction and the predominance of this isoform in myoepithelial cells, we hypothesized that smooth muscle α-actin is essential for myoepithelial cell function and tested this postulate by using a smooth muscle α-actin deficient mouse. Here, we show smooth muscle α-actin deficient mice have a novel mammary gland phenotype such that dams lacking smooth muscle α-actin are unable to nurse their offspring effectively and nursing pups die shortly after birth due to malnutrition. The phenotype was rescued in cross-fostering experiments with wild type mice, excluding a developmental defect in smooth muscle α-actin null pups. Null mammary glands exhibited ductal distension during lactation as well as reduced milk stasis, continued ductal dilation, and premature involution during lactation. Premature involution occurred in null mammary glands shortly after parturition within 4-6 days and was marked by a massive increase in the number of apoptotic cells as revealed by TUNEL analysis (at 6.5 days postpartum null (-/-) glands exhibited 12.3% versus wild type (+/+) glands which exhibited 0.95% TUNEL positive cells, p<0.001. The mechanism for the underlying lactation phenotype is due to an apparent developmental arrest in and an impaired contractility of myoepithelial cells in smooth muscle α-actin null mammary glands, despite normal expression of other actin species. Contraction in isolated myoepithelial cells from null mammary glands was severely compromised (53% reduction compared to +/-/+ cells, p<0.001, n=6) when measured on collagen lattices. These findings reveal an absolute requirement for smooth muscle α-actin in myoepithelial cell contraction, which appears to be necessary for lactation.

Three-dimensional Culture induces F-actin Dependent Cytoplasmic Extensions

M. L. Marquette, L. Vergara, D. Byerly, M. Sognier; 1Neuroscience and Cell Biology, University of Texas Medical Branch, Galveston, TX, 2NASA-Johnson Space Center, Houston, TX, 3Universities Space Research Association, Houston, TX

Identifying cellular and morphological changes of myoepithelial cells during differentiation in three-dimensional (3D) culture may provide novel insight into skeletal muscle morphogenesis. Our previous observations indicate that numerous cytoplasmic extensions (podula) are present on single cells in 3D culture conditions. Similar structures were described on cells during microgravity/modeled microgravity exposure. References to cytoplasmic extensions have also been reported in other culture conditions; i.e., when substrate adhesion is prevented in anchorage-dependent cells. The purpose of these studies was to determine if 3D culture increased podula formation in single cells. C2C12 cells, a murine myoblast cell line, were grown in 3D conditions using Synthecon’s Rotary Cell Culture System (RCCS) for 3, 6, 9 hours, fixed, and stained. Cells cultured in Petri dishes, precoated to prevent cell adhesion, served as controls. Immunofluorescent staining and confocal microscopy analysis revealed that the podula of cells cultured in the RCCS were significantly more numerous than those in suspension control (p<0.05, n=15). In rat myoepithelial cells, RCCS culture resulted in an absolute increase in podula formation compared to 2D control (p<0.05, n=15). In conclusion, this study reveals an absolute requirement for smooth muscle α-actin in myoepithelial cell contraction, which appears to be necessary for lactation.

S100B Protein Regulates the Rho/ROCK Axis and Akt via P33-K in Giblollastoma Cells: Implications for Astrocyte Activation and Tumor Growth

F. Brozzi, C. Arcuri, R. Donato; Department of Experimental Medicine & Biochemical Science, University of Perugia, Perugia, Italy

Contrary to the abundant information about the regulatory effects of the astrocyte, Ca2+-modulated protein of the EF-hand type, S100B, in neuroprotection and neurodegeneration once released by astrocytes, little is known about the functional role(s) of S100B within astrocytes in relation to their proliferation and participation in inflammation and/or tumor growth. In the normal brain tissue, S100B is an abundant protein that is expressed in astrocytes. In addition, S100B is expressed in a variety of normal and abnormal cells including neurons, glia, inflammatory cells, and tumors. In the current study, we examined the changes in S100B expression, motility, migration, and proliferation by calculating the mitotic index (MI). Results show that S100B deficient mice have a novel mammary gland phenotype such that dams lacking smooth muscle α-actin are unable to nurse their offspring effectively and nursing pups die shortly after birth due to malnutrition. The phenotype was rescued in cross-fostering experiments with wild type mice, excluding a developmental defect in smooth muscle α-actin null pups. Null mammary glands exhibited ductal distension during lactation as well as reduced milk stasis, continued ductal dilation, and premature involution during lactation. Premature involution occurred in null mammary glands shortly after parturition within 4-6 days and was marked by a massive increase in the number of apoptotic cells as revealed by TUNEL analysis (at 6.5 days postpartum null (-/-) glands exhibited 12.3% versus wild type (+/+) glands which exhibited 0.95% TUNEL positive cells, p<0.001). The mechanism for the underlying lactation phenotype is due to an apparent developmental arrest in and an impaired contractility of myoepithelial cells in smooth muscle α-actin null mammary glands, despite normal expression of other actin species. Contraction in isolated myoepithelial cells from null mammary glands was severely compromised (53% reduction compared to +/-/+ cells, p<0.001, n=6) when measured on collagen lattices. These findings reveal an absolute requirement for smooth muscle α-actin in myoepithelial cell contraction, which appears to be necessary for lactation.
Myosin-Ic Binding to Hair-Cell Stereotipic Tips Is Mediated by a Calmodulin-Free Second IQ Domain and Does Not Occur in Cadherin 23 Mutant Mice

K. R. Phillips, R. Goodyear, S. Tong, G. P. Richardson, J. L. Cry; Sensory Neuroscience Research Center, West Virginia University School of Medicine, Morgantown, WV, School of Life Sciences, University of Warwick, Falmer, Brighton, United Kingdom, Sensory Neuroscience Research Center and Departments of Otolaryngology and Biochem. and Mol. Pharmacology, West Virginia University School of Medicine, Morgantown, WV.

In hair cells, the sensory receptor cells of the inner ear, deflections of the hair bundle due to sound or head movements opens cation-selective transduction channels located at the tips of stereocilia, actin-filled processes that comprise the mechanosensitive hair bundle. In the prevailing model of transduction, hair-bundle deflection tenses fine interstereociliary extracellular linkages called tip links, which in turn opens transduction channels. During prolonged stimuli, transduction-current magnitude decreases within tens of microseconds in a process called adaptation. Adaptation is powered by myosin-Ic (MyoIC), which is located in stereocilia and is part of the transduction complex. We have developed an in situ binding assay to visualize the binding of recombiant MyoIC fragments to the tips of stereocilia, the site of hair-cell transduction. Using this assay in previous work, we have ascertained that the calmodulin-binding neck region of MyoIC is sufficient for binding to stereotipic tips. In our current work we have determined that the second IQ domain of MyoIC mediates this interaction and also mediates interactions with phosphatidylinositol 4,5-bisphosphate (PIP 2) in a nitrocellulose-based assay. Furthermore, we find that MyoIC binding to stereotipic tips is sensitive to calcium chelators and lanthamide ions, conditions that are known to break tip links, and does not occur in hair cells of mice lacking the protein cadherin 23, a proposed component of the tip link, although these cells do contain PIP 2.

Myosin-Ia Powers the Sliding of Apical Membrane along Microvillar Actin Bundles

R. E. McConnell, M. J. Tsuda; Cell and Developmental Biology, Vanderbilt University Medical Center, Nashville, TN

Myosin-Ia (MyoIA) is a plus-end directed, actin-based motor found in brush border (BB) microvilli. Within the microvillus, MyoIA forms a highly-ordered array of bridges that link the plasma membrane to the underlying actin core. MyoIA molecules in this array are uniformly oriented due to the polarized nature of the actin filaments in the supporting bundle. Based on this unique arrangement, we expect the microvillar population of MyoIA to exert substantial plus-end directed forces on the apical membrane. To test for the presence of these forces, we attempted to reactivate the mechanical activity of MyoIA in isolated BBs. When millimolar ATP alone was added to fluorescently labeled BBs, time-lapse spinning disk confocal microscopy revealed a rapid and robust loss of apical membrane from microvilli. Kymograph analysis of time-lapse data showed that membrane loss is the result of tip-directed (plus-end directed) translation; upon reaching microvillar tips, membrane is released or "shed" into solution in the form of small vesicles. Ultrastructural analysis demonstrated that ATP addition increases the length of exposed actin bundle at the base of microvilli and confirmed the striking vesiculation of membrane at microvillar tips. Membrane shedding is insensitive to blebbistatin, suggesting that this activity is independent of myosin-2, the most abundant myosin in the BB. The rate of membrane shedding does, however, scale with ATP concentration and is significantly inhibited by low levels of ADP, a predicted feature of MyoIA motor activity. Finally, BBs isolated from MyoIA KO mice exhibit significantly lower levels of membrane shedding compared to WT preparations. Taken together, these data indicate that: (1) ATP activates the plus-end directed translation of apical membrane along microvillar actin bundles, and (2) MyoIA powers this movement. We anticipate that the membrane translation and "shedding" described here may hold significant implications for MyoIA function in vivo.

Acanthamoeba Myosin IC Has Equal Affinity for Phosphatidyserine and Phosphatidylinositol Bisphosphate

K. Hwang, F. Mahmoudian, J. Gruschus, E. D. Korn, H. Brezsa; Laboratory of Biophysical Chemistry, NHLBI, NIH, Bethesda, MD, Laboratory of Cell Biology, NHLBI, NIH, Bethesda, MD

Acanthamoeba myosin IC (AMIC) binds to acidic lipids through the basic region of its motor (Bubb et al. Cell Motil. Cytoskelet. 39, 134-46, 1998). Recent work shows that mammalian myosin IC tail binds PIP 2 with high affinity and specificity. By NMR and homology modeling, we have investigated the affinity of AMIC for unilamellar phosphatidylcholine vesicles containing charge-equivalent amounts of PIP 2 or phosphatidylserine (PS). AMIC has a high affinity for PIP 2, K1/2=2.3 μM based on surface-accessible PIP 2, similar to the affinity of mammalian MIC for PIP 2. However, in contrast to mammalian MIC, the affinity of AMIC is equally high for PS, when corrected for its 5-fold difference in negative charge, i.e. K1/2=28 μM for vesicles containing 25% PS. Similarly, AMIC binds with equal affinity, K1/2=2-3 μM, to vesicles containing 5% PIP2-25% PS and vesicles containing 50% PS. The binding affinities are the same for constructs that contain only the basic region of the tail, confirming that the acidic lipid-binding site is in the basic region, and demonstrating that folding of the full-length tail, as shown by cryo-electron microscopy (Ishikawa et al. PNAS 101, 12189-94, 2004) and NMR, does not affect the affinity of AMIC for acidic lipids. The fact that AMIC has 10-fold higher affinity than phospholipid vesicles containing 5%PIP2+25%PS than for vesicles containing only 25%PS suggests that under physiological conditions AMIC might be targeted to regions of membranes enriched in PIP 2, which concentrates at the leading edge of migrating Acanthamoeba (Bubb et al. Cell Motil. Cytoskelet. 39, 134-46, 1998).

Myosin I Substrate Specificity of the Dictyostelium Pak Family

S. W. Crowley, Y. Yang, A. Bigg, G. P. Côté; Biochemistry, Queen's University, Kingston, ON, Canada

In vitro and in vivo studies indicate that activation of the motor activity of myosin requires a negative charge at the TEDS site in the motor domain. While all the myosin I isoforms from Dictyostelium (D. discoideum) contain a serine or threonine at this site and are therefore subject to regulation by phosphorylation. We have previously purified a p21-activated kinase, PakB, which is capable of phosphorylating and activating the Dictyostelium class I myosin MyoD. MyoD is also capable of being phosphorylated and activated by other members of the Pak family including the budding yeast Paks Ste20p and Cla4p and mammalian Pak3. Interestingly, however, the closely related class I myosin MyoB is not a substrate for either Dictyostelium PakB or mammalian Pak3. Dictyostelium possess two other characterized Pak isoforms, PakA and PakC. In order to define the substrate specificity of the Pak family we have expressed in Dictyostelium and purified, using actin and FLAG-tag affinity steps, five class I myosin head constructs (MyoA, B, C, D, and E) and tested them with the catalytic domains of Dictyostelium PakA, B and C expressed and purified from E. coli. In conjunction with this, we have performed studies to investigate which myosin I isoformes directly interact with PakB. In pull down assays, a GST-fusion of the SH3 domain of MyoB, but not MyoC or MyoD, was shown to bind to an N-terminal fragment of PakB containing residues 1-120. This may indicate that, although MyoB is not a substrate for PakB, it may function to localize the kinase to the leading edge of chemotaxing cells.

Myosin Binds PIP2 through a PH Domain

D. E. Hokanson, J. M. Laakso, T. Lin, E. M. Ostap; Physiology, University of Pennsylvania School of Medicine, Philadelphia, PA

MyoIC is a member of the myosin superfamily that binds PIP2, links the dynamic actin cytoskeleton to the membrane, and plays roles in mechanosignal transduction and membrane trafficking. We located and characterized two distinct membrane binding sites within the regulatory and tail domains of this myosin. We found that the tail domain binds tightly and specifically to PIP2, in a non-cooperative manner. It binds with slightly higher affinity to Ins(1,4,5)P3 as well as other inositol phosphates which may act as inhibitors to membrane binding in the cell. By sequence and secondary structure analysis, we identified this phosphoinositide binding site in the tail to be a putative pleckstrin homology (PH) domain. Point mutations of residues known to sequence and secondary structure analysis, we identified this phosphoinositide binding site in the tail to be a putative pleckstrin homology (PH) domain. Point mutations of residues known to be essential for phosphoinositide binding in previously characterized PH domains inhibit myoIC binding to PIP2 in vitro and eradicate correct localization and membrane binding in vivo. The extended sequence of this binding site is conserved within many other myosin-Is across species, suggesting they too contain a putative PH domain. We also characterized a previously identified membrane binding site within the IQ motifs in the regulatory domain. This region is not phosphoinositide specific, but binds anionic phospholipids in a calcium dependent manner; nevertheless, this site is not essential for in vivo membrane binding. As a result, we have determined that myoIC contains two lipid binding sites, a polybasic region that binds to high levels of PS in a calcium dependent manner, and a putative PH domain that binds tightly and specifically to phosphoinositols.

Calmodulin Binding to the MyoIC Regulatory Domain

S. D. Mancheva, T. Lin, H. Pham, Y. E. Goldman, E. M. Ostap; Physiology, University of Pennsylvania School of Medicine, Philadelphia, PA
Myo1c is an unconventional short-tailed myosin-I involved in cell signaling and membrane dynamics. Calcium binding to calmodulin (CaM) bound to the myo1c regulatory domain affects myo1c motor properties. However, the effect of calcium on myo1c kinetics, mechanics, and function are not fully understood. In order to characterize the effect of calcium and CaM on the regulation of myo1c, we must first understand the biochemical parameters that define the CaM-regulatory-domain interaction. We have performed fluorescence spectroscopy and stopped-flow kinetics to measure the binding and stoichiometry of CaM to the three IQ motifs in the myo1c regulatory domain. We measured the binding of a fluorescently labeled CaM mutant (N111C) to recombinant myo1c and peptides containing the three IQ motifs. In the absence of calcium, the CaM bound to the IQ motif adjacent to the motor domain (IQ1) has the slowest dissociation rate, and the IQ motif adjacent to the tail domain (IQ3) has the fastest dissociation rate. In the presence of saturating concentrations of calcium, IQ1 has the fastest rate of dissociation. Calcium accelerates the actomyosin ATPase rate, but this increase is suppressed by the addition of > 1 μM calmodulin. As shown previously, calcium inhibits actin gliding in the in vitro motility assay, but is rescued by addition of 1 μM calmodulin. Our data suggest that the CaM bound to the IQ motif adjacent to the motor domain is rapidly exchangeable in the presence of calcium and is responsible for regulation of myo1c ATPase and motility activity.

176
Biochemical and Structural Characterization of Calcium Regulation of Myo1b
Myo1b is an unconventional myosin which has a proposed role of mediating membrane tension. Being located close to the cell membrane subjects myo1b to rapid and drastic changes in calcium concentration. Since the lever arm of myo1b binds the light chain calmodulin, calcium could be a potent regulator of myo1b activity. This supposition was borne out when the steady-state ATPase rate was found to be calcium dependent, increasing with increasing calcium concentration. Moreover, it was found that calcium abrogates actin motility in gliding assays using myo1b. In order to determine a mechanism for calcium regulation, the calcium dependence of key steps in the ATPase cycle of a myo1b with a truncated lever arm was explored at 37°C using a stopped-flow apparatus. In this study, it was found that while calcium had no effect on ADP release and only a minimal effect on ATP binding, the rate of phosphate release was increased nearly four-fold. For multiple myo1b motors acting in concert, introduction of calcium could create a considerable increase in the effective duty ratio. To determine if the calcium effect occurs on a physiologically relevant time scale, the rate of calcium binding to myo1b during phosphate release was determined. The basis of calcium regulation is likely a conformational change in each of the IQ motifs that is triggered by calcium binding.

Roles for Drosophila melanogaster Myo1B in Maintenance of Enterocyte Brush Border Structure and Resistance to Bacterial Pathogens
P. S. Hegaz1, V. Merrell, M. S. Mooseker2; MCD Biology, Yale University, New Haven, CT, 2MCD Biology, Cell Biology, Pathology, Yale University, New Haven, CT
Drosophila myosin IB (Myo1B) is one of two class I myosins in the Drosophila genome. In the larval and adult midgut enterocyte, Myo1B is present within the microvilli (MV) of the apical brush border (BB) where it forms lateral tethers between the MV membrane and underlying actin core. Expression of GFP-Myo1B tail in the larval gut showed that the tail domain is sufficient for localization of Myo1b to the BB. A deletion mutation was created in the Myo1B gene in order to assess the role of Myo1b in the larval midgut. Basic gut physiology (food uptake and clearance, gut pH) appears normal. However, there is a 3 fold increase in the number of apoptotic cells in the Myo1B mutant midgut epithelium based on TUNEL staining of enterocyte nuclei. Ultrastructural analysis of mutant gut revealed many perturbations in the BB, including irregular MV length, MV vesiculation, and membrane tethering defects. Biochemical purification of BBs showed that the loss of Myo1b causes the BB to become destabilized as compared to heterozygous control guts. Ultrastructural analysis of purified mutant BBs shows the loss of cross bridges between the actin core and plasma membrane, which appears to cause the filaments of the central actin core of the MV to be less tightly bundled than in control BBs. Although Myo1B is not essential for the absorptive functions of the gut, it may play a critical role in gut barrier functions. Myo1B mutant larvae exhibit enhanced sensitivity to infection by the bacterial pathogen Pseudomonas entomophila. Survival of orally infected Myo1b mutant larvae is decreased by up to 50%, and severe cytoskeletal defects are observed in the BB of epithelial cells soon after infection. Resistance to P. entomophila infection is restored in Myo1b mutant larvae expressing a Myo1B transgene.

178
Myosin Surface Loop 4 Modulates Association of Myosin IB with Actin-Tropomyosin
A. M. Lieto-Trivedi, S. Dash, L. M. Coluccio; Boston Biomedical Research Institute, Watertown, MA
Structural studies of the class I myosin, Myo1, led to the predictions that loop 4, a surface loop near the actin-binding region that is longer in class I myosins than in other myosin subclasses, might limit binding of myosins I to actin when actin-binding proteins, like tropomyosin, are present; and might account for the exclusion of myosin I from stress fibers. To test these hypotheses, mutant myosins with the related mammalian class I myosin, Myo1b, in which loop 4 was truncated (from amino acid sequence RNMGLDEE to NGGLD) or replaced with the shorter and distinct loop 4 found in Dictyostelium myosin II (GAGEGA), were expressed in vitro and their interaction with actin and actin-tropomyosin was tested. Increasing amounts of expressed fibroblast tropomyosin-2 or tropomyosin-5a resulted in a decrease in the actin-activated Mg 2+-ATPase activity of wild-type Myo1b, but had little or no effect on the actin-activated Mg 2+-ATPase activity of the two mutants. In motility assays, few actin filaments bound tightly to Myo1b-coated cover slips when tropomyosin-2 was present; however, actin filaments bound and were translocated by Myo1b-NGLD or Myo1b-GAGEGA in both the presence and absence of tropomyosin-2. When expressed in mammalian cells, like wild type, the mutant myosins were largely excluded from tropomyosin-containing actin filaments indicating that in the cell additional factors besides loop 4 determine targeting of myosins I to specific subpopulations of actin filaments.

179
Analysis of Intracellular Functions and Binding Partners of Myosin IE
M. Krendel, M. S. Mooseker; Molecular, Cellular, and Developmental Biology, Yale University, New Haven, CT
Class I myosins are actin-dependent motor molecules expressed in various organisms from yeasts to humans. All class I myosins contain a head (motor) domain, a light chain-binding neck domain, and a tail, which can be either short, consisting only of a membrane-binding TH1 domain, or long, including an SH3 domain in addition to TH1. In mice and humans, there are eight myosin I (Myo1) heavy chain genes, which encode both short- and long-tailed myosins. Little is known about the intracellular functions of long-tailed myosins I in vertebrates and no binding partners for their SH3 domains have been identified to date. We characterized intracellular functions, localization, and binding partners of a human long-tailed myosin, myosin IE (Myo1E). Using dominant-negative constructs and RNAi, we observed that inhibition of Myo1E led to disruption of receptor-mediated endocytosis of transferrin. We also found that Myo1E interacted with two endocytic proteins, synaptojanin-1 and dynamin, via its SH3 domain. Using TIRF microscopy, we observed colocalization of myosin IE with clathrin-coated vesicles and dynamin, which required presence of both TH1 and SH3 domains in Myo1E tail. These findings suggest that Myo1E is involved in clathrin-dependent endocytosis and interacts with components of endocytic machinery via its tail domain.

Interaction of Chara Myosin with Actin
T. Sokkenari, Y. Ichikawa, K. Ito, K. Yamamoto; Biology, Chiba University, Chiba, Japan
Chara myosin is the fastest motor protein known so far. It can move actin filaments at the maximum velocity of 50 μm/sec in the in vitro motility assay. This velocity is about 10 times higher than that of the skeletal muscle myosin. Although such high velocity can mostly be explained by the kinetic parameters such as ADP release rate from AM-ADP complex or the rate of ATP induced AM dissociation, there are reports suggesting that the surface interaction between Chara myosin and actin is quite different from that between skeletal muscle myosin and actin. For example, muscle tropomyosin completely inhibited the interaction between Chara myosin and actin whereas it did not affect that between skeletal muscle myosin and actin. Such studies were done using crude Chara myosin. Since we recently succeeded in expressing fully functional recombinant Chara myosin2, we studied its interaction with actin by chemical cross-linking with water-soluble carbodiimide and also studied the effect of tropomyosin on its interaction with actin. It was found that (1) major cross-linked site of Chara myosin to actin was not loop 2 and (2) tropomyosin inhibited the motility of Chara myosin but it affected the actin-activated ATPase activity only partially. 1 Sugie Higashin-Fujime et al. Proc. Jpn. Acad. 76, 118–122 (2000). 2 Kohji Ito et al. Biochem. Biophys. Res. Commun. 312, 958–964 (2003).
Isomorphic Specific Functions of Nonmuscle Myosin II in MDA-MB 231 Breast Cancer Cell Adhesion

V. Betapudi, T. T. Egloff; Biology and Physiobiology, Case Western Reserve University, Cleveland, OH

Cell migration in Limulus is critical for the formation of lamellipodia, formation of focal complexes, translocation of cell body and posterior end detachment. Most of these steps are force and tension dependent and are widely believed to be driven by actin polymerization; however, the exact mechanical roles of nonmuscle myosin II during these events remain remarkably poorly understood. Earlier, we reported a significant enhancement and reduction of lamellipodial extension by myosin II and IIB isoforms-depleted MDA-MB 231 breast cancer cells, respectively by unknown mechanism. Here, we present our further studies to understand isomorphic specific functions of myosin II in the formation of focal complexes and focal adhesions during spreading. Our preliminary results show reduced attachment to fibronectin coated surface when cells are treated with myosin II inhibitors ML-7, Blebbistatin and Y-27632 or transfected with myosin IIA and HB sRNAs. Cells treated with ML-7 or transfected with myosin IIB sRNA form focal complexes/focal adhesions in cortical regions but not in the central region of the cells. However, there was a significant reduction in the formation of focal complexes/focal adhesions by cells experienced in the presence of Y-27632 or transfected with myosin IIA sRNA. Western blot analysis of cells depleted with myosin II isoforms reveals reduced phosphorylation of vinculin but no change in the expression of vinculin. However, paraxin expression decreases when myosin IIB is depleted in the cells. These results suggest that both the isoforms are critical for the mechanism of cell migration, with myosin IIA appearing to have roles in both the assembly process of focal complexes and focal adhesions whereas myosin IIIB may be contributing to the maturation of focal complexes into focal adhesions.

Kinetics of the Kinase and Motor Domains of Human Myosin IIIA

J. E. Moore, 1 S. Ananthanarayanan, 1 B. Burns2, A. C. Dose, 1 C. M. Yengo1; 1Biology, University of North Carolina at Charlotte, Charlotte, NC, 1Molecular and Cell Biology, University of California at Berkeley, Berkeley, CA

Myosin IIIA is specifically expressed in photoreceptors and coelchea and is important for the phototransduction and hearing processes. In addition, myosin IIIA contains a unique N-terminal kinase domain and C-terminal actin binding motif. We examined the kinetic properties of baculovirus expressed human myosin IIIA containing the kinase, motor, and two IQ domains. The rate of autophosphorylation by the kinase domain was found to be linearly dependent on ATP concentrations in the range of 0.1 to 1 mM, while manATP binding to the kinase domain was relatively fast. Thus, autophosphorylation activity may be limited by an ATP-dependent conformational change. The maximum actin-activated ATPase rate is relatively slow (VMAX = 0.77 ± 0.08 s⁻¹), and high actin concentrations are required to fully activate the ATPase rate (KATPase = 34 ± 11 µM). However, actin co-sedimentation assays suggest that myosin IIIA has a relatively high steady-state affinity for actin (Kact = 7 µM). The rate of ATP binding to the motor domain is quite slow both in the presence and absence of actin (KATPase = 0.020 and 0.001 µM⁻¹ s⁻¹, respectively). The rate of actin-activated phosphate release is more than 100-fold faster (85 s⁻¹) than the VMAX, while ADP release in the presence of actin follows a two-step mechanism (7.0 s⁻¹ and 0.6 s⁻¹). Thus, our data suggests a transition between two actomyosin ADP states is the rate limiting step in the actomyosin ATPase cycle. Our kinetic model indicates that both the actin attached hydrolysis and the Pi release steps determine the over-all cycle rate. While the stable steady state intermediates of acto-myosin IIIA ATPase reaction are not typical strong actin binding intermediates, the affinity of the stable intermediates for actin is much higher than conventional weak actin binding forms. The present results suggest that myosin IIIA can spend a major of its ATP hydrolysis cycling time on actin.

Myosin III Loop 2 Phosphorylation In Vivo: A Mass Spectrometric Study

H. L. Cardasis, K. E. Kempler, S. M. Stevens, B. A. Battelle; 1Proteomics Core, ICBR, University of Florida, Gainesville, FL, 2Chemistry, University of Florida, Gainesville, FL, 3The Whitney Laboratory of Marine Bioscience, University of Florida, St. Augustine, FL

Myosin III is a photoreceptor specific protein in Limulus. Phosphorylation of this protein by cyclic AMP dependent kinase (PKA) correlates with changes in photoreceptor structure and function. Our objective in this work was to verify the in vivo phosphorylation sites in Limulus Myosin III and to determine the effect of the circadian clock on levels of phosphorylation at each of these sites in vivo. Both lateral eyes from the each animal were used. The lateral optic nerve to one eye on each animal was cut to eliminate clock input, while the optic nerve to the control eye was kept intact. Eyes were extracted one week later at midnight (when circadian input is at a maximum) and under infrared illumination (to avoid the influence of light on the biochemistry of the eye). Eyes were homogenized in protease inhibitors, phosphatase inhibitors, and reducing agents, and Myosin III was purified by SDS-PAGE and digested in-gel with trypsin. Myosin III digests were analyzed by liquid chromatography - tandem mass spectrometry (LC-MS/MS) in conjunction with both differential labeling and label-free methods for relative quantitation. Three phosphorylation sites were verified in endogenous Limulus Myosin III preparations (S-796, S-841, S-846). Two of these sites are located within loop 2, the actin binding region of the protein (S-841 and S-846), while the third site (S-796) is located just upstream of loop 2. In response to circadian clock input, S-796 and S-846 demonstrate a significant 2-fold increase in their levels of phosphorylation. Both of these sites are putative substrates for PKA. S-841, a predicted substrate for protein kinase C (PKC), showed no change in levels of phosphorylation in response to clock input. Our findings support our hypothesis for an actomyosin interaction that is regulated at night by the circadian clock via loop 2 phosphorylation.

Myosin III Changes Distribution in Limulus Photoreceptors with Circadian Clock Input and Light

B. Battelle, N. Robinson; Whitney Laboratory, University of Florida, St. Augustine, FL

Limulus myosin III (LpMyoIII) is phosphorylated in photoreceptors in response to signals from a central circadian clock. Clock signals reach the eyes via a octopaminergic effector projection that is activated nightly by the central clock. OA activates a AMP cascade causing the PKA-phosphorylation of LpMyoIII at sites within and near loop 2, reducing the net charge in this region. In other myosins, actin affinity increases with the net positive charge of loop 2. Therefore clock input and other treatments that decrease the net positive charge of loop 2 via PKA phosphorylation of LpMyoIII may reduce its affinity for actin. Light appears to reverse the effect of PKA. Our findings support our hypothesis for an actomyosin interaction that is regulated at night by the circadian clock via loop 2 phosphorylation.

Functional Analysis of MYO7A in Human Fetal Primary RPE Cells: An Ex Vivo Model for Usher Syndrome 1B

D. Gibbs, T. Dieck; J. Khamodsre, C. Lillo, A. Klomp, J. Hsu, D. Bok, D. S. Williams; 1Pharmacology and Neurosciences, UCSD School of Medicine, La Jolla, CA, Jules Stein Eye Institute, UCLA, Los Angeles, CA

Mutations in the gene encoding MYO7A underlie Usher syndrome 1B. In the mouse retina, the majority of MYO7A is expressed in the apical region of RPE cells, associated with melanosomes. In homologous Zombie 46265B mutant mice, MYO7A protein levels are undetectable. In the absence of MYO7A, melanosomes in the RPE are mislocalized in vivo, and have been reported to fuse with melanin particles.
aberrant transport dynamics in primary culture. Abnormal localization and digestion of ingested phagosomes is also evident. To test if MYO7A functions similarly in the human retina we have determined the distribution of MYO7A in human retinas, and analyzed the expression and function of MYO7A in human primary fetal RPE cells (HRFPE). The distribution of MYO7A in human retina was comparable to mouse retina. HRFPE cells were also found to express MYO7A at a level comparable to mouse primary RPE cells, and with a similar pattern of distribution. Analysis of phagocytic ability identified HRFPE cells as active phagocytes of rod outer segments. Live cell imaging demonstrated that the melanosomes in HRFPE cells were moving, and exhibited the same constrained, rapid movements seen in primary mouse RPE. Using siRNA we have successfully knocked down MYO7A in a human RPE cell line (ARPE19). These siRNAs are being used to knockdown MYO7A in HRFPE primary cells. These results confirm that MYO7A expression is similar between human and mouse retinas. Cellular processes dependent on the function of MYO7A are also preserved in cultures of primary HRFPE cells. Primary cultures of HRFPE cells can represent a physiologically relevant model system of human origin for the study of RPE function and disease, and will be useful for testing therapies for Usher 1B. The comparable expression, distribution and function of MYO7A in HRFPE cells and primary mouse RPE cells validate the Shaker1 4626SB mouse as a model for Usher 1B.

**Functional Analysis of Dynactin Mutations Associated with Amyotrophic Lateral Sclerosis**

R. Dixit, M. Tokio, E. Holzbaur; Physiology, University of Pennsylvania, Philadelphia, PA

The molecular motor cytoplasmic dynein and its associated activator dynactin are critical components of normal axonal transport, and their functional disruption is linked to neurodegenerative disease. Dynactin facilitates dynein processivity and cargo recruitment, and may also regulate motor activity. The p150<sup>Glued</sup> subunit of dynactin binds to both microtubules and dynein. A G59S mutation in p150<sup>Glued</sup> results in decreased microtubule affinity and enhanced p150<sup>Glued</sup> aggregation and is associated with motor neuron disease in humans. Recently, additional p150<sup>Glued</sup> missense mutations (M571T, R785W, R1101K, and T1249I) were identified in amyotrophic lateral sclerosis patients; however, the functional consequences of these mutations are not understood. To test whether these p150<sup>Glued</sup> mutations lead to functional disruption of dynein-dynactin activity, we have used myc-tagged versions of mutant proteins to assay their in vivo and in vitro activities. Our results indicate that these mutations do not perturb microtubule binding of p150<sup>Glued</sup> when expressed in COS7 cells and in vitro microtubule binding assays. Likewise, when overexpressed in COS7 cells, both the wild-type and mutant p150<sup>Glued</sup> proteins disrupt normal Golgi distribution; indicating that the mutant forms of p150<sup>Glued</sup> retain the ability to poison the endogenous dynein-dynactin complex. Sucrose density gradient fractionation of COS7 cell lysates showed no difference in the level of incorporation of wild-type and mutant human p150<sup>Glued</sup> in COS7 cell dynactin-dynein complex. Additionally, none of these mutations results in aberrant p150<sup>Glued</sup> aggregation when expressed in COS7 or PC12 cells. The M571T and R785W mutations reside in the region of p150<sup>Glued</sup> known to interact with the dynein intermediate chain (DIC). However, DIC pulldown assays showed that none of the four mutations significantly decreased p150<sup>Glued</sup>-DIC binding affinity compared to wild-type controls. Our results suggest that these p150<sup>Glued</sup> mutations result in relatively subtle defects in dynactin function or that these mutations represent polymorphisms in the p150<sup>Glued</sup> sequence.

**Mechanism of Dynactin - Microtubule Interactions**

A. D. Stephens, T. L. Culver, S. A. Lex, S. J. King; School of Biological Sciences, University of Missouri-Kansas City, Kansas City, MO

Dynactin, a multi-subunit protein complex, links cytoplasmic dynein and other motors to cargo, and is involved in organizing radial microtubule arrays (Schroer, TA, 2004; Quintyne, NJ, 1999). The largest subunit of dynactin, p150<sup>Glued</sup>, binds the intermediate chain of cytoplasmic dynein and has an N-terminal microtubule-binding domain. To examine the role of microtubule binding by p150<sup>Glued</sup> in vivo, we replaced the wild-type p150<sup>Glued</sup> in cultured Drusenella S2 cells with mutant ΔN-p150, lacking amino acid residues 1-200. ΔN-p150 is unable to bind microtubules. Strikingly, while movement of both membranous organelles and mRNP complexes by cytoplasmic dynein and conventional kinesin is absolutely dependent on dynactin, the role in the dynamics of dynactin-dependent organelle transport. To further analyze the regulation of MT-binding and release of p150<sup>Glued</sup> dynactin function. Removal of the acidic tail of tubulin via subtilisin treatment lowers the relative number of binding events but does not prevent the CAP-Gly domain or the basic sequence.

**Microtubule Binding by p150<sup>Glued</sup> Is Not Required for Cargo Transport but Essential for Spindle Assembly**

H. Kim, 1 C. K. C. Rogers, 2 C. R. Berg, 1 P. R. Selvin, 1 S. L. Rogers, 1 V. I. Gelfand 1; 1Cell and Molecular Biology, Northwestern University, Chicago, IL, 2Biology, University of North Carolina, Chapel Hill, NC, 3Biophysics, University of Illinois, Urbana, IL

Microtubule (MT) tip-tracking is a controversial behavior thought to reflect the dynamic binding of proteins to MT plus-ends. Phosphorylation has been implicated as one mechanism of release and aggregation when expressed in COS7 or PC12 cells. The M571T and R785W mutations reside in the region of p150<sup>Glued</sup> known to interact with the dynein intermediate chain (DIC). However, DIC pulldown assays showed that none of the four mutations significantly decreased p150<sup>Glued</sup>-DIC binding affinity compared to wild-type controls. Our results suggest that these p150<sup>Glued</sup> mutations result in relatively subtle defects in dynactin function or that these mutations represent polymorphisms in the p150<sup>Glued</sup> sequence.

**Dynamic Binding of p150<sup>Glued</sup> to Microtubules Dictates the Function of Tip-Tracking**

M. Raycroft, P. S. Vaughan, K. T. Vaughan; Biological Sciences, University of Notre Dame, Notre Dame, IN

The N-terminus of dynactin p150 contains two microtubule-binding domains that exhibit different properties. The p150 CAP-Gly domain binds stably to microtubules and can inhibit dynein motility along microtubules. The p150 basic domain binds to microtubules but can exhibit one-dimensional diffusion along the microtubule. Additionally, the basic domain increases the processivity of the cytoplasmic dynein motor. Therefore, the p150 basic domain, but not the CAP-Gly domain, helps dynein to act as a second molecule processivity factor for cytoplasmic dynein. Here, we are investigating the mechanism by which these microtubule-binding domains interact with microtubules. In particular, we are examining the role of the acidic C-terminus of tubulin upon dynactin function. Removal of the acidic tail of tubulin via subtilisin treatment lowers the relative number of binding events but does not prevent the CAP-Gly domain or the basic domain from binding microtubules.

**mTOR Kinase Regulates Tip-Tracking Proteins and Cytoplasmic Dynein**

L. Casaletti, K. T. Vaughan; Biological Sciences, University of Notre Dame, Notre Dame, IN

The mammalian target of rapamycin (mTOR) modulates a large number of major cellular processes and has been identified recently as another potential kinase that regulates microtubule (MT) dynamics. mTOR modulates both microtubule plus-end specificity and dynein IC phosphorylation complexity, and the coordination of other tip-tracking proteins during tip-tracking. Our lab has proposed that lagging recruitment of MAP4 with CLIP-170, EB1, and p150<sup>Glued</sup> is the basis of MT plus-end specificity in overexpression experiments. To test the “lagging recruitment” model we co-transfected MAP4 with CLIP-170, EB1, and p150<sup>Glued</sup>. MAP4 decorated the MT lattice but displayed differential binding at MT plus-ends; compared to p150<sup>Glued</sup> MAP4 lagged during recruitment and was slower to label plus-ends during elongation. This supports the possibility that delayed recruitment of dynactin kinases plays an important role in the dynamics of dynactin-dependent organelle transport. To further analyze the regulation of MT-binding and release of p150<sup>Glued</sup>, we engineered a G59S mutation linked to late-onset motor neuron disease into p150<sup>Glued</sup> and assessed the impact on dynein-driven transport. As an initial assessment, the G59S mutant failed to bind MTs in tip-tracking assays consistent with previous work. The G59R mutation also failed to rescue normal transport after siRNA-driven depletion of normal p150<sup>Glued</sup>, suggesting that MT binding is critical to dynactin function. Imaging of p150<sup>Glued</sup>, EB1 and CLIP-170 in fixed cells has suggested that all three colocalize on MT plus-ends. Because only a subset of these proteins is preserved after fixation, we co-expressed each combination for live imaging. EB1 labeled the very plus-end of the MTs, whereas p150<sup>Glued</sup> and CLIP-170 lagged behind slightly. p150<sup>Glued</sup> overlapped with some of the EB1, however CLIP-170 was most clearly separated. This suggests a hierarchy of plus-end binding and coordinate regulation.

2006 ASCB Annual Meeting Abstracts
rapamycin-treated COS-7 cell extracts. Rapamycin-treated extracts decreased the affinity of p150Glued for MTs (via p150Glued phosphorylation) consistent with our imaging results. Together these results suggest that multiple pathways regulate dynein and dynactin and that mTOR kinase regulates phosphorylation complexity through a new mechanism.

192 Neuronal Targeting of Cytoplasmic Dynein through Isoform-specific Phosphorylation of Intermediate Chains S. Tautaha, 1 W. S. Lane, 1 K. K. Pfister, 1 P. S. Vaughan, 1 K. T. Vaughan, 1 1Biological Sciences, University of Notre Dame, Notre Dame, IN, 2Biological Sciences, Harvard University, Cambridge, MA, 3Cell Biology, University of Virginia Health Sciences Center, Charlottesville, VA

Neuronal cytoplasmic dynein is a motor protein implicated in axonal transport. Although a single dynein heavy chain is expressed in neurons, a total of six dynein intermediate chain (IC) isoforms are expressed through the expression of two gene products and alternative splicing of each. The function of this IC isoform expansion is unclear, although the IC may function in the assembly or dimerization of the IC. We observed formation of heterodimers in the absence of dynein LCs, but the formation of IC homodimers when LCs were present. The potential significance of this assembly emerged during analysis of motile dynein where we determined that the phosphorylated form of the ICs is responsible for dynein targeting. We performed MS/MS analysis on each neuronal IC isoform and determined that each isoform displays phosphorylation in the p150Glued-binding domain of the ICs. Interestingly, the specific sites of phosphorylation were unique to each isoform and appear to be recognized by different kinases. To test if these phosphorylated peptides bound different binding partners, we used squid axolotl to phosphorylate each protein and measured binding using overlay assays. Squid axolotl recapitulated the phosphorylation specificity we mapped by MS/MS analysis and provided biochemical chemical analysis of the phospho-protein. Binding assays demonstrated that the phospho-version of each protein reduced binding to p150Glued and revealed interactions with new binding partners. This suggests that neuronal dynein modulates cargo specificity through differential phosphorylation of IC isoforms.

193 In Vitro Interactions of the N-terminal Region of BicD2 with Dynactin and Dynactin E. W. Schmitt, 1 D. Splinter, 1 A. Akhmanova, 2 S. J. King 1 1University of Missouri-Kansas City, Kansas City, MO, 2Department of Cell Biology and Genetics, Erasmus Medical Center, Rotterdam, The Netherlands

BicD2 is a mammalian homologue of Bicaudal D (BicD), a coiled coil, evolutionarily conserved protein that acts in the same pathway as the microtubule based motor protein dynein and its activator dynactin. Recent work has shown that targeting the N-terminal region of BicD2 (BicD2-NT) to mitochondria and peroxisomes induced their relocalization via dynein mediated transport. Recent work suggests that BicD2 helps dynein and dynactin to form a higher order complex with each other. However, it is unknown whether BicD2 accomplishes this by binding directly to each megadalton complex or by working through other cellular proteins. We have used purified proteins in in vitro biochemical assays to test BicD2 binding to purified dynein and dynactin. We now report the direct interaction of purified BicD2-NT to purified dynein and dynactin when all three proteins are present. We are now investigating how BicD2-NT affects dynein motor functions.

194 Defective Cytoplasmic Dynein-driven Transport as the Basis of Niemann Pick Type C Disease K. Huelg, K. T. Vaughan; Biological Sciences, University of Notre Dame, Notre Dame, IN

Niemann Pick Type C (NPC) disease is characterized by the formation of abnormal lipid storage organelles in neurons and hepatocytes. Mortality arises from neuronal defects, although the etiology of these defects remains controversial. The identification of two genes (NPC1 & 2) linked to NPC disease has focused most work on defects in cholesterol metabolism. However, because the defective membranes in NPC disease resemble membranes induced by expression of dynein phosphorylation site mutants, we assessed the impact of NPC1 mutations on the morphology and motility of membranes by cell live imaging. Using a GFP-NPC1 expression construct, we observed that NPC1 membranes were highly motile and produced tubulo-vesicular extensions which probed several membrane compartments. Membrane motility and extension were ablated by nokedazole treatment, indicating that NPC1 membranes require an intact microtubule array. Expression of dominant-negative dynactin (p50 dynamitin) and cytoplasmic dynein intermediate chain (S84A) mutants blocked normal bidirectional membrane transport and lead to the accumulation of engorged NPC1 membranes at the plasma membrane. To test if NPC1 mutations disrupt normal NPC1 function by blocking motility, we generated GFP-NPC1 harboring the I1061T mutation and compared wild-type and mutant NPC1 in living cells. In contrast to the behavior of the wild-type protein, I1061T mutant NPC1 membranes were immobile, engorged in cholesterol and lacked the formation of tubulo-vesicular extensions. These phenotypes could not be rescued by cholesterol depletion. Analysis of additional NPC1 mutants (C98S, P692S, and Y635C) confirm the loss of motility and tubule formation as a common theme among mutant NPC1 membranes. Together these studies suggest that NPC1 mutations affect lipid metabolism by perturbing motor-driven transport of NPC1 membranes.

195 Molecular Analysis Reveals a Role for the Cargo-binding Domain of Cytoplasmic Dynein Heavy Chain in Mitochondrial Transport D. Varma, R. B. Vallee; Cell Biology and Pathology, Columbia University, New York, NY

Cytoplasmic dynein is a complex motor protein (1.2 MDa) involved in a wide range of cellular functions. The dynein heavy chain consists of an ~120 kDa N-terminal cargo-binding and self-association domain, and a 380 kDa motor domain. We have analyzed the cargo binding domain both for its potential value as a motor-dead (“headless”) form of dynein and for an understanding of cargo binding control. In previous work we evaluated a series of dynein heavy chain N-terminal truncation mutants (MBC 14:313a). We found that the longer constructs decorated kinetochores without displacing other dynein subunits, dynactin, or L151, and potently inhibited mitosis. We now find that live imaging of mitotic cells transfected with a minimal headless fragment arrested in prometaphase with severe defects in chromosome alignment. In monopolar spindles, both monotectically and symmetrically attached kinetochores were observed, all of which were positive for the headless dynein construct. These results support a role for dynein in its own removal from kinetochores. We also tested the effect of headless dynein on mitotic or microtubule motility, for which a role for dynein has been relatively difficult to establish. Cos7 cells overexpressing this fragment showed ~ 40% increase in the number of cells with dispersed mitochondria in comparison to control GFP overexpressing cells where they were focused towards the cell center. Low to medium overexpression of the GFP-tagged fragment in polarized neuronal CAD cells specifically interfered with the minus-end directed motility of mitochondria which was reduced ~ 4 fold in comparison to control cells. The effect was stronger in high overexpressers, which induced mitochondrial clumping within axonal processes and producing a complete inhibition of all mitochondrial movements. Together these results indicate an important role for cytoplasmic dynein in mitochondrial transport and suggest that headless dynein should be valuable tool for studying dynein function in mitosis. Supported by GM47434

196 Biochemical Analysis of a Dynactin-independent Interaction between Cytoplasmic Dynein and Huntingtin J. P. Caviston, J. L. Ross, M. S. Antony, M. K. Tokito, E. L. F. Holzhaar; Physiology, University of Pennsylvania School of Medicine, Philadelphia, PA

To further our understanding of how the minus-end directed microtubule motor dynein targets vesicular cargo, we conducted a two-hybrid screen to identify dynein-interacting proteins. We isolated a 162aa fragment of Huntingtin (Htt) that interacts with dynein intermediate chain (DIC). Htt is a vesicle-associated protein thought to play a role in vesicular transport. Huntington Associated Protein 1 (HAP-1) has previously been shown to interact with dynactin, suggesting that Htt and dynactin could interact in a complex with HAP-1 and dynein to facilitate dynein-based vesicular transport. We loaded mouse brain cytosol onto an affinity column generated using a recombinant fragment of Htt (536-698) and demonstrated that both dynein and dynactin bind specifically. We also observed that FPLC-purified dynein, which lacks dynactin, bound to the affinity matrix, indicating that dynactin is not required to mediate the interaction with Htt. To identify the Htt binding site of DIC, we analyzed a series of DIC truncation constructs and demonstrated by yeast two-hybrid that 1-283aa of DIC are required for binding to Htt. To map the DIC binding site of Htt, four constructs spanning the full length of Htt were in vitro translated and incubated with beads conjugated to DIC. Htt fragment 1-1483 bound specifically to the DIC beads, thus confirming that the region of Htt encompassed by 600-698aa is both necessary and sufficient for binding to DIC. Htt and DIC are both present on vesicles purified from mouse brain and in vitro vesicle motility assays suggest that Htt acts to mediate binding of vesicles to microtubules. Cellular studies also support a functional role for Htt in vesicular transport. Together, these findings indicate that Htt binds to dynactin independently of dynactin and may act in a complex to recruit dynactin to vesicles and facilitate vesicular transport. Supported by NIH GM48661.
Cytoplasmic Dynein Motility In Vivo: Transport of and Regulation by Growth Factor Receptors

J. Ha,1 M. K. Humm,1 K. R. Myers,1 T. M. Carr,1 K. W. Lo,1 R. A. Segel,1 K. K. Pfister;1 Cell Biology, University of Virginia, Charlottesville, VA, 2Neurobiology, Harvard Medical School, Boston, MA

Cytoplasmic dynein is the motor for retrograde microtubule-based transport in cultured cells, as well as neurons. To directly analyze dynein behavior and regulation in vivo, dynein intermediate chain (IC)-green fluorescent protein (eGFP) fusion proteins were constructed and stable PC12 cell lines expressing low levels of the fusion proteins were made. Biochemical characterization of the fusion proteins demonstrated that GFP-ICs were incorporated into functional dynein complexes. IC-2C is the ubiquitous intermediate chain isoform. In PC12 cell neurites, punctate dynein with GFP-IC-2C co-localized with vesicle markers, including early endosomes. When living cells were imaged, movement of these GFP-dynein puncta in both the anterograde (0.4 +/- 0.05 μm/sec) and retrograde (0.6 +/- 0.05 μm/sec) directions was observed (~10% switch direction). The partial co-localization of dynein puncta with kinesin and secretory vesicle markers, as well as the significant difference between the anterograde and retrograde dynein velocities (p< 0.001), suggest that the anterogradely moving dynein is transported as cargo by kinesin. Internalization and retrograde transport of growth factor receptors and their transporters is essential for axonal survival. Addition of nerve growth factor, which activates the TrkA tyrosine kinase receptor, resulted in a two-fold increase in the relative number of dynein puncta moving in the retrograde direction, and there was partial overlap of IC-2C and IC-2B dynein with the TrkA receptor. Hippocampal neurons were co-transfected with GFP-TRK growth factor receptor and either IC-2C or IC-1A monomeric red fluorescent fusion proteins. When their axons were observed in real time with two color imaging, the co-incidental movement of TRK and dynein was observed. This is the first direct visualization of the transport of a physiological cargo by vebtrate dynein in vivo. Importantly, neuronal TrkB is more likely to be transported by dynein containing a neuron specific intermediate chain, IC-1A, than dynein containing the ubiquitous 2C intermediate chain.

Regulation of Dynein Motor Function by Num1 and PP1/Glc7

J. K. Moore, J. A. Cooper, Cell Biology, Washington University, St Louis, MO

In many eukaryotes the microtubule motor dynein directs the placement of organelles relative to the microtubule cytoskeleton. For the budding yeast Saccharomyces cerevisiae, dynein provides the force to draw the mitotic spindle toward the nascent daughter cell, and across the plane of cytokinesis. This requires that dynein motor activity be tethered to specific sub-domains of the cell cortex in order to translocate the spindle along the axis of division. To determine how dynein motor activity is coordinated with the asymmetry of this cell division, we sought to characterize the role of Num1 in this process. Genetic analyses suggest a role for Num1 in linking dynein to the cell cortex. Here we show that Num1 directs dynein to the tip of the bud late in the cell cycle. Our results suggest that while the cortical localization of Num1 is dependent on a carboxy-terminal PH domain, PIP2-binding does not account for the localization of Num1 to the bud tip. In addition, we provide evidence that the association of dynein with cortical Num1 is regulated by the type 1 protein phosphatase, Glc7.

Kinetochores Coordinate Two Populations of Cytoplasmic Dynein to Control the Spindle Assembly Checkpoint

J. Bader,1 J. Whyte,1 S. Taudaha,1 M. Raycroft,1 J. Hornick,1 E. Hinchcliff1, W. S. Lane,1 G. Chan,1 K. Pfister,1 P. Vaughan,1 K. T. Vaughan1,1 Biological Sciences, University of Notre Dame, Notre Dame, IN, 2Biological Sciences, Harvard University, Cambridge, MA, 3Oncology, University of Alberta, Edmonton, AB, Canada, 4Cell Biology, University of Virginia Health Sciences Center, Charlottesville, VA

Kinetochores play several crucial roles during mitosis, including microtubule capture, chromosome movement and generation of potent anaphase inhibitors. Defects in kinetochore function result in aneuploidy and chromosomal instability. It remains unclear how kinetochores coordinate these different tasks, however cytoplasmic dynein is implicated in each. In this study we identified multiple populations of dynein at kinetochores and defined their functions during mitosis. Proteomic mapping of the cytoplasmic dynein intermediate chains revealed a novel phosphorylation site which regulates binding to the dynactin complex. Despite reduced affinity for dynactin, phosphorylated dynein is recruited to kinetochores during prometaphase and in nocodazole-treated cells. Kinetochores retain phosphorylated dynein until metaphase where dynein undergoes dephosphorylation that is linked to chromosome alignment. Dephosphorylation was blocked using taxol to relieve tension or calicin to A inhibit phosphorylation. To determine the impact of changes in phosphorylation, we identified binding partners for both forms of dynein. Consistent with previous work, dephosphorylated dynein bound to p150<sub>glued</sub>. In contrast, phosphorylated dynein bound directly to the checkpoint protein zw10. To elucidate the specific roles for each dynein population, we inhibited phosphorylation or dephosphorylation dynein to kinetochores selectively and assessed mitotic defects. Kinetochores which could not recruit phosphorylated dynein displayed diminished recruitment of BubR1 and initiated premature anaphase onset. Kinetochores that could recruit phosphorylated dynein but not retain dephosphorylated dynein completed congress but failed to shed BubR1 after chromosome alignment resulting in metaphase arrest. These findings suggest that phosphorylation defines two populations of kinetochore dynein and that each plays an important role in the spindle assembly checkpoint.

Defining Elements of Yeast Cytoplasmic Dynein Required for Motility

A. P. Carter, C. Cho, S. L. Reck-Petersen, R. D. Vale; Cell and Molecular Pharmacology, UCSF, San Francisco, CA

Cytoplasmic dynein is a microtubule motor protein with many important functions in eukaryotic cells. The dynein heavy chain consists of an N-terminal tail domain responsible for cargo binding and dimerization and a C terminal motor core. The motor core is made up of a linker element and a ring of six AAA+ domains and binds microtubules via a ~18nm coiled coil stalk. In order to understand how dynein generates movement it would be helpful to address which elements of the motor core are required for motility. To address this we have used S.cerevisiae as an expression system, which has the advantage that homologous recombination can be used to readily manipulate the genomic copy of cytoplasmic dynein. Starting with a 331KD fragment of yeast dynein (equivalent to the 380KD construct defined by labs working with dictyostelium and rat dynein) we made a series of truncations along the linker region towards the first AAA+ domain in order to determine changes in phosphorylation, we identified binding partners for both forms of dynein. Consistent with previous work, dephosphorylated dynein bound to p150<sub>glued</sub>. In contrast, phosphorylated dynein bound directly to the checkpoint protein zw10. To elucidate the specific roles for each dynein population, we inhibited phosphorylation or dephosphorylation dynein to kinetochores selectively and assessed mitotic defects. Kinetochores which could not recruit phosphorylated dynein displayed diminished recruitment of BubR1 and initiated premature anaphase onset. Kinetochores that could recruit phosphorylated dynein but not retain dephosphorylated dynein completed congress but failed to shed BubR1 after chromosome alignment resulting in metaphase arrest. These findings suggest that phosphorylation defines two populations of kinetochore dynein and that each plays an important role in the spindle assembly checkpoint.

The Role of ATP Hydrolysis at Distinct ATP Binding Sites in Cytoplasmic Dynein

S. L. Reck-Petersen,1 C. Cho,1 D. Applewhite,1 E. Riehaca,2 R. Vale1; Cellular and Molecular Pharmacology, UCSF, San Francisco, CA, 2Cell and Molecular Biology, Northwestern Medical School, Chicago, IL, 3Physics, University of Maryland, College Park, MD

Dynein is a member of the AAA+ superfamily of ATPases with a characteristic ring structure composed of four functional ATP binding modules. Dynein differs from the other cytoskeletal motor proteins, kinesin and myosin, which both contain a single ATP binding site per motor domain. To elucidate the role of dynein’s multiple nucleotide binding sites, we expressed a panel of recombinant dynein dimers in S. cerevisiae predicted to block ATP hydrolysis in each of dynein’s 4 conserved AAA+ domains. Minimal functional dimers were created by fusing the motor domain to glutathione-S-transferase (GST), which forms a stable homodimer. For each mutant, we assayed the motor function by ATPase activity, speed in a multiple motor microtubule gliding assay, and processivity and speed of single dynein dimers in a total internal reflection- based single molecule motility assay. As expected, mutation of AAA1 blocks dynein motor activity. Surprisingly, we find that mutation of AAA4 dramatically enhances dynein processivity, but has no effect on the motor’s single molecule velocity. Our results suggest that the AAA4 mutant has a higher affinity for microtubules, indicating that nucleotide hydrolysis at this site functions to coordinate dynein’s microtubule association with its mechanochemical cycle.

Reversion Analysis of the Cytoplasmic Dynein Motor: A Trip Around the Ring

M. Plamann, D. Madole, R. Schnitker, E. Wulf; School of Biological Sciences, University of Missouri-Kansas City, Kansas City, MO

Cytoplasmic dynein is a large, microtubule-associated motor complex that facilitates minus-end-directed transport of various cargoes. Dynein heavy chain (DHC) is ~4000 residues in length, with the last two-thirds of the heavy chain forming the motor head. Six domains within the dynein motor exhibit varying degrees of homology to the AAA+ superfamily of ATPases. These domains are followed by a distinct C-terminal domain and together form a ring-like structure from which a microtubule-binding domain (MTBD) protrudes. Using a genetic assay, we have isolated over 50 DHC mutants of Neurospora that produce full-length proteins that are defective in function. We have identified DHC point mutations in nearly all domains within the dynein motor. Consistent with previous work, dephosphorylated dynein bound to p150<sub>glued</sub>. In contrast, phosphorylated dynein bound directly to the checkpoint protein zw10. To elucidate the specific roles for each dynein population, we inhibited phosphorylation or dephosphorylation dynein to kinetochores selectively and assessed mitotic defects. Kinetochores which could not recruit phosphorylated dynein displayed diminished recruitment of BubR1 and initiated premature anaphase onset. Kinetochores that could recruit phosphorylated dynein but not retain dephosphorylated dynein completed congress but failed to shed BubR1 after chromosome alignment resulting in metaphase arrest. These findings suggest that phosphorylation defines two populations of kinetochore dynein and that each plays an important role in the spindle assembly checkpoint.

2006 ASCB Annual Meeting Abstracts

37
motor head. We have now isolated revertants for a subset of these DHC mutants and have identified the respective intragenic suppressor mutations in >100 revertants. Interestingly, we have found that two mutations within the MTBD are suppressed by mutations in various domains around the ring. These results suggest that the conformational states of the MTBD and motor head are tightly coupled. Most DHC mutations examined to date revert exclusively by intragenic suppression. However, 30 to 90% of the AAA6 and C-terminal domain DHC revertants result from extragenic suppression. These results suggest that AAA6 and C-terminal domain mutations are readily bypassed by mutations in other genes.

Characterization of the Dynein Microtubule Binding Domain

D. S. Razansky, D. Madole, R. Schnittker, C. T. Cuppock, M. C. Martinez, M. Plamann, S. J. King; School of Biological Sciences, University of Missouri, Kansas City, MO

Dynein is a minus-end directed microtubule motor protein which functions to carry a variety of cargoes, including nuclei, throughout a cell. Dynein is composed of multiple polypeptides including heavy (DHCl), intermediate, light intermediate and light chains. The DHCl is ~4500 amino acids in length and contains a single ~125 amino acid microtubule binding domain (MTBD). The MTBD is located on the end of a long anti-parallel coiled-coil with the microtubule contact region at the tip. We have characterized the wild-type MTBD using biochemical and biophysical techniques such as gel filtration, co-sedimentation, Raman spectroscopy, analytical ultracentrifugation, and single molecule assays. We identified a number of mutations within the MTBD of Neurospora crassa that cause a ropy hyphal growth phenotype, indicative of a non-functional dynein motor. In addition to the ropy phenotype, we observed altered nuclear migration in all of these MTBD mutants. We also identified intragenic suppressors that rescue these mutant phenotypes to varying degrees. Using these approaches we hope to determine how the MTBD functions as a unit of the DHCl.

The ATPase-dependent ON/OFF Switching of MT Binding of Cytoplasmic Dynein and Its Coordination with the Tail Swing

R. Ohkura, K. Sutoh, K. Inamura, T. Kon, K. Sutoh; Department of Life Sciences, University of Tokyo, Tokyo, Japan

Cytoplasmic dynein is a minus-end directed microtubule (MT) motor protein. It moves along MT filament with repetitive dissociation/re-association cycle that is tightly coupled with the ATP hydrolysis cycle. Here, we measured the nucleotide-dependent MT affinity of a single-headed cytoplasmic dynein, which clearly demonstrated ON/OFF switching of the MT binding that takes place in the course of ATP hydrolysis. By means of mutational analysis, we determined that AAA1 ATPase site is responsible for the MT binding among multiple ATPase sites of dynein. It has been indicated previously that this ATPase site is also responsible for the tail swing, and thus the ON/OFF switching and the tail swing are regulated by the identical ATPase site, enabling the tight coordination of the two processes as walking along MT filament. Indeed, recovery stroke of dynein is ensured by staggering timing of the ON-to-OFF transition and the tail swing. Furthermore, we provide here direct evidences that stalk head is a solo MT-binding site of dynein that activates dynein ATPase upon MT binding and senses nucleotide state of the ATPase site, suggesting that communication between the ATPase site and the MT-binding site is actually carried out via stalk coiled-coil as has been generally expected.

Distinct Response of Kinesin and Dynein to Microtubule Cross-Over Versus Illuminates Their Differential Cellular Functions

J. L. Ross, H. Shuman, E. L. F. Holzbaur, Y. E. Goldman; Pennsylvania Muscle Institute, University of Pennsylvania, Philadelphia, PA

Kinesin and cytoplasmic dynein are microtubule-based motor proteins that actively transport material throughout the cell. The microtubules form a polarized network that is primarily radial, but microtubules intersect at a variety of angles both near the nucleus and at the cell periphery. The behavior of kinesin and dynein at these intersections has implications for transport efficiency and accuracy. Intersecting microtubules serve as tracks for direction alteration but also as obstacles to motion. In order to test motor function at microtubule intersections, cross-overs of microtubule tracks were arranged in vitro using flow to orient successive layers of filaments. Kinesin and cytoplasmic dynein-dynactin were fused with green-fluorescent protein and observed one at a time during translocation using total internal reflection fluorescence microscopy. Kinesin is most likely to pass or dissociate at an intersection, while dynein-dynactin has a variant response that includes reversing direction and switching between the intersecting tracks. When many kinesin molecules are attached to artificial head cargos (0.8-1 µm diameter), the transporters were forced to pass or switch at an intersection, independent of motor density on the head. Interestingly, dynein-dynactin cargos are more likely to pass the intersection or switch microtubules at low surface density, but becomes more likely to pause or stop at higher density. This result implies that a simple mechanism of adding motors could change a motile cargo into an anchored one at intersections, consistent with dynein’s proposed tethering functions in the cell. The different actions of dynein and kinesin when encountering an intersection most likely reflect their inherent structural differences, and give new insight into the functions of these motors in the complex cellular environment. Supported by NIH grant AR051174.

The Interaction of Cytoplasmic Dynein with Bub3 Is Mediated by the DYNLT3 Light Chain: A Link for Kinetochore to Pole Transport of Spindle Checkpoint Proteins

K. W. Lo, J. M. Kogoy, K. K. Pfister; Cell Biology, University of Virginia, Charlottesville, VA

Cytoplasmic dynein is composed of six subunits: heavy chain, intermediate, light chain, protraction, and two additional regulatory proteins, as a binding partner of DYNLT3. The spindle assembly checkpoint delays mitosis until all kinetochores are attached to spindle microtubules. Several proteins including Mad1, Mad2, Bub1, Cdc20, and Bub3 assemble into the checkpoint complex. This complex undergoes cytoplasmic dynein-dependent depletion from kinetochores in response to the formation of kinetochore microtubules (Howell et al., 2001, JCB, 155:59). However, the molecular link between the checkpoint protein complex and dynein was unknown. GST-bub3 pull-down assays probing lysates from tissue culture cells expressing either myc-DYNLT3 or mCherry-DYNLT3 demonstrated the specific binding of Bub3 with DYNLT3. GST-Bub3 binds endogenous dynein from mitotic cell extracts. Bub3 co-immunoprecipitates with the dynein heavy chain from mitotic cell extracts, confirms that Bub3 interacts with the cytoplasmic dynein complex, not just DYNLT3. DYNLT3 co-localized with both the CREST antigen and Bub3 on kinetochores at prometaphase, but not at later mitotic stages. DYNLT3 was also depleted from the kinetochore as mitosis proceeded. Overexpression of DYNLT3-GFP in LLCPK cells disrupted mitosis, causing an increase in the number of cells in a prometaphase-like state. Preliminary results suggest that siRNA knockdown of DYNLT3 also cause a mitotic defect in NRK cells. These data support a model for the binding of checkpoint proteins to the cytoplasmic dynein complex via DYNLT3, in order to transport checkpoint proteins from the kinetochore to the pole. These results also support the hypothesis that subunit isoforms contribute specificity to dynein cargo interaction.

NudE and NudEL Are Required for Mitotic Progression and Play a Novel Role in Dynein Recruitment to Kinetochores

S. A. Stehman, Y. Chen, R. B. Valle´; Pathology, Columbia University, New York, NY

NudE and NudEL are related proteins that interact with cytoplasmic dynein and LIS1, a dynein regulator responsible for the brain developmental disease, lissencephaly. LIS1 and dynein play known roles in mitotic progression (NCB 2:784, JCB 170:935) and recent work has implicated a similar role for NudE in this process (Neuron 44:279). Little is known, however, about the mitotic functions of NudE and NudEL at the cellular level. We previously observed that NudE and NudEL each localize to mitotic kinetochores prior to dynein and LIS1 and remain at these sites until early anaphase, well after dynein, dynactin, and LIS1 have departed (MBC 15:394a). To determine the significance of this early localization, we injected an anti-NudE/EL antibody into mitotic cells and followed them by phase-contrast microscopy. This antibody specifically blocks the binding of NudE/EL with dynactin but not LIS1 and potentially interferes with mitosis. 83.3% of injected cells were defective in mitotic progression with the most prominent phenotype being metaphase arrest followed by cell death. We saw no defects in congression, unlike with LIS1 inhibition, and no defects in chromosome segregation, in contrast to ZW10 mutant cells. Localization analysis showed that NudE and NudEL, as well as ZW10, remained at the kinetochores of injected cells but, surprisingly, dynein and dynactin were lost. Additionally, many injected cells exhibited misoriented sister chromatids and defective microtubule attachment. Live analysis of cells expressing the kinetochore targeting region of NudE exhibited similar mitotic defects. To determine the mechanism for NudE-mediated kinetochore anchoring, we coexpressed it with dynein subunits and found a striking interaction with dynein intermediate chain. Although NudE and NudEL exhibit very different brain developmental phenotypes, we show a common localization site for both proteins at mitotic kinetochores and identify a novel role for NudE and NudEL in recruiting dynein to kinetochores and regulating mitotic progression.

Hexon-mediated Dynein Recruitment to Adenovirus Reveals Mechanistic Differences between Normal and Pathogenic Cargo

K. H. Bremer, R. B. Valle´; Pathology, Columbia University, New York, NY

38
Cytoplasmic dynein is the predominant minus end-directed microtubule motor in interphase cells and transports a range of subcellular cargoes. It has also been implicated in the translocation of a number of viruses to the nucleus, including adenovirus. The aim of this study was to define the molecular basis of the adenovirus-dynein interaction in order to further our understanding of dynein cargo binding mechanisms in general, and determine the extent to which pathogenic forms of cargo utilise physiological mechanisms. We have previously observed colocalization of both dynein and adenovirus on the surface of ciliates (75%) of incoming adenovirus particles (MBC 8:60a). We have since found colocalization with adenovirus particles of polypeptides N1α, N1β, N2α, N2β, Nuc, but not with N10 or L11. In studies of other processive motors, a mechanism has been proposed in which two identical motor domains alternately swing forward at each step while one motor domain remains attached on intermediate zone upon knockdown of LIC2 alone. Collectively, these results strongly argue that the LICs have both co-related and distinct functions, but are uniquely extraneous in dynein function at the Golgi, suggesting their involvement in a specific subset of dynein functions, thereby allowing for more refined modulation of dynein activity.

210

Conformational Changes of Inner-Arm Dynein-f from Chlamydomonas Coupled with Phosphorylation of Its Intermediated Chain IC138

S. H. Sakakibara,1 S. Burgess,2 Y. Sakai,1 K. Oiwa1; 1Kobe Advanced ICT Research Center, National Institute of Information and Communications Technology, Kobe, Japan, 2Institute of Molecular and Cellular Biology, University of Leeds, Kobe, United Kingdom

Inner-arm dynein subcomplexes f (dynein-f or the 1 complex) of Chlamydomonas is a double-headed dynein composed of two different heavy chains, three intermediate chains and a number of light chains. It has been shown that an axonemal casein kinase 1 (CK1) phosphorylates the 138K intermediate chain (IC138) and that this phosphorylation is involved in regulation of flagellar activity in phototaxis. To elucidate the mechanism of regulation of IC138 phosphorylation, we compared molecular conformation of dynein-f molecules with and without IC138-phosphorylation using negative-staining electron microscopy and single-particle image processing. When images of dynein-f were aligned with respect to the tail domain and averaged the two heads of IC138-phosphorylated dynein-f appeared more smeared than those without IC138-phosphorylation. Although no systematic conformational changes coupled to IC138-phosphorylation were observed, the differences found in averaged images suggest that IC138-phosphorylation increased flexibility of the molecule. We have confirmed these observations using dynein-f molecules purified from the mutant strain 212, a photo-taxis mutant that has high level of the phosphorylated form of IC138. The change in flexibility of the molecule could modify the interactions between the two heads and/or between dynein-f and the adjacent B-tubule in the axoneme.

211

Motility of the 1α and 1β Heavy Chains of the Inner Arm Dynein 11 of Chlamydomonas Flagella

S. Tosa,1 H. Sakakibara,1 M. E. Porter,2 W. S. Saku,2 K. Oiwa,1 Kove Advanced ICT Research Center, National Institute of Information and Communications Technology, Kobe, Japan, 1Institute of Molecular and Cellular Biology, University of Leeds, Kobe, United Kingdom

Inner arm dynein 11 of Chlamydomonas flagella, also known as dynein 1, is a protein complex composed of two distinct heavy chains, three intermediate chains and a number of light chains. We performed conventional in vitro motility assays showing that dynein 11 translocated microtubules at the comparatively low velocity of about 1.5 μm/sec. The velocity increased slightly as surface density of dynein 11 increased. From this dependence, we estimated the duty ratio of dynein 11 to be 0.6-0.7. Moving microtubules observed at low dynein densities rotated erratically about a vertical axis through a fixed point on the surface, at which a single dynein 11 complex is presumably located, while still progressing. Thus, we concluded that dynein 11 is a processive motor. In studies of other processive motors, a mechanism has been proposed in which two identical motor domains alternately swing forward at each step while one motor domain remains attached on the axonemal dynein. In the dynein 11, however, its heterogeneous motor domains do not need to behave the same to perform the role of each motor domain in processive movement, we took advantage of mutants lacking the 1α or 1β motor domain (Myster et al., 1999, Perrone et al., 2000). Negative-staining electron microscopy and area-gel electrophoresis confirmed that the mutant molecule was intact except lacking one head domain. The 1β and the 1α translocate microtubules smoothly on glass surface at 0.8 μm/sec and 1.0 μm/sec at 0.5 mM MgATP, respectively. Thus, we concluded that the motor domain of the 1α and the 1β are each sufficient for microtubule translocation. The velocities of these mutants are, however, significantly lower than those of intact dynein 11. A certain coordination mechanism may exist between each motor domain of an intact dynein 11 complex, such that one head assists power stroke of the other.

Image-based Quantitative Scattering Analysis Reveals Differential Effects of Drugs on Adhesion and Motility

D. Loerke,1 J. De Rooij,1 A. Kerstens,2 C. Waterman-Storer,3 G. Danuser2; 1The Scripps Research Institute, La Jolla, CA, 2Department of Cell Biology, Netherlands Cancer Institute, Amsterdam, The Netherlands, 3College of Engineering, The University of Texas at El Paso, El Paso, TX

In response to HGF growth factor stimulation, cultured MDCK cells lose cell-cell junctions and acquire a migratory phenotype, causing cell clusters to scatter in space. This process is a commonly used in vitro model system for cancer metastasis, and the antimitastatic potential of a drug can be tested by evaluating its efficiency in inhibiting MDCK cell scattering. The time course of MDCK cell scattering can be evaluated over a range of hours with phase-contrast imaging, which has the advantage that it is non-invasive and avoids the phototoxic effects or bleaching associated with fluorescence probes. However, phase-contrast image analysis is non-trivial, and quantitative analysis of scattering (as well as the evaluation of potential scattering inhibitors)
has previously been limited to relatively small sample sizes, or to those select parameters that lend themselves to automated analysis, notably cell centroid velocity. We developed a software package that enhances velocity information by automated motion correlation and spatial clustering analysis. It performs time-resolved quantitative analysis of the spatial dynamics of the scattering process on large sample sizes, allowing us to perform a screen of selected inhibitors of signaling intermediates downstream of HGF. Focusing on MAPKinase signaling inhibitors, we find that different drugs differentially affect motility-related and adhesion-related aspects of the scattering process. This highlights the importance of analyzing these contributions separately, particularly since using an automated velocity-only-based approach may incorrectly predict a high inhibitory potential for drugs with low efficiency in preventing the disruptions of cell-cell adhesions. Thus, our live-cell microscopy-based assay permits the differential evaluation of the contributions of migration regulation and cell-cell adhesion disruption in HGF-treated MDCK cells, and can be used as a useful tool for screening new potential pharmacological agents against tumor metastasis.

214 Role of Slit2 in Neural Crest Cell Migration
M. E. de Bellard, 1 M. Brommer-Fraser, 1 L. Correa, 1 A. Ochou; 1Biology, CSUN, Northridge, CA; 2Biology, Caltech, Pasadena, CA

The neural crest are cells that emerge by delamination from the dorsal neural tube shortly after neural tube closure and give rise to the wide variety of neuronal, glial and non-neuronal derivatives that make a large number of head structures and the peripheral nervous system. These cells go from a non-motile, epithelial-adherent cell type, to a highly motile one that allows them to migrate rapidly throughout the embryo and reach distant areas where they differentiate. Little is known about the underlying mechanism directing these processes. The following experiments tried to further examine the role of Slits and their Robo receptors may have in selective neural crest delamination and migration and the dual function of Slit in both inhibiting and stimulating motility of neural crest cells. In order to determine the function of Slit expression by non-migrating neural crest cells, I constitutively expressed Slit2 in or Slit2 in pre-migratory neural crest by electroporating plasmids in chicken embryos. I found that ectopic expression of both Slit molecules in trunk neural tube caused defects in their epithelial to mesenchymal transition, as shown by the reduced numbers of neural crest cells in the sympathetic ganglia by the aorta and the reduced migration in cultured neural tubes after Slit electroporation. However, control transfectied cells were observed to migrate in larger numbers and farther away than those from Slit electroporated neural tubes. In order to determine what was happening to the cells after Slit electroporation, neural crest cells were visualized under confocal microscopy live imaging. Movies showed that control GFP electroporated cells were migrating normally, while Slit expressing cells were behaving differently, moving less smoothly, were slower and were rounding-up and extending at intermittent times. Thus Slit molecules may play a role in keeping neural crest cells from delaminating from the neural tube ahead of time.

215 Enhanced Ordering of Interacting Filaments by Molecular Motors
P. Kralikvski, 1 R. Lipowsky, 1 J. Kierfeld; 1Theory, Max Planck Institute of Colloids and Interfaces, Potsdam, Germany; 2University of Connecticut Health Center, Farmington, CT

We theoretically study the cooperative behavior of cytoskeletal filaments in motility assays in which immobilized motor proteins bind the filaments to substrate surfaces and actively pull them along these surfaces. Because of the repulsive interaction of filaments, the motor-driven dynamics of filaments leads to a nonequilibrium phase transition which generalizes the isotropic-nematic phase transition of the corresponding equilibrium system, the hard-rod Liquid. Long-time dynamics simulations and analytical theory show that the motor activity enhances the tendency of filaments to arrange in a nematic order, which is responsible for the formation of focal adhesions. We develop a theory for the location of the phase boundary as a function of motor density. At high detachment forces of motors, we observe the formation of filament clusters because of blocking effects; at low detachment forces, cluster formation can be controlled by the density of inactive motors.

216 Kinking, Rather Than Corkscrewing, Generates Thrust in Spiroplasma Motility
J. Y. Lee, J. W. Shaevertz, D. A. Fletcher; UC Berkeley, Berkeley, CA

Prokaryotes use a variety of mechanisms to maneuver through their environments. One family of bacteria, called Spiroplasma, is capable of swimming in the absence of flagella by changing their cell shape. In a previous study, we showed that Spiroplasma can swim by rotating to unwind their helical bodies, resulting in a progressive change in helicity that forms kinks in the cell axis. Because Spiroplasma lack cell walls, an internal cytoskeleton must be responsible for the dynamic cell shape they use for motility. However, the hydrodynamic details of this propulsive mechanism remained unclear since motility involves both rotation of the helical cell body and kinking of the cell axis. Rotation of a helix may generate thrust by causing a cell to “corkscrew” through liquid medium at a velocity related to helical pitch. Processive kinking of the cell axis from front to back, on the other hand, propels the cell forward at a velocity weakly dependent upon pitch. To determine the relative importance of pitch, kink angle and kink propagation speed, we measured cell kinematics of four morphologically varied species of Spiroplasma during free-swimming. Our results indicate that cell velocity varies between species and that this cell velocity correlates with kink propagation speed. However, changes in cell velocity are not correlated with morphological parameters such as helical pitch and kink angle. Because cell velocity appears to be independent of morphological changes, thrust is most likely dominated by the kinking of the cell axis rather than the rotation of the helical body.

217 Modifying Cellular Microenvironments in Real Time with 3D Lithographic Microfabrication
B. Kaehr, R. Nelson, J. Shear; Chemistry and Biochemistry, UT Austin, Austin, TX

The ability to control physical and chemical properties of cellular microenvironments is important in addressing a range of compelling biological questions. Various lithographic techniques, for example, have been developed for patterning adherent cells through modification of surface properties, providing a level of control over the spatial relationships between adherent cells. However, current approaches cannot readily confine and direct active, motile or developing cells. To overcome these limitations, we have developed microfabrication strategies to confine cells in well-defined three dimensional microstructures under conditions that remain suitable for monitoring and perturbing cell growth and development. Moreover, our techniques typically allow microfabrication in the presence of living cells. Using two-photon photochemistry, we are able to fabricate high resolution matrices (with feature dimensions of less than 1 µm) composed of crosslinked proteins that commonly retain catalytic and physical functionalities. Using this approach, we are thus able to define local topographic and chemical microenvironments of cultured cells in real time. Here, we demonstrate an ability to corral and redirect neurite outgrowth in situ - an important step towards engineering inter-cellular networks, and show that microstructures can be fabricated on tissue scales fast enough to confine actively motile cells such as E. coli and fish keratocytes. These results demonstrate new capabilities for directing, trapping and incubating individual cells of interest - an advance that will enable key questions regarding cell motility and development to be addressed.

218 Enhanced EGFP-CALI Using Deficient Cells Rescued with Functional EGFP-fusion Proteins: Application to Capturing Protein and Mena
E. A. Vitriol, 1 A. Uetrecht, 1 F. Shen, 2 K. Jacobson, 1 J. E. Bear; 1Department of Cell and Developmental Biology, University of North Carolina at Chapel Hill, Chapel Hill, NC; 2Department of Pharmacology, University of North Carolina at Chapel Hill, Chapel Hill, NC

Chromophore Assisted Laser Inactivation (CALI) is a loss of function approach that offers precise spatiotemporal control of protein inactivation. EGFP has been used effectively for CALI and of Pharmacology, University of North Carolina at Chapel Hill, Chapel Hill, NC of the RhoA free for normal regulation by GDI (Sequence in chain = RhoA-CFP-Citrine-RBD, where RBD is Rhotekin binding domain that binds only to activated RhoA). We have recently developed a single chain FRET biosensor of RhoA activation, used to examine the spatio-temporal dynamics of RhoA activity during cell morphological changes and growth factor stimulation. Unlike other single chain biosensor designs, the two GFP mutants undergoing FRET (CFP and Venus) were placed on the internal portion of the chain, leaving the C-term of RhoA free for normal regulation by GDI (Sequence in chain = RhoA-CFP-Citrine-RBD, where RBD is Rhotekin binding domain that binds only to activated RhoA). We have
extended this approach by substituting other target proteins and corresponding binding domains to produce biosensors for RhoC and for Rhog. FRET response was optimized through use of circularly permuted GFP mutants and optimization of linker lengths. The spectral characteristics and biological applications of these two new biosensors will be presented. Extension of this design to study Rho, Rac and Cdc42 interaction with GDI will also be discussed.

220 Monitoring Global Protein Conformational Changes within Cells under Mechanical Force
C. Johnson, D. Discher, A. Engler, D. Speicher; Chemical and Biomolecular Engineering, University of Pennsylvania, Philadelphia, PA, Wistar Institute, Philadelphia, PA
Changes in protein structure in response to mechanical forces are believed to mediate a variety of cellular responses, and may take the form of either rearrangement in the fold of the protein, or dissociation of protein-protein complexes. Recent studies have attempted to identify force sensitive proteins and the induced conformational states associated with mechanotransduction. However, there is currently no facile methodology to scan for mechanical force induced conformational changes on a global level within the cell, and no direct in vivo evidence exists. To address this shortcoming, we have developed an in-cell technique that allows for the probing of force induced conformational changes in a high throughput fashion. As an initial test of our method, erythrocyte ghosts were monitored for signs of shear induced spectrin unfolding. Subsequently, the methodology has also been applied to nucleate cells in order to identify mechanosensitive proteins involved in cardiomyocyte contraction and stem cell differentiation.

222 Direct Observation of Microtubule Dynamics in Live Brain Tissue
J. Tsai, R. B. Vallee; Pathology and Cell Biology, Columbia University, New York, NY
Recent studies from our laboratory have used in vitro electrophoresis of neural progenitor cells to determine the cellular roles of the lissencephaly protein LIS1. We monitored the behavior of GFP-tagged neural progenitors in 400μm thick brain slices under control and LIS1 RNAi conditions, and identified multiple roles of LIS1 during neurogenesis (JCB, 176:935). We are now using a variety of subcellular markers to understand neural progenitor subcellular behavior in vivo (Tsai and Vallee, MBC abst., in press). The behavior of cytoskeletal networks and their associated motor proteins in these cells have been largely beyond the reach of conventional microscopic methods. Here we describe methods we have developed to image microtubule dynamics in neural progenitors migrating through live brain tissue. Using in vitro electrophoresis, we have labeled neural progenitors with a GFP-tagged version of the microtubule end-binding protein EB3 and RFP-centrosome. To solve the problem of scattering in thick slices and from conventional culture methods, we embedded the brain slices in Matrigel directly on a coverglass to enable direct fluorescent imaging with high N.A. objectives. EB3 "surfing" movements were readily observed throughout the cell. In bipolar cells undergoing glia-guided migration, microtubules exhibited a relatively constant rate of surfing revealed microtubules to emanate from an astrom from and move in association with the highly motile centrosome during migration. Microtubules in the leading process were arranged unidirectionally and in parallel, whereas the trailing microtubules were clamped and formed a cage-like network around the nucleus, suggesting different forces acting on the microtubule network in the two cases. We are currently investigating the dynamics of the microtubule network at different steps during neural progenitor migration and its changes in cells subjected to LIS1 and dynein RNAi treatments. 222 Intrinsic Dynamic Behavior of Fascin in Filopodia
Y. S. Aratyn, D. Vignjevic, O. Dancu, J. Pelsyin, S. Koijima, E. Taylor, G. Borisy; Cell and Molecular Biology, Northwestern University, Chicago, IL, Equipe de Morphogenese et Signalisation cellulaires, CNRS/Institut Curie, Paris, France, Cell and Molecular Biology, University of Wisconsin, Madison, WI
Fascin is required for the formation of tightly cross-linked actin bundles in filopodia. We performed fluorescence microscopy techniques to investigate the incorporation and dynamics of fascin cross-links in order to model the disassembly of filopodia formation. First, fluorescence photobleaching revealed no fluorescence recovery of GFP-fascin in B16/F1 mouse melanoma cells along with rapid fluorescence recovery of GFP-fascin, with t1/2 = 9 ± 6 seconds (n = 41) and 96 ± 37% fluorescence recovery, indicating that fascin undergoes cycles of dissociation and association in filopodia. Photobleaching experiments were repeated in S2A mouse neuroblastoma cells and revealed rapid exchange of GFP-fascin in filopodia, t1/2 = 7 ± 3 seconds (n = 18), confirming that dynamic cross-links are a general phenomenon in filopodia. Second, in vitro fluorescence photobleaching experiments of Alexa488-fascin in reconstituted filopodia-like bundles yielded rapid fluorescence recovery, with t1/2 = 19 ± 18 seconds (n = 18) and 96 ± 25% fluorescence recovery, suggesting that fascin exchange is an intrinsic property of the fascin molecule. Lastly, photobleaching recovery data indicate the existence of mobile and immobile fractions of cross-links prompting us to investigate the proportion of bound fascin molecules in filopodia. On average, we found that filopodia contain one fascin cross-link per 20 actin monomers and that about 90% of those cross-links are bound. These results indicate that fascin exchange in filopodia is primarily governed by mobile, highly dynamic cross-links.

222 Reconstitution In Vitro of MSP-based Filodipodium Extension in Nematode Ascaris suum Sperm
L. Miao, K. Yi, J. M. Mackey, N. Rowley, T. M. Roberts; Department of Biological Science, Florida State University, Tallahassee, FL
The MSP motility system in nematode sperm is best known for propelling the movement of mature sperm, where it has taken over the role usually played by actin in amoeboid cell motility. However, MSP filaments also drive the extension of filopodia, which are transient organelles, each with a core bundle of MSP filaments, that form in the late in sperm development. We have reconstituted this process in vitro whereby thin bundles of MSP filaments, then enveloped by a membrane sheath at the growing end, elongate at rates up to 18 μm/min. These slender protrusions often exceed 500 μm in length but are comprised of filaments that are only 1 μm long. The reconstituted filopodia assemble in the same sperm extract that produce MSP fibers, columnar meshesworks that assemble behind a membrane vesicle and reconstitute the dynamics of the lamellipodial filaments system that propels sperm movement. Indeed, filopodia and fibers both have a membranous structure at their growing end, share five MSP accessory proteins, and respond identically to agents that modulate protein phosphorylation. However, filopodia are much thinner than fibers and elongate 3-4 fold faster. The reconstitution of filopodial extension shows that, like actin, MSP filaments can adopt two architectures, bundles and meshesworks, each capable of pushing membranes, In the bundle condition the filaments exert force against a concave membrane surface whereas MSP filament meshesworks push against a flat membrane sheet. Supported by NIH Grant R37 GM29994

224 Time-lapse Videography of Photomovement in Filamentous Blue-Green Alga Oscillatoria sp
S. J. Lee, G. H. Kim; Biology, Konji National University, Konji, Republic of Korea
Filament motility in Oscillatoria was recorded more than a century ago, but the basic underlying mechanisms are still obscure and pose a major biological research problem. The effects of monochromatic light and cytoskeletal inhibitors on the photomovement of Oscillatoria sp. were studied using time-lapse videography and image analysis program (Image pro 5.1). Under blue light (peak at 470 nm), the filaments showed faster gliding movement than blue light. The glding movement was much faster under UV light, showing negative photokinetics. The pattern of photomovement was similar under two types of UV light (254 and 365 nm). Moreover, filaments took determined orientation and quickly moved away from the original position. A reversible inhibition of the movement was observed when the cyanobacteria were treated with myosin inhibitor, IDM (50~100 μM), or Ca²⁺ inhibitor, EDTA (10 μM), indicating that the movement was based on acto-myosin system. The filament motility in Oscillatoria was observed for the first time with FITC-phalloidin. Actin has never been reported as present in prokaryote cells, but some similar kind of proteins are present in prokaryotes instead of actins. This is first report of acto-myosin system working in filamentous blue green algae.

225 Seeing More by Seeing Less: New Actin Cytoskeletal Dynamics Revealed by Photoactivatable Thresholding
C. G. Galbraith, A. Galbraith; NIDCR, NIH, Bethesda, MD, NINDS, NIH, Bethesda, MD
During cell migration, the cytoskeleton undergoes rapid movement, assembly, and disassembly. Visualizing and analyzing cytoskeletal dynamics has always been challenging - dense labeling of the cytoskeleton obscures the visualization of movement, while sparse labeling requires extensive computational analysis and information about the protein trajectory within the cytoskeletal network. To investigate actin dynamics at the leading edge of migrating cells, we exploited the properties of photoactivatable GFP (PaGFP) to adjust the amount of protein that is visible in an individual cell. By regulating the intensity of the activating light, we can titrate the level of photoactivation to continuously adjust the "threshold" of visible cytoskeleton during cell migration.

226 Collectible Contractile Dynamics in Confluent Epithelial Cells Are Highly Coherent
T. E. Angelini; Department of Engineering and Applied Science, Harvard University, Cambridge, MA

We have studied the collective contractile dynamics of confluent Cos-7 epithelial cells during migration in several contexts. We patterned cells in single file lines on confluent PDMS rubber bands, and quantified substrate deformation by tracking embedded fluorescent particles over the course of approximately 10 hours. Deformations confined to one dimension, well over ten microns in magnitude, correlated over distances exceeding the millimeter scale were observed. On unpatterned PDMS, collective substrate deformations in two dimensions were over ten times smaller, and exhibited acoustic-like spectral properties. Three dimensional matrix deformation was studied by embedding cells at high density in 1mg/ml collagen. Since collective network deformations are difficult to quantify in the microscope, a dynamic small angle light scattering technique was adapted. With this technique, we have spectrally characterized the three dimensional mechanical network deformations during cell migration, and observed collective behavior similar to the measurements on compliant surfaces.

227 Cytoplasmic Pressure Differential in Migrating Adherent Cells
T. Iwashaki, Y. Wang; University of Massachusetts Medical School, Worcester, MA

Amoeboid movement is known to involve a pressure differential along the cell length, with contractions in the posterior region driving cytoplasmic streaming toward the front. While this process is believed to play a critical role in amoeboid cells, a parallel transport process has yet to be demonstrated in cultured adherent cells during migration. To probe the distribution of intracellular pressure, we microinjected high molecular weight, linear polyacrylamide (PAA) as a passive force gauge into migrating NIH3T3 fibroblasts. Injected PAA appeared as amorphous aggregates that underwent shape changes and directional movements in response to differential forces exerted by the surrounding environment. PAA injected into the posterior region immediately moved toward the front, while PAA in the anterior region remained stationary relative to the cell center. This forward movement was observed only in moving cells. In addition, disruption of myosin II activity by blebbistatin inhibited the forward translocation of PAA, while cell migration persisted in a disorganized fashion. These results suggest that myosin II in the posterior region generates a gradient of cytoplasmic pressure, which may be responsible for the transport of some essential cytoplasmic components to the anterior region. This myosin II-dependent cytoplasmic flow may in turn play an important role in maintaining the directional stability of cell movement.

228 Actin Meshwork Pore Size in the Lamellipodium Varies with Local Actin Barbed End Density
K. Keren,1 P. T. Yam,1 G. Marriott,1 J. A. Theriot1; 1Dept. of Biochemistry, Stanford University, Stanford, CA, 2Dept. of Physiology, University of Wisconsin, Madison, WI

The actin meshwork in the lamellipodium of moving cells has a central role in propelling the cell forward and is also the major determinant of the cytoarchitecture in that region. While the basic biochemical mechanisms involved in its assembly are largely known, the large-scale organization of this dynamic structure and the relationship between the structure and its function as the motility apparatus are still not understood. Using various probes, we have characterized the actin meshwork structure and its influence on the distribution of soluble cytosolic components in the lamellipodium of epithelial keratocytes. By examining both stationary and moving cells we were able to study and compare the lamellipodium in two different cell states using the same cell type. We measured the size dependent distribution and diffusion of inert soluble components (different sized dextrans, PEG-coated quantum dots) in the lamellipodium of live cells and correlated that with actin barbed end distribution in live cells labeled with TRITC-kabramide1c and with F-actin distribution in fixed cells labeled with phalloidin. In stationary cells we found a dramatic enhancement in the concentration of large soluble probes compared to smaller ones at the lamellipodial periphery, suggesting that the effective pore size was larger there. This peripheral enhancement correlated with more organized and slightly lower density of F-actin and a higher concentration of barbed ends We also observed an enhancement of large soluble probes at the leading edge of some moving cells. This correlated with a higher concentration of barbed ends but not with changes in the overall F-actin distribution, again demonstrating the influence of local actin meshwork structure on the distribution of inert soluble components. Our results reveal a substantial degree of heterogeneity within the lamellipodium and indicate that in both stationary and moving keratocytes there are at least two distinct structures in the lamellipodium.

229 Ena/VASP Anticapping Activity Modulates Cell Morphology and Migration
C. I. Lacayo,1 Z. Finchus,1 M. van Duin2,1 C. Wilson,1 D. Fletcher,1 F. Gertler,1 A. Mogilner,1 J. A. Theriot1; 1Biochemistry, Stanford University, Stanford, CA, 2Bioengineering, University of California at Berkeley, Berkeley, CA, 3Biological, Massachusetts Institute of Technology, Cambridge, MA, 4Mathematics and Center for Genetics and Development, University of California at Davis, Davis, CA

Variations in cell migration and morphology are consequences of changes in underlying cytoskeletal organization and dynamics. Since Ena/VASP proteins play critical roles in cell migration and actin dynamics, we examined their role in the migration and morphology of fish epithelial keratocytes, which are among the fastest locomoting eukaryotic cells. Keratocytes have broad, flat lamellipodia and generally migrate persistently in a gliding fashion while exhibiting a characteristic smooth-edged “canoe” shape, but they may also exhibit less regular morphologies with rougher edges and less persistent movement. We found that VASP strongly localizes as a thin line at the “smooth” but not “rough” leading edges in lamellipodia. Ena/VASP mislocalization and overexpression altered the proportion of “smooth” and “rough” keratocytes within a population as well as trajectory curvature. When different keracteyte morphological and behavioral features were examined quantitatively, we found that they correlated with each other and described a spectrum of coordinated phenotypes. One extreme of this spectrum contained canoe-shaped, smooth-edged, fast, straight moving keratocytes with high VASP and peaked F-actin distributions along the leading edge. The opposite extreme encompassed more circular-shaped, rough-edged, slow, turning keratocytes with low VASP at the leading edge and flat F-actin distributions. We termed these extremes of the spectrum “coherent” and “decohere,” respectively, and found that individual cells could be converted from “coherent” to “decohere” behavior by increasing actin barbed end capping activity. After mechanically displacing VASP from the leading edge by stalling protrusion, we observed that the leading edge of nascent lamellipodia accumulated VASP in irregular protruding microregions that subsequently matured into “smooth” morphology. We have developed a mathematical model that fully accounts for the observed spectrum of coordinated cell morphologies and movement behaviors as a function of leading edge by stalling protrusion, we observed that the leading edge of nascent lamellipodia accumulated VASP in irregular protruding microregions that subsequently matured into a smooth-edged, slow, turning keratocytes with low VASP at the leading edge and flat F-actin distributions. We termed these extremes of the spectrum “coherent” and “decoherent,” respectively, and found that individual cells could be converted from “coherent” to “decoherent” behavior by increasing actin barbed end capping activity. After mechanically displacing VASP from the leading edge by stalling protrusion, we observed that the leading edge of nascent lamellipodia accumulated VASP in irregular protruding microregions that subsequently matured into “smooth” morphology. We have developed a mathematical model that fully accounts for the observed spectrum of coordinated cell morphologies and movement behaviors as a function of leading edge.

230 A Computational Model for the Cell Adhesion Clutch: Theoretical Prediction and Direct Observation of Substrate Oscillations
C. E. Chan, D. J. Odde; Biomedical Engineering, University of Minnesota, Minneapolis, MN

F-actin retrograde flow and localized traction forces are prominent features of the exploratory, leading edge structures of many cells undergoing substrate-dependent motility. The motor-clutch hypothesis of cell motility explains these features by assuming that F-actin networks are pulled rearward by myosin motors, molecular clutches engage the network and transmit traction forces to the substrate to drive the cell forward. To investigate the relationship between retrograde clutch flow and traction forces, we constructed a computational model for the motor-clutch system by assuming: 1) a force-dependent motor sliding velocity, and 2) spring-like molecular clutches that fail in a force-dependent manner. We found that the model successfully replicates the F-actin retrograde flow velocities that we observed experimentally in filopodia of GFP-actin-transfected embryonic chick forebrain neurons (ECNFs) growing on polyethyleneimine-coated glass substrates. Although the vast majority of cell migration studies have been conducted on such stiff glass substrates, cells crawl over substrates of far lower stiffness in vivo. Interestingly, under these in vivo conditions, the model predicts that the system develops traction forces that are periodically lost as clutches abruptly lose engagement. This causes the underlying substrate to repeatedly load and relax, a behavior we refer to as substrate oscillation. To test whether oscillations occur on soft substrates, we plated ECNFs on soft polyacrylamide gel substrates embedded with fluorescent beads and found that beads near filopodia oscillated (period of ~10-100 seconds) as predicted by the computational model. The model also predicts that the retrograde flow rate on soft substrates will be reduced, compared to stiff substrates, which was confirmed experimentally. Further computational studies revealed that maximal force transmission, minimal...
Coordinating Actin Meshwork Flow during Persistent Cell Movement and Turning
C. A. Wilson,1 P. T. Yam,2 L. J.3 G. Danuser,4 J. A. Theriot1; 1Biochemistry, Stanford University, Stanford, CA, 2Cell Biology, The Scripps Research Institute, La Jolla, CA

The persistent movement of crawling cells depends on the proper spatial coordination of actin polymerization, actin depolymerization and myosin contraction, with actin polymerization biased toward the cell’s leading edge and myosin contraction strongest at the rear. We characterize the coordination of F-actin flow dynamics across regions of cells undergoing different movement behaviors such as transient and sustained turns, and in the presence of drugs such as the myosin-II inhibitor blebbistatin. Notably, ciliated keratocytes moving at steady state do not lose polarity or stop moving when treated with blebbistatin alone. However, when jasplakinolide, which slows actin depolymerization, is combined with blebbistatin, cell motion and actin movement cease. This arrest cannot be achieved in these cells by treatment with jasplakinolide alone, but is a synergistic effect of the two drugs. This suggests that myosin activity contributes to rear retraction and forward movement not by directly pulling the cell rear forward but by promoting actin meshwork disassembly in the rear. Myosin activity is also implicated in directional persistence, which is altered in the presence of blebbistatin. We propose that imbalances in myosin-driven contractility and/or meshwork disassembly at the cell rear may contribute to changes in cell orientation and movement direction, and may be involved in coupling orientation with direction such that the cell maintains its shape even as it turns. Overall these results demonstrate that events at the rear of the cell are critical to the overall coordination of cytoskeletal organization and dynamics in cell motility, contributing to persistent forward motion and choice of direction.

The Initiation of Cell Polarization Involves Asymmetry of Actin Retractosome Flow, Which Depends on Myosin Activity, and Is Stabilized by Microtubules
S. Bohet1, S. Schub,2 J. Meister,1 A. B. Verkhovsky1; 1Lab of Cell Biophysics, Swiss Federal Institute of Technology, Lausanne, Switzerland, 2UMR 144, Institut Curie, Paris, France

Cell polarization and directional locomotion are believed to involve asymmetry in actin assembly, contractility, and substrate adhesion. We investigated how this asymmetric behavior first develops during random polarization of fish epidermal keratocytes, which were rendered isotropic and then induced to polarize by first depleting and subsequently restoring bivalent cations in culture media. We analyzed the distribution and dynamics of actin and myosin II using fluorescence speckling, conventional fluorescence microscopy and computer tracking, and studied the dynamics of substrate adhesions with interference reflection microscopy. In the isotropic state, the cells exhibited lamellipodia with the uniform rate of actin retractosome flow all around the cell perimeter. Upon initiation of directional movement, retractosome flow accelerated at the prospective rear of the cell, but the lamellipodia initially persisted all around the perimeter. The assembly of actin network also continued all around the cell. Surprisingly, the rate of network extension (calculated as the sum of the rate of advance of the cell edge and the rate of actin retractosome flow) was even higher in the rear lamellipodia than in the front lamellipodia. In contrast to the smooth lamellipodia at the cell front, the lamellipodia at the rear developed filopodia-like ridges, which transformed into the retraction fibers when the rear lamellipodia eventually retracted. Interference reflection microscopy indicated local areas of detachment from the substrate at the base of rear lamellipodia. Treatment with myosin inhibitor blebbistatin blocked the polarization nearly completely, while depolymerization of microtubules with nocodazole resulted in attenuated polarization, which was usually preceded by a stage when protrusion/retraction wave traveled around the cell periphery without net cell movement. The results suggest that initial polarization results from asymmetry in actin retractosome flow, which is induced by myosin-dependent contraction and stabilized by microtubules. Supported by Swiss National Science Foundation.

Modeling Yeast Cell Polarization Induced by Pheromone Gradients
T. Yi, Developmental and Cell Biology, UCI, Irvine, CA

Yeast cells respond to spatial gradients of mating pheromones by polarizing and projecting up the gradient toward the source. It is thought that they employ a spatial sensing mechanism in which the cell compares the concentration of pheromone at different points on the cell surface and determines the maximum point, where the projection forms. Here we constructed a spatial mathematical model of the yeast pheromone response that describes the dynamics of the heterotrimeric and Cdc2p G-protein cycles, which are linked in a cascade. Two key performance objectives of this system are (1) amplification -- converting a shallow external gradient of ligand to a steep internal gradient of protein components and (2) tracking -- following changes in gradient direction. We used simulations to investigate amplification mechanisms that allow tracking. We identified specific strategies for regulating the spatial dynamics of the protein components (i.e. their changing location in the cell) that would enable the cell to achieve both objectives. We have experimentally examined some of the modeling predictions.

Polarization of Yeast Cells in Microfluidically-Generated Spatial Alpha-Factor Gradients
T. Yi1, T. I. Moore,1 N. Jeon2; 1Developmental and Cell Biology, UCI, Irvine, CA, 2Biomedical Engineering, UCI, Irvine, CA

Yeast cells were exposed to spatial gradients of alpha-factor generated in microfluidics chambers. Segall was the first to report this type of response in yeast using a micropipette to administer the alpha-factor. Microfluidics offer the advantage of greater control over the properties of the gradient. We reproduced many of Segall’s findings, verifying that wild-type cells have the capability of detecting shallow gradients over a broad range. We compared the response of cells containing mutations in the pheromone response pathway versus wild-type cells. In addition, we found that yeast will employ alternative strategies to improve the accuracy of the gradient-sensing. Finally, we imaged specific proteins tagged with GFP to determine if localization of mating response components are similar to yeast cells exposed to uniform alpha-factor.

The Cell Polarity Protein Par-1 Regulates Cell Migration and Adhesion in Drosophila
J. A. McDonald,1 C. Brooks1, D. J. Montell1; 1Dept. of Molecular Genetics, Cleveland Clinic Foundation, Cleveland, OH, 2Dept. of Biological Chemistry, Johns Hopkins University School of Medicine, Baltimore, MD

The serine/threonine kinase Par-1 (also known as MARK/EMK/KIN1) plays a well-conserved role in regulating the polarity of many cell types in species as diverse as C. elegans, Drosophila, Xenopus, mice, and humans. In addition, Par-1 homologs are known to regulate microtubule stability and Wnt signaling. Here, we present the finding that Drosophila Par-1 regulates the migration of border cells, a group of cells that undergoes a process analogous to tumor invasion and metastasis. In a genetic screen, we identified three alleles of par-1 that disrupted border cell migration. Further analysis revealed that about half of border cells mutant for par-1 failed to detach properly from the epithelium. In addition, clonal analysis indicated that par-1 functions in both border cells and adjacent epithelial cells. While Par-1 protein localized to the basolateral membrane of all epithelial and border cells, a phosphorylated form of Par-1 was specifically enriched in migrating border cells. This phosphorylation site is important for Par-1 function, because expression in the ovary of the non-phosphorylatable mutant form of Par-1 resulted in both border cells and adjacent epithelial cells. While Par-1 protein localized to the basolateral membrane of all epithelial and border cells, a phosphorylated form of Par-1 was specifically enriched in migrating border cells. This phosphorylation site is important for Par-1 function, because expression in the ovary of the non-phosphorylatable mutant form of Par-1 resulted in both border cells and adjacent epithelial cells. This arrest cannot be achieved in these cells by treatment with jasplakinolide alone, but is a synergistic effect of the two drugs. This suggests that myosin activity contributes to rear retraction and forward movement not by directly pulling the cell rear forward but by promoting actin meshwork disassembly in the rear. Myosin activity is also implicated in directional persistence, which is altered in the presence of blebbistatin. We propose that imbalances in myosin-driven contractility and/or meshwork disassembly at the cell rear may contribute to changes in cell orientation and movement direction, and may be involved in coupling orientation with direction such that the cell maintains its shape even as it turns. Overall these results demonstrate that events at the rear of the cell are critical to the overall coordination of cytoskeletal organization and dynamics in cell motility, contributing to persistent forward motion and choice of direction.
polarized. Our previous data showed that Rho/ROCK inhibited cultures migrate farther and faster as observed with Wnt inhibition data, but outgrowth cells are not polarized. Currently we are investigating the source and type of Wnt responsible for F9 parietal endoderm migration and plan to perturb other modulators of the PCP pathway.

S-adenosylhomocysteine Hydrolyase Concentration with F-actin at the Front of Chemotaxing Dictyostelium and Neutrophils Suggests a Role for Transmethylation during Chemotaxis S. Shu, X. Liu, D. Mahadeo, C. A. Parent, W. Liu, E. D. Korn; Laboratory of Cell Biology, NHLBI, NIH, Bethesda, MD, Laboratory of Cellular and Molecular Biology, NCI, NIH, Bethesda, MD

Bacterial chemotaxis requires regulated methylation of chemoreceptors. However, despite considerable effort in the 1980s, transmethylation has never been established as a component of eukaryotic cell chemotaxis. S-adenosylhomocysteine (SAH), the product formed when the methyl group is transferred from the universal methyl donor, S-adenosylmethionine, to an acceptor molecule, is a potent inhibitor of all transmethylation reactions. In eukaryotic cells, this inhibition is relieved by hydrolysis of SAH to adenosine and homocysteine, a reaction catalyzed by S-adenosylhomocysteine hydrolase (SAHH). Therefore, SAHH is an important component of the methylation machinery. Recent studies showed that SAHH is sequestered into actin rods in Dictyostelium spores but diffusely distributed in the cytoplasm of vegetative amoebae. We have confirmed, by immunofluorescence microscopy and live cell imaging of GFP-fused SAHH, the diffuse distribution of SAHH in the cytoplasm of non-motile cells, but find that SAHH concentrates with F-actin at the front of motile, chemotaxing Dictyostelium amoebae and human neutrophils. Interestingly, SAHH concentrates in pseudopods but not in filopodia or at the very leading edge, in contrast to coronin, an F-actin binding protein that localizes with F-actin in all these regions. Tuberculid, an inhibitor of SAHH, substantially inhibits chemotaxis of Dictyostelium and neutrophils at concentrations that have little effect on cell viability. This inhibition is specific as tuberculid does not inhibit phagocytosis or capping of concanavalin A receptors in Dictyostelium, nor does SAHH localize with F-actin in either of these activities. Tuberculid treatment does not affect the starvation-induced expression of the cAMP receptor, cAR1, nor does it affect the ability of cAMP to activate adenyl cyclase activity and polymerize actin in Dictyostelium. These results add SAHH to the list of proteins that redistrubute in response to chemotactic signals, and strongly suggest a role for transmethylation in chemotaxis of eukaryotic cells, although the methyl acceptor(s) has yet to be identified.

Embryonic morphogenesis requires the coordinated polarization of cells and tissues. We are using the morphogenic movements of the C. elegans embryonic epidermis as a model system to understand the initiation of polarity in migrating tissues. These movements include cell shape changes and migrations of the epidermal tissue as it encloses the football-shaped C. elegans embryo. We have identified mutations that affect these initial polarization of the cells that allows directed tissue movement, but they do not interfere with the cell identity of the tissue. This allows us to test a fundamental question in developmental biology: how are tissues that have assumed the correct cell fate polarized to move during morphogenesis? Some of the genes we have identified encode homologs of the WAVE/SCAR complex that regulates actin dynamics in multicellular organisms from plants to humans. Others genes we have identified are not yet molecularly identified but likely represent newly discovered regulators of the complex. Our phenotypic studies suggest all of the WAVE/SCAR components contribute to complex function. In vivo imaging suggests that epithelial cells can form protrusions but they fail to migrate, suggesting a more specific roles for these regulators of the Arp2/3 complex in actin regulation during morphogenesis. Our biochemical studies suggest that all components of the WAVE/SCAR complex contribute to complex stability while some complex components appear to be modified but only when they are in the complex. These studies suggest that some of the regulation of the WAVE/SCAR complex components may be due to in vivo modifications that regulate the activity of individual components of the WAVE/SCAR complex. Supported by grants from the American Heart Association (00415424T).

The Regulation and Function of Lamellipodin in Directed Cell Migration M. Michael, M. Krause; Randall Division of Cell and Molecular Biophysics, King's College London, United Kingdom

Lamellipodin (Lpd), a member of the MRL (MIG-10, RIPM, Lamellipodin) family of proteins is localised at the leading edge of migrating cells. It contains a Ras GTPase and a phospholipid binding domain that is specific for PI(3,4)P2. Furthermore Lpd interacts with Efa/VASP proteins, important regulators of the actin cytoskeleton. There is good evidence that both Ras GTPases and 3' phosphorylated inositol lipid products are required for the establishment of cell polarity downstream of chemotactic receptors. Therefore, Lpd may link membrane signals from chemotactoic receptors to direct effectors of the actin cytoskeleton. The aim of this study is to investigate the role of Lpd in directed cell migration and the mechanisms by which upstream signals regulate its function. We are using biochemistry and functional studies to unravel the mechanism by which Lpd is regulated either through its interaction with Ras GTPases or by phosphorylation. Lpd has been implicated in the regulation of lamellipodial protrusion, an important step in cell migration. We generated Lpd overexpression and knockdown Rat2 fibroblasts cell lines to test the role of Lpd in directed cell migration using video microscopy imaging techniques in the scratch/wound healing assay. Our results suggest that Lpd plays an important role in directional cell migration.

A Phosphorylation-independent Mechanism of Cofilin Activation Involving PIP; during EGF-stimulated Carcinoma Cell Motility J. van Rheezen, Anatomy & Structural Biology, Albert Einstein College of Medicine, Bronx, NY

Lamellipodial protrusion and directional migration of carcinoma cells towards chemoattractants depend upon the spatial and temporal control of actin dynamics. Cofilin, an actin severing protein, has been implicated to be important for the initial steps of actin remodeling in response to epidermal growth factor (EGF). However, the spatial and temporal control of cofilin activity during chemotaxis is not fully understood. In contrast to neutrophils and other motile cells, cofilin is initially activated following EGF stimulation of carcinoma cells by a mechanism that does not involve serine 3 dephosphorylation (Song et al. (2006) J. Cell. Sci. 119:2871). Alternatively, in vitro studies have suggested that the plasma membrane phospholipid PIP2; inhibits cofilin’s severing activity, however, this regulatory mechanism has not been demonstrated to be important in cells. Using several chemical and biophysical techniques, we have identified a membrane-bound fraction of cofilin in carcinoma cells. Upon EGF-stimulation, PIP2; is rapidly hydrolysed, resulting in the release of the membrane-bound fraction of cofilin, and subsequent increase in cofilin severing activity. In conclusion, we propose that the initial activation of cofilin after EGF involves the release of a pool of membrane-bound cofilin through PLC-dependent PIP2; hydrolysis thereby determining the direction of cell motility in metastatic cancer cells.

Cytosplastic Polyadenylation Element Binding Protein Regulates Beta Catenin Synthesis and Localization to the Leading Edge of Migrating Astrocytes K. J. Jones, E. Korb, D. G. Wells; MCDL, Yale University, New Haven, CT

Directed cell migration involves the coordination of several cellular processes including cell polarization, the rearrangement of cytoskeletal elements, and the clustering of signaling components to the leading edge. One such protein that localizes to the leading edge of a migrating cell is beta catenin (Etienn-Manneville and Hall 2003). Since beta catenin has many diverse functions in the cell, we investigated whether this increase in beta catenin protein could be the result of local mRNA translation at the leading edge. Using in situ hybridization, we show that beta catenin mRNA is localized to the leading edge of migrating astrocytes, where it co-localizes with the RNA binding protein cytoplasmic polyadenylation element binding protein (CPEB). Further, we demonstrate that the increase in beta catenin protein at the leading edge is a result of new mRNA translation. CPEB binds to the 3'-untranslated region of specific mRNAs, and regulates translation by controlling polyadenylation. Therefore, we examined the poly(A)-tail length of beta catenin mRNA and show an increase in polyadenylation precedes beta catenin protein localization. Consistent with this, a polyadenylation inhibitor, cordycepin, blocks beta catenin protein localization to the leading edge. Finally, expression of a dominant negative CPEB mutant protein also inhibits localization of beta catenin protein to the leading edge. These results suggest a role for CPEB mediated local protein synthesis in astrocyte migration.

Investigating the Role of the Arp2/3 Complex during C. elegans Gastrulation M. Rob, B. Goldstein; University of North Carolina, Chapel Hill, NC

243

Dictyostelium discoidium signaling during chemotaxis.
Cellular actin architecture is remodeled based on signalling events and upstream actin regulators in diverse cell types. One such regulator is the Arp2/3 complex. This complex acts to nucleate new actin filaments off existing actin filaments and, thus, affects overall actin organization. In C. elegans, actin organization is regulated by the expression of two endosomal precursor cells, Ea and Ep. The apical region of the E cells construct, thereby pulling in the neighboring cells such that they cover the E cells as the E cells ingress into the interior (Lee and Goldstein, 2003). In addition, myosin is also activated in the apical region of the E cells, as indicated by an accumulation of phosphorylated myosin light chain (Lee et al., submitted). Depleting C. elegans Arp-related proteins, ARX-2 and ARX-3, result in gas- trulation defects. In these embryos, gastrulation is not initiated and the E cells divide on the surface of the embryo (Severson et al., 2002). Currently, the effects of Arp2/3 components on the actin cytoskeleton and/or polarity of the cells, particularly Ea and Ep, are unknown. However, our preliminary evidence suggests that active myosin still accumulates in the apical region of the E cells, but the E cells still fail to ingress (D. Marston, pers. comm.). Using a combination of live and fixed microscopy, we are determining whether the polarity is altered in Ea and Ep. We are also determining which cells require Arp2/3 function through blastomere isolation techniques, and we are analyzing the effects of depleting Arp2/3 components on actin architecture.

FRAP Experiments Reveal Differences in Binding Rates of PTEN between Front and Back of Polarized Dictyostelium Cells

L. Yang, 1 C. Janetopoulos, 1 P. N. Devreotes, 2 P. A. Iglesias; 1Electrical Engineering, Johns Hopkins University, Baltimore, MD, 2Biological Sciences, Vanderbilt University, Nashville, TN, 3Cell Biology, Johns Hopkins Medical Institutions, Baltimore, MD

Dictyostelium cells are able to sense shallow chemotactic gradients and respond with highly polarized changes in cell morphology and motility during chemotaxis. The complementary regulation of PKB/Akt and PTEN binding sites through parallel Local Excitation and Global Inhibition (LEGI) mechanism is able to account for the spatially amplified PTEN(3,4,5)P3 response observed in Latrunculin-treated Dictyostelium cells. However, models based on this complementary regulation do not exhibit the same degree of polarized response measured in moving cells. We hypothesized that differences between polarized and unpolarized cells in the binding rates of these enzymes could account for the observed differences in the amplification. To test this hypothesis we measured the binding rates of PTEN using Fluorescence Recovery After Photobleaching (FRAP). In vegetative and unpolarized cells we found two distinct populations differentiated by the binding rates: approximately 75% of PTEN had binding off rates with a time constant of ~6 seconds; the remaining fraction of PTEN had sub-second binding off rates. In polarized cells, we again observed two populations. However, the relative fraction between fast and slow binding off rates differed significantly between the front and rear of the cell. These results suggest a model in which PTEN(3,4,5)P3, found in greater abundance at the anterior part of the cell, regulates the binding rate of PTEN, making PTEN less abundant at the front. Mathematical models reveal that this positive feedback scheme can increase the degree of PT(3,4,5)P3 amplification by up to 50%. It is reasonable to suppose that other feedback pathways also exist and would act to improve the amplification factor.

Quantitative Analysis of Chemotactic Responses in C. Elegans

C. Janetopoulos, M. Sammons, C. Elzie; Biological Sciences, Vanderbilt University, Nashville, TN

Chemotaxis is an important cellular response that mediates cell movements during development and the immune response and is a critical factor in many forms of cancer and disease. Experiments in the social amoeba, D. discoideum and neutrophils have shown that local accumulations of PI(3,4,5)P3 mediate the ability of cells to migrate directionally. During directional sensing, it is a discrete step in the signaling pathway, downstream of G protein activation but upstream of the accumulation of PI(4,5)P2, that controls the initial asymmetry. We have previously shown that the localization is dependent on the relative chemotactant gradient, and the final distribution of PI(3,4,5)P3, is amplified, even without the presence of an actin cytoskeleton. Various stimuli paradigms on latrunculin treated cells can lead to bi-modal responses, which can be extinguished and redistributed by shifting the concentration gradients. The enzymes PI3K and PTEN regulate local levels of PI(3,4,5)P3 and move to the anterior and posterior of the cell, respectively. This PI(3,4,5)P3 polarization circuit is essential for proper migration and disrupting the regulation of these enzymes has the ability to completely change cell morphology and reduce motility. We have previously characterized these PI(3,4,5)P3 responses by quantitatively measuring the dynamic distribution of GFP-tagged signaling markers in a rapid perfusion chamber and by the use of multi-stimulus inputs. Our results suggest that a local excitation, global inhibition mechanism is at work during gradient sensing.

Physical Obstacles Redirect PIP3, Distribution and Migration of Chemotaxing Cells

M. M. vanDuijn, 1 J. A. Theriot, 1 D. A. Fletcher; 1Dept of Bioengineering, UC Berkeley, Berkeley, CA, 2Dept of Biochemistry, Stanford University, Stanford, CA

Migrating cells navigate through challenging environments in order to reach their destination. Chemical gradients can provide cues to the cell for directional control, but cells in vivo are often prohibited from taking a direct path to the source of the chemotactant. This can require navigating around physical structures the cell encounters. Not much is known about the way structural features affect the migration of chemotaxing cells, nor about how the signaling pathways that specify polarity adapt to changes in the physical environment. Here, we investigated HL-60 cells chemotaxing on a micropipette with a chemotactant on a substrate decorated with a maze of microfabricated obstacles. When the obstacles prevented movement along a direct path towards the source, we found that the cells could circumnavigate the obstacles by tracing their edge, which required migrating at an angle to the gradient. In freely chemotaxing cells, phosphorylatedinositol-3,4,5-trisphosphate (PIP3) is enriched at the leading edge of the cell, facing towards the gradient. Using a fluorescent probe, we investigated the distribution of PIP3 in cells tracing the edge of an obstacle. The formation of PIP3 by phosphatidylinositol-3-kinase, is directly downstream of the chemotactant receptor. Interestingly, we found that PIP3 was enriched at the leading edge of these cells, rather than remaining oriented towards the chemical gradient. This observation shows that the contact with a physical structure can affect the signal that generates PIP3, and specifies the direction of migration. We propose that these effects are due to the actin-dependent positive feedback loops that enhance PIP3 polarization. As actin is prevented from polymerizing by the presence of a barrier, the feedback loop is disrupted. Positive feedback can then reinforce polymerization at sites that do allow productive protrusion. At chemotactic edges, a combination of physical cues create a direct path towards the source when possible, and navigation around obstacles when necessary.

Dynamics of PI3K- and PKC-dependent Motility Processes during Cell Spreading

M. Weiger, J. Haugh; North Carolina State University, Raleigh, NC

Cell spreading and migration involve surface attachment and cytoskeletal reorganization, leading to membrane extension and ultimately cell polarization, processes that are stimulated and coordinated through intracellular signal transduction pathways. In fibroblasts and many other cells, activation of the phosphoinositol-3-kinase (PI3K) pathway is required for motility. PI3Ks generate several lipid products, which act as downstream second messengers, and the spatial pattern of 3' PI density in the membrane is thought to control the directionality of membrane protrusion and cell migration. Using total internal reflection fluorescence microscopy in conjunction with a fluorescent 3' PI probe, we have observed spontaneous activation of PI3K during spreading of mouse fibroblasts that is independent of integrin-mediated adhesion (fibronectin vs. poly-lysine) and is frequently localized to areas of active, membrane protrusion. Inhibition of PI3K blocks active cell spreading, whereas inhibition of actin polymerization halts spreading but not PI3K signaling. Inhibition of phosphatidylcholine polymerization gives rise to a dynamic motility phenotype that is also sensitive to PI3K inhibition. Inhibiting protein kinase C (PKC), isoforms of which are known mediators of PI3K signaling, prevented cell spreading and, surprisingly, led to a significant decrease in PI3K activity that could not be rescued by stimulation with platelet-derived growth factor. The kinetics of these effects suggests roles of PKC both upstream and downstream of PI3K. Taken together, we conclude that PI3K and PKC are spontaneously and dynamically activated during cell spreading, in a manner that is independent from known receptor-mediated stimulation or feedback from F-actin/microtubules, and PI3K/PKC signaling is required for actin-based protrusion.

PKA Regulates Phospholipid Dynamics during Growth Factor-induced Membrane Ruffling

P. B. Deming, S. L. Campbell, L. C. Baldor, A. K. Howe; Pharmacology, University of Vermont, Burlington, VT

Previously, our laboratory has shown that the activity of the CAM-dependent protein kinase (PKA) is required for chemotactic cell migration. PKA plays an important role in growth factor-induced cytoskeletal re-organization in part by sustaining the activity of Rac at the leading edge. Consistent with these findings, live cell imaging revealed that inhibition of PKA activity significantly altered the dynamics of PDGF-induced peripheral membrane ruffles. Given the established role for phospholipids in membrane and cytoskeletal dynamics during ruffling, the connection between PKA and phospholipid metabolism in growth factor-stimulated cells was investigated. Imaging of live cells expressing the PH domain of PLC-gamma suggested that inhibition of PKA activity decreased the dynamics of phosphatidylinositol-4,5 bisphosphate (PIP2) in PDGF-induced membrane ruffles. Immunofluorescence of fixed cells using a PIP2
antibody inhibition that showed that PKA attenuated PDGF-induced accumulation of PI(2) while arrest activation of PKA by treatment with forskolin enhanced basal PI(2) immunoreactivity in the absence of growth factor. Moreover, PI(2)K, an enzyme that regulates PI(2) synthesis, was markedly enriched and phosphorylated by PKA in pseudopodia purified from chemotactic cells. Assessment of phosphatidylinositol 3, 4, 5 triphosphate (PI(3)P) via immunofluorescence demonstrated that PKA can also modulate PI(3)P levels. Pretreatment of cells with forskolin dramatically increased PI(3)P localization to membrane ruffles following PDGF stimulation, while inhibition of PKA reduced the levels of PDGF-induced PI(3)P. Together, the data support a model in which PKA can govern phospholipid dynamics at the leading edge which may, in turn, regulate growth factor-induced membrane ruffling during cell migration.

Light-induced Repression of Direction Change during Diatom Movement
S. A. Cohn, D. Hans, K. Marabar, J. E. Shurbo; Biology, DePaul University, Chicago, IL
Previous work has indicated that exposure to high irradiance light at the leading tips of moving diatoms can induce a reversal of cell direction (Diat. Res. 19:167). Initial characterization has shown that several different diatom species display this behavior, each with species-specific sensitivities to the wavelength of the irradiating light. Our current work has shown that generation of a light-induced direction change represses additional direction changes in the cell for about one minute and that high irradiance exposure to the trailing end of moving diatoms can similarly repress subsequent light-stimulated direction changes for about one minute. In addition to tracking the cell migration, the fluorescence intensity of nuclear H2B-GFP provided a DNA analog for tracking ploidy through the cell division cycle. We extend the algorithms to hESCs to track their migration and establish cell lineages during differentiation. In contrast to the 3T H2B-GFP model, differentiating stem cell colonies are usually composed of all cell layers and cell types. In particular, we have observed and immunohistochemically verified differentiation of hESCs into endothelial blood vessel-like structures as well as neurons. To investigate formation of these biological units, we acquired three-dimensional time-lapse (3-D) movies of H2B-GFP-transfected differentiating hESCs and generated "migration maps". We also incorporated deconvolution methods to assist in removing out-of-focus light per z-plane, which aids in subsequent image processing routines in Matlab for the generation of 3-D tracks and cell lineages.

Migrational Behavior of Differentiating Human Embryonic Stem Cells in Culture
J. Russo, N. Pirozhina, A. Pekurovsky, J. Price; Barnham Institute for Medical Research, La Jolla, CA
Differentiation of human embryonic stem cells (hESC) in culture most likely follows a subset of developmental codes that the inner cell mass executes during embryogenesis. It is known that during normal development, the cells composing the inner cell mass undergo coordinated migration and differentiation program. While studying embryodiff culture is fairly difficult, analysis of hESCs behavior in culture provides a simplified model system to investigate the relationship between migration and differentiation. We previously (Shen et al, 2006) developed automated tracking algorithms and demonstrated them on multi-field two-dimensional time lapse movies of 3T3 cells expressing fluorescent marker histone 2B-GFP (H2B-GFP). In addition to automatically tracking the cell migration, the fluorescence intensity of nuclear H2B-GFP was used as an analog for tracking ploidy through the cell division cycle. Recent evidence indicates that chemotaxis requires spatial regulation of signals that drive morphological polarization characterized by the formation of a leading pseudopodium and a rear cell body compartment. Howev
by the breakdown of the paternal and maternal pronuclei. This data suggests that Aurora-A acts as, or is directly responsible for, a soluble signal at centrosomes that promotes timely NEBD.

Centrosome Attachment to the Nucleus Requires the SUN-1 Mediated Localization of ZYG-12 to the Outer Membrane of the Nuclear Envelope

I. Minn, C. J. Malone; Biochemistry and Molecular Biology, The Pennsylvania State University, University Park, PA

Although the localization of proteins specifically to the outer membrane of the nuclear envelope is thought to be required for attachment of the centrosome to the nucleus, the mechanism of this localization is unknown. Work from our lab and others has recently identified a novel class of proteins with KASH domains that specifically localize to the outer membrane of the nuclear envelope via an interaction with SUN proteins. We have shown that two isoforms of the C. elegans protein ZYG-12, which contain KASH and transmembrane domains, localize to the outer membrane of the nuclear envelope in a SUN-1 (also called MTF-1) dependent manner. ZYG-12 is required for attachment of the centrosome to the nucleus in C. elegans. Both epistasis accessibility and fluorescent protease protection assays using in vivo nuclei in combination with protease protection assays using microsomes revealed that ZYG-12 and SUN-1 are type II membrane proteins of the outer and inner membrane of the nuclear envelope, respectively. In support of ZYG-12 being a type II membrane protein, ZYG-12 physically interacts with the cytoplasmic protein dynein via the N-terminus of ZYG-12 and is required for the localization of dynein to the nucleus. SUN-1 directly interacts with KASH domain of ZYG-12. The interaction occurs between the KASH domain and the internal domain of SUN-1 as mapped by a membrane based two-hybrid assay and a pull-down assay. The functional importance of this interaction was demonstrated in vivo by driving the localization of ZYG-12 to the ER of cells expressing chimeras of SUN-1 and the ER resident protein RAMP4. ZYG-12 at the outer nuclear membrane is necessary for centrosome attachment. Our results suggest that the inner nuclear membrane protein SUN-1 confines localization of ZYG-12 to the outer nuclear membrane via direct binding in the lumen of the nuclear envelope.

255

DdCenB, an Unusual Centrin with Predominant Nuclear Localization

S. Mana-Capelli, D. A. Larochelle; Department of Biology, Clark University, Worcester, MA

Centrins are a subclass of calcium-modulated proteins with a typical array of 4 helix-loop-helix domains (EF-hands). These proteins typically localize to the centrosome and may function in centrosome duplication, among other things. In Dicystostelium discoideum, a divergent member of this family had previously been described (DdCcrp). More recently, a second centrin-related protein has been identified through the Dicystostelium genome sequencing project and has been named DdCenB (DdCrp has been renamed to DdCenA). In order to study DdCenB we have cloned and expressed the coding sequence for this protein behind the red fluorescent protein tag (RFP). Indirect immunofluorescence using anti-DdCP224 and anti-tubulin antibodies was used to visualize centrosomes. DAPI staining was carried out to visualize nuclei. Interestingly, RFP-DdCrp shows no centrosomal localization. Rather, it is found predominantly in the nucleus in interphase cells. Furthermore, this nuclear localization disappears as the cells enter mitosis (recall that Dicystostelium cells undergo a closed mitosis in which the nuclear envelope does not breakdown). DdCenA, on the other hand, does localize to the centrosome, although it also displays a cell cycle dependent re-localization in which it is lost from the centrosome during mitosis.

Identification and Isolation of Maternal Procentrosomes from Oocytes of Spisula solidissima

J. Guo, D. E. Crane, D. Hull, X. Wu, T. Ohita, R. Kuriyama, R. E. Palazzo; 1 2 Biology and Center for Biotechnology and Interdisciplinary Studies, Rensselaer Polytechnic Institute, Troy, NY, 1 Department of Molecular Biosciences, University of Kansas, Lawrence, KS, 2 Dept. of Genetics, Cell Biology, and Development, University of Minnesota, Minneapolis, MN, 3 Wadsworth Center New York State Dept. of Health, Albany, NY, 4 Marine Biological Laboratory, Woods Hole, MA

We have identified procentrosomes in oocytes of the surf clam Spisula solidissima. Oocytes are arrested at the G2/M border of meiosis I and can be activated to complete meiosis I and II by fertilization or treatment with KCl. No centrosomes have previously been identified in unactivated oocytes and de novo centrosome assembly and maturation were thought to be induced by oocyte activation. We isolated centrosomes from KCl activated oocytes (activated centrosomes) to generate anti-centrosome antibodies. Some of these recognize a 300-350 kDa centrosome protein (Spicen). Immunofluorescence with Spicen antibodies revealed the presence of two procentrosomes in oocytes. Comparison of isolated procentrosomes to activated centrosomes revealed a) procentrosomes are smaller and of lower density as determined by migration in sucrose density gradients, 2) unlike activated centrosomes, procentrosomes are unable to nucleate microtubules and 3) procentrosomes may not contain centrioles while activated centrosomes clearly do. Importantly, treatment of procentrosomes with oocyte lysate derived from activated eggs induces microtubule nucleation, while treatment with lysate from unactivated eggs has no affect. We conclude that Spisula solidissima oocytes contain maternal centrosome precursors, which we term procentrosomes, that are induced to undergo maturation upon oocyte activation. Centrosome maturation includes a) recruitment and assembly of centrosome components to increase centrosome mass, b) induction of microtubule nucleation potential, and c) the assembly and duplication of centrioles.

257

Function and Regulation of γ-Tubulin and Its Associated Proteins

B. Raynaud-Messina, C. Vérollet, N. Colombi, T. Daunon, M. Wright, A. Merdes; CRPS, UMR2587 CNRS-Pierre Fabre, Toulouse, France

γ-tubulin is critical for initiation and regulation of microtubule assembly at the centrosome. In Drosophila, it acts within two main cytosolic complexes: the γ-TuSC (γ-Tubulin Small Complex, ~300kDa) and the γ-TuRC (γ-Tubulin Ring Complex, ~3000kDa). In metazoans, it is assumed that nucleation of microtubules at the centrosome depends on the fully assembled γ-TuRC. However, the mechanisms of γ-tubulin recruitment and regulation have not been fully investigated. To approach the functional specificities of γ-TuRC components and the roles of the cytosolic complexes, we took advantage of the efficiency of RNAi in cultured cells and the availability of mutant strains. γ-TuSC proteins are essential for viability and the assembly of a functional bipolar spindle. While these proteins do not appear redundant, their levels are closely co-regulated, indicative of the importance of the integrity of this complex. In contrast in cells lacking γ-TuRC, γ-tubulin is still recruited to the poles but mitotic processes are partly disrupted, leading to a transient mitotic accumulation and a poor density of microtubules. Therefore, we suggest that, in Drosophila, organization and partial functionality of the mitotic spindle could be achieved even in the absence of fully assembled γ-TuRC. In parallel to the role of γ-TuRC in microtubule assembly, γ-TuSC could be recruited to the poles and perform at least partially microtubule nucleation activity.

258

HCα66, a Novel Centrosomal Protein Regulating γ-Tubulin Stability

X. Fant, A. Merdes; Wellcome Trust Centre for Cell Biology, University of Edinburgh, Edinburgh, United Kingdom

The centrosome is the main microtubule organising centre in metazoan cells. It contains a pair of centrioles surrounded by pericentriolar material (PCM), a fibrous mass containing proteins involved in microtubule nucleation. Several proteins of the PCM exhibit a dynamic association with the centrosome in a cell cycle dependent manner. For example, gamma-tubulin has been shown to accumulate at the centrosome before mitosis, resulting in an increase of microtubule nucleation during spindle formation. To investigate changes in the composition of the PCM during the cell cycle, centrosomes were isolated at different stages, during G1 and early S phase. Pericentriolar material was solubilised by salt-stripping of centrosomes, and analysed by gel electrophoresis followed by MALDI-TOF mass spectrometry. We identified HCα66 as a novel protein that localises temporarily to the centrosome from S to M-phase, and that also resides in the nucleus. The sequences responsible for centrosomal and nuclear localization were mapped using GFP-fusion constructs. Overexpression of the centrosome-targeting region leads to an increase in centrosome mass, b) induction of microtubule nucleation potential, and c) the assembly and duplication of centrioles.

259

NEDD1 Targets γ-Tubulin to the Centrosome in Mammalian Cells

L. Haren, M. Remy, I. Bazin, M. Wright, A. Merdes; UMR2587, CNRS, Toulouse, France
260 A Kinesin-9 Family Member Ki66 Localizes to Centrosomes and Is Required for γ-tubulin-mediated Microtubule Nucleation K. Wang,1 C. E. Walczak;1 2Department of Biology, Indiana University, Bloomington, IN, 2Medical Sciences, Indiana University, Bloomington, IN
Ki66 is a Kinesin-9 family member that has been identified in various vertebrate organisms, yet the function of Ki66 is not understood. We identified and characterized both human and Xenopus laevis Ki66. Ki66 has its conserved kinesin motor domain at the N-terminus and a non-conserved stalk-tail (ST) domain at the C-terminus, which contains two predicted coiled-coil domains. Immunofluorescence staining showed that Ki66 localized on the mother centrosome during G1 through early G2 but was found on both centrosomes at late G2/phase. As the cells entered mitosis Ki66 staining decreased at centrosomes/poles, but accumulated at midzone/midbodies during late anaphase/early telophase. Overexpression of human Ki66 constructs in U2OS and HeLa cells showed that GFP-Ki66ST localized to centrosomes better than full-length GFP-Ki66, indicating that the centrosome-targeting domain of Ki66 is contained within the ST domain. Interestingly, Ki66 overexpression caused a decrease in gamma tubulin on centrosomes, and inhibited microtubule reorganization by interphase centrosomes after cold treatment. These results suggest that Ki66 is necessary for gamma-tubulin mediated centrosomal microtubule nucleation. The overexpression of Ki66ST caused a similar albeit stronger defect, supporting the idea that the ST domain of Ki66 is required for targeting and thus the function of Ki66. Consistent with our findings in U2OS and HeLa cells, depletion of Ki66 from meiotic Xenopus egg extracts inhibited the formation of asters induced by addition of purified centrosomes. Together our data support a model in which Ki66 helps tether gamma tubulin to centrosomes via its stalk-tail domain. This activity is then critical for proper microtubule nucleation both during interphase and in mitosis.

261 γ-Tubulin Is Essential for Noncentrosomal Microtubule Nucleation P. Binarova,1 J. Pochankova,1 J. Vole,1 V. Cenklka,1 G. Pihal;1 E. Bogre;1 2Institute of Microbiology ASCR, Prague, Czech Republic, 3Institute of Experimental Botany ASCR, Oломouc, Czech Republic, 4School of Biological Sciences, Royal Holloway, University of London, Egham, United Kingdom
It has recently emerged that microtubules (MTs) nucleated independent of defined microtubule organizing centres such as centrosomes or spindle pole bodies play an important role in designing cytoskeleton architecture. γ-Tubulin is required for MT nucleation at defined microtubule organizing centres but its role in nucleation of noncentrosomal MTs is much less understood. In higher plants, where all somatic organs are flanked by a centrosomal, there are several microtubule arrays and girders, which are organized during cell cycle progression from undefined dispersed sites. Well characterized γ-tubulin ring complexes that are essential for centrosomal MT nucleation in animal cells have not yet been identified in plants. Rather we found the presence of heterogeneous protein complexes of γ-tubulin in cytoplasm, in association with membranes and MTs. Large γ-tubulin complexes (>1MD) were active in microtubule nucleation, but nucleation activity was not observed for the smaller complexes. To further analyze the role of γ-tubulin, we conditionally downregulated γ-tubulin by inducible expression of RNAi constructs in Arabidopsis thaliana. After induction of RNAi γ-tubulin was gradually depleted from all known cellular locations including the microtubular and the microtubular fraction. We found that γ-tubulin acts as a component of cortical nucleation templates guides cortical MTs. The regrowth of MTs from perinuclear membrane rich region after drug depolymerization was delayed in cells with reduced γ-tubulin levels. Similarly, immunodepletion of γ-tubulin from A. thaliana extracts strongly compromised the in vitro polymerization of MTs. Almost complete RNAi depletion of γ-tubulin led to the absence of microtubules. In summary, we showed that γ-tubulin is essential for MTs nucleation from dispersed sites in acentrosomal plant cells. Further characterization of γ-tubulin forms and their protein interactions is under progress. Supported by grants PC L54-MSMT CR and A3020302 from GA CAS.

262 Characterization of NIP2/Centrinob, a Novel Substrate of Nek2, and Its Potential Role for Microtubule Stabilization Y. Jeong, J. Lee, S. Kim, K. Rhee; School of Biological Sciences, Seoul National University, Seoul, Republic of Korea
Nek2 is a mitotic kinase whose activity oscillates during the cell cycle. It is well known that Nek2 is involved in centrosome splitting. A number of experimental evidence indicated that Nek2 is also critical for maintaining the integrity of noncentrosomal microtubule structure and the microtubule nucleation activity. In the present study, we report that NIP2, previously identified as Centrinob, is a novel substrate of Nek2. NIP2 was daughter centrosome-specific, but was also found in association with stable microtubule network of cytoplasm. Ectopic NIP2 formed aggregates but was resolved by Nek2 into small pieces and eventually associated with microtubule. Knockdown of NIP2 showed significant reduction of microtubule organizing activity, cell shrinkage, defects in spindle assembly and abnormal nuclear morphology. Based on the results, we propose that NIP2 has a role in stabilizing the microtubule structure. Phosphorylation may be critical for mobilization of the protofibril to a fresh microtubule and stabilizing it.

263 Identification and Analysis of γ-Tubulin Complex Proteins of Aspergillus nidulans Y. Xiong, T. Nayak, E. Szewczyk, H. Edgerton, B. R. Oakley; Molecular Genetics, Ohio State University, Columbus, OH
Although γ-tubulin has a well-documented role in microtubule nucleation in both animal and plant cells, its role in mitotic and cell cycle regulation, the functions of proteins that form complexes with γ-tubulin (γ-tubulin complex proteins or GCPs) are not well understood. Indeed, the complexity of γ-tubulin complexes varies among organisms. Saccharomyces cerevisiae has only two γ-tubulin complex proteins, Spc97p and Spc98p. These proteins are ubiquitous in eukaryotes and their homologs in animal cells are called GCP2 and 3. Schizosaccharomyces pombe has two additional γ-tubulin complex proteins and animals have five GCPs, homologs of GCP2 and 3 plus three additional GCPs. A search of the Aspergillus nidulans genome revealed homologs of all of five animal GCPs. We have designated these proteins AnGCP2-6. Animal γ-tubulin complexes contain an additional protein that contains WD40 repeats, but identification of an A. nidulans homolog of this protein is problematic because this motif is found in many proteins. We have confirmed that AnGCP2-6 are, indeed, γ-tubulin complex proteins by GFP tagging their C-terminal and observing their localizations in living cells by single-time-point and time-lapse microscopy. Like γ-tubulin, they localize to the spindle pole body throughout the cell cycle. To investigate their functions, we have deleted each of the genes. AnGCP2 and 3 are essential, but AnGCP4-6 are not. In vivo observations with an mCherry γ-tubulin fusion reveal, not surprisingly, that AnGCP4-6 are not required for γ-tubulin localization at the spindle pole body. Although AnGCP2 and 3 are essential, heterokaryon rescue was used to determine the effects of AnGCP2 and 3 deletions on γ-tubulin localization. Each deletion eliminated γ-tubulin localization at the spindle pole body. These data indicate that in A. nidulans, GCP2 and 3 homologs are essential for γ-tubulin localization but the other GCPs have other, inessential, functions. Supported by the NIGMS.

264 The RSA Protein Complex Targets Phosphatase Protein 2A to Centrosomes and Regulates Mitotic Spindle Assembly in Caenorhabditis elegans Embryos A. Schlaits,1 M. Srayo,1 A. Dammermann;2 N. Wielsch;3 A. Shevchenko;1 K. Oegema;2 A. A. Hyman;2 2Max Planck Institute of Molecular Cell Biology and Genetics, Dresden, Germany, 3Department of Cellular and Molecular Medicine, Ludwig Institute for Cancer Research, University of California, San Diego, CA
The microtubule cytoskeleton undergoes an extensive reorganization during the cell cycle in order to assemble the mitotic spindle. Mitotic kinases are known to regulate many events leading to spindle formation, however, little is known about their counteracting phosphatases. Moreover, it is unclear how the cell coordinates and integrates the various processes that lead to spindle formation. We have identified a Protein Phosphatase 2A (PP2A) complex in C. elegans that is required for mitotic spindle assembly. This phosphatase complex consists of the new protein RSA-1 (Regulator of Spindle Assembly 1), which is a targeting regulatory subunit for the phosphatase catalytic subunit LET-92, and the previously uncharacterized RSA-2 protein, which binds RSA-1 and thereby recruits it to centrosomes. While the PP2A catalytic subunit LET-92 has multiple functions in the early C. elegans embryo, RSA-1 and RSA-2 are specifically required for microtubule outgrowth from centrosomes and spindle assembly. The correct targeting of PP2A catalytic activity by the RSA complex may regulate these functions by controlling the localization of two key mitotic effectors, TPXL-1 and KLP-7, the C. elegans homologs of TPX2 and MCAK. The RSA complex is recruited to the centrosome by a phospho-dependent interaction with the centrosomal motor protein KLP-7 at centrosomes and might thereby allow the appropriate number of microtubules to grow out. In addition, the RSA complex recruits the critical regulator of spindle assembly TPXL-1 to centrosomes, thus promoting spindle assembly. By affecting the centrosomal localization of two essential players of mitotic spindle assembly, the RSA-PP2A complex may constitute a tool for coordinating different events in spindle assembly. In summary, we show that the RSA-1/RSA-2 protein complex recruits the PP2A catalytic subunit LET-92
to centrosomes. We suggest that this complex thereby regulates a subset of PP2A functions that coordinate microtubule outgrowth from centrosomes and kinetochore microtubule stability in the forming mitotic spindle.

265 Using Monopolar Spindles in Cenarchochitlids elegans to Study Bipolar Spindle Function

The faithful segregation of genetic material is the ultimate goal of mitosis. Cells employ a microtubule-based bipolar spindle to ensure correct chromatin separation and the production of genetically identical daughter cells. This same structure is also used to introduce an asymmetry in the size of these daughter cells by displacing slightly toward the posterior during anaphase. Thus key events in the early embryo are a result of bipolar spindle orientation and positioning. While it is assumed that the separation of the poles is largely responsible for chromatid separation in anaphase, we wanted to investigate the role of forces that might push chromatids apart independently of pole-kinetochore forces. To investigate this problem, we study chromatid movement in monopolar spindles. A temperature-sensitive mutation in the kinase ZYG-1 abrogates its activity under non-permissive conditions. Up-shifted embryos are essentially normal in the first cell division due to the sperm contributed pair of centrioles, but the lack of ZYG-1 prevents subsequent centriole duplication. Therefore daughter cells inherit only one centriole from the mother and form monopolar mitosis. Using zyg-1 (dby-1 ts) worms we observe that sister chromatids congress, align on a metaphase plate and form a monopolar spindle which is half the size of a bipolar spindle. A reproducible separation of the sister chromatids occurs and we are investigating what forces are causing this movement. We have also analysed the positioning of the single centrosome and the monopolar spindle. Each monopolar spindle in zyg-1 ts embryos is orientated orthogonal to that of the wild type spindle. Furthermore we see increased oscillations of the single centrosome in the posterior cell of a two-cell stage embryo lacking functional ZYG-1, indicating that second centrosome is required to stabilize the position of the centrosome-nuclear complex.

266 The Microtubule Anchoring Activity Is Regulated by Centrosomal Kinases
G. Mao, J. Baxter, A. M. Fry; Department of Biochemistry, University of Leicester, Leicester, United Kingdom

Centrosomes are the centre of microtubule organization in animal cells. They are essential for cell division and cell structure. Microtubule nucleates from and anchors at centrosome. This involves numerous centrosomal proteins including ninein like protein, Nlp. Nlp recruits γ-tubulin and stimulates microtubule regrowth in vivo. Nlp interacts with and is co-ordinately regulated by two centrosomal kinases, Nek2 and Pkl1. Regulation of Nlp at the transition of G2/M is important for microtubule dynamics at mitotic entry of eukaryotic cell. The coiled-coil(CC) domain of Nlp interacts with γ-tubule and is phosphorylated by Nek2 and Pkl1. Overexpression of this CC-rich domain does not affect the localization of CNap-1 but γ-tubulin and like full length wild type Nlp, its overexpression can cause dramatic reorganization of the cellular microtubule network at microtubule regrowth, which is not associated with centrosome. Importantly, this domain alone can form aggregates and be displaced from centrosome by phosphorylation of Nek2. Truncation study shows Nlp may interact with other proteins in order to anchor at centrosome. It is concluded that Nlp stimulates microtubule regrowth by recruiting γ-tubulin. This interaction is regulated by phosphorylation of Nlp CC domain by Nek2 and Pkl1. This is important for microtubule structure changes at mitotic entry that lead to the formation of the mitotic spindle.

267 A Genome-wide Visual RNAi Screen to Identify New Centrosome Components
J. Dubbelaere, J. Raff; Gordon Institute, Cambridge, United Kingdom

The centrosome is the main microtubule organising center in animal cells, and it plays an important part in cell cycle progression, organisation of the mitotic spindle and cell division. The centrosome consists of a pair of centrioles surrounded by an amorphous pericentriolar material (PCM) that is the site of microtubule nucleation. During interphase, the centrosome organises a small amount of PCM and nucleates a small number of microtubules. As cells enter mitosis, however, centrosomes "mature" and there is a dramatic recruitment of PCM around the centrioles, and the centrosomes organise many more microtubules. Our goal is to understand the function of the centrosome during the cell cycle and how it is regulated during these different phases. To identify new components and regulators of the PCM, we designed a genome-wide RNA interference screen in Drosophila S2R+ cells. Cells treated with a specific dsRNA for 4 days are stained with a Centrosomin- (Cnn, a PCM Marker) and a phospho-histon3 antibody (H3P, marks mitotic cells). We developed automated protocols to plate the cells, to microscope different wells and to score defects (using Cell Profiler). In addition, manual scoring is performed to detect subtle defects. Initial screening of the genome revealed the PP2A phosphatase as a major regulator of Centrosome function. At this stage we are completing the genomic screen and analysing PP2A centrosome function in more detail.

268 Dissecting the Centriole Proteome
L. C. Keller,1 E. Romijn,2 I. Zamir,1 R. D. Sloboda,3 J. R. Yates,2 W. F. Marshall;1 Biochemistry, UCSF, San Francisco, CA, 1Cell Biology, The Scripps Research Institute, La Jolla, CA, 2Biological Sciences, Dartmouth College, Hanover, NH

We used mass-spectrometry-based MudPIT to identify the protein composition of basal bodies (centrioles) isolated from the green alga Chlamydomonas reinhardtii. This analysis detected the majority of known centriole proteins, including centrin, epsilon-tubulin, and the cartwheel protein BLD10p. Through a bioinformatics cross-validation approach, we identified two classes of proteins: Basal-body proteins with L preregulated Genes (BUGs) and Preregulated of The Centriole proteins (P ocs). We have confirmed centriolar localization for many of the human homologs of candidate proteins in both Hela and U2OS cells. We are in the process of using microscopy, RNA-interference, and biochemical methods to examine the centriole assembly pathway in both Chlamydomonas and in centriole-overduplicating mammalian cell lines.

269 Proteomic Characterization of Tetrahymena thermophila Basal Bodies
C. L. Kilburn,1 C. G. Pearson,1 E. Romijn,2 T. Giddings,1 J. R. Yates,2 M. Winery;1 Molecular, Cellular and Developmental Biology, University of Colorado, Boulder, Boulder, CO, 1Department of Cell Biology, Scripps Research Institute, San Diego, CA

Centrosome duplication is an important event in cell cycle progression. Errors in this process are evident in the majority of tumor cells. However, centrosome duplication is not a well-understood process, partly because many of the molecular components of this organelle are not known. Centrioles form the core of the centrosome and are structurally identical to basal bodies for ciliary function. We used shotgun proteomics to define the basal body proteome in the ciliated protozoan Tetrahymena thermophila and novel components were then studied by immunofluorescence and immunoelectron microscopy. Mass spectrometry analysis of two separate basal body enrichment preparations was used to identify novel basal body proteins. First, cell cortices were isolated in wild-type cells and cells in which basal bodies had been genetically disrupted. In this approach, both samples were analyzed with Multidimensional Protein Identification Technology (MudPIT) to identify the proteins present in these complex mixtures. The identified proteins found only in the sample with basal bodies were retained for the study. Second, a basal body preparation was isolated from oral apparati, an organelle enriched for basal bodies, and subjected to MudPIT. Using the two methods a total of 357 proteins were identified. An organellar enriched fraction was used for MudPIT. The used methods a total of 357 proteins were identified. The organellar enriched fraction was used for MudPIT. The identified proteins were classified using GO Codes, homology and domain searches. We identified 97 proteins (27% of the total list) as known centriole components or potential candidate proteins in both Hela and U2OS cells. We are in the process of using microscopy, RNA-interference, and biochemical methods to examine the centriole assembly pathway in both Chlamydomonas and in centriole-overduplicating mammalian cell lines.

270 The Basal Bodies/Centrioles as a Giardia lamblia Cellular Control Center
T. Lauwaet,1 D. Reiner,1 E. Romijn,2 S. R. Birkeland,3 C. J. Michael,1 D. Palm,3 B. Davids,3 S. Pacocha,3 S. Svard,3 A. McArthur,3 J. Yates,2 F. D. Gillin1; 1Department of Pathology, Division of Infectious Diseases, UCSD, San Diego, CA, 2The Scripps Research Institute, La Jolla, CA, 3Marine Biological Laboratory, Woods Hole, MA, 5Woods Hole Oceanographic Institution, Woods Hole, MA

Eccystation and excystation are differentiations crucial to the pathogenesis of Giardia lamblia, a major protozoan cause of waterborne diarrheal disease. The signaling underlying the dramatic remodeling of the cytoskeleton throughout the giardial life cycle in response to rapidly changing signals from the host, is still poorly understood. Previous studies have shown that signaling
molecules involved in growth cessation during encystation and in the resumption of motility and cytokinesis during excystation, all localize constitutively to the basal bodies/centrioles, while their localization to other cytoskeletal structures varies. We propose that the basal bodies may be a cellular control center while other cytoskeletal elements may have specialized effector functions that are reflected in their distinct protein compositions. We isolated basal bodies from *Giardia* cytoskeletons with sucrose density fractionation. Fractions were analyzed by immunofluorescence analysis and ELISA for the presence of known giardial basal body proteins (calmodulin, PKA, PP2A and centrin). The protein composition of the basal body enriched fraction was analyzed by Multidimensional protein identification technology (MudPIT) and revealed a total of 400 proteins. Comparative genomic analysis showed that about 25% of these proteins are homologous to basal body, centrosomal, centriolar or spindle pole body proteins in other organisms. Selected proteins with no homology to any other protein were cross-validated by epitope tagging and all localize to the basal bodies. Moreover, transcriptome analysis demonstrated that 24 of the proteins found in our basal body fraction are highly upregulated in cysts and early excystation. The protein composition of the *Giardia* basal bodies will help in unraveling the complex signaling in the *Giardia* life cycle and increase global understanding of conserved basal body/centriole function.

271

**Genes Required for Basal Body Assembly Show Hypersensitivity to Taxol**

J. M. Esparza, Genetics, Washington University School of Medicine, St. Louis, MO

Basal bodies are morphologically complex structures. We identified mutations in two genes, *TNS1* and *BLD11*, through a non-complementation screen and an inserational mutant screen, which result in morphological abnormalities of basal bodies in *Chlamydomonas*. In wild-type cells, a ring of amorphous material (<40 nm in depth) assembles at the proximal end of basal bodies and we hypothesize that it participates in basal body microtubule nucleation. In the *tns1-1* strain, the amorphous material extends 200 nm throughout the length of a staggered, aberrant full-length basal body. The defect appears to arise during assembly as basal bodies have a normal ring of amorphous material. The *bld11-1* mutant strain lacks basal body microtubules but contains amorphous material. Fibers associated with the basal bodies become thicker and longer. Additionally, these mutant strains show increased sensitivity to taxol compared to wild-type cells. The *tns1-1* and *bld11-1* strain arast on taxol-containing medium at a concentration of 0.75 µg/ml, whereas wild-type *Chlamydomonas* strains arrest at concentrations of 8 µg/ml. We are currently testing if the mutant strains contain hyperstabilized microtubules using an antibody to acetylated α-tubulin and if the mutant strains are sensitive to microtubule destabilizing drugs. The mutant strain, *tns1-1*, is a linked dominant enhancer of the *bld2* mutation, which encodes α-tubulin. Interestingly, three independent fragments of DNA rescue the mutant phenotypes of *tns1-1* cells. Included in these fragments is e-tubulin, which plays an essential role in basal body assembly (Dutcher et al., 2002). Dosage-dependent suppression of the *tns1-1* mutant phenotype by a few genes may compensate for the absence of functional *Tns1p* to allow for flagellar assembly. We are currently assaying the mutant and rescued strains by immunofluorescence using antibodies to basal body proteins to interrogate the assembly process in these strains.

**Rotating of Centrioles and Detachment from the Centrosome in Drosophila centrosin (cnn) Mutants**

E. P. Lucas, J. W. Raff; Wellcome Trust/CR-UK Gurdon Institute, Cambridge, United Kingdom

Centrosomes are major organizers of animal cell division and their dysfunction has been implicated in several human diseases, such as cancer and primary microcephaly. The Drosophila Centrosin (Cnn), a putative ortholog of the human microtubule protein MCPH3/CDK5RAP2 and Myomegalin, has been implicated in centrosome organization and microtubule nucleation during mitosis, although its ability to directly recruit and anchor PCM components to the centrosome has not been demonstrated. In contrast to previous reports, here we show that PCM components can, in fact, be recruited to the centrosome in the absence of Cnn. High-resolution live imaging of several PCM markers shows that, in *cnn* mutant embryos, the PCM is initially recruited but then abnormally dispensed from the centrosome in a microtubule-dependent manner. Strikingly, dual imaging of several GFP-PCM components and GFP-centrosomes reveals that, in *cnn* mutant embryos, the centrosomes move abnormally and are not tightly linked to the PCM, in contrast to wild-type, but in most cases still remain attached to the dispersed PCM. Additionally, in live *cnn* mutant neuroblasts, centrosomes also move abnormally and are not properly positioned at the spindle poles and therefore, are unequally partitioned between dividing cells, leading to an asymmetric cell division failure. Furthermore, centriole missegregation and spindle defects occur in male meiosis. Thus, unlike what was shown previously, we demonstrate that Cnn is not required for the recruitment of PCM components to the centrosome, but instead, maintains the structural integrity of the centrosome by keeping an intact and strong connection between the centriole and the PCM.

273

**Role of Mammalian Homologues of Drosophila centrosin in Centrosome Function and Asymmetric Cell Division**

J. A. Barrera, L. K. Kao, R. E. Hammer; 1Pharmacology, UT Southwestern Medical Center, Dallas, TX, 2Biochemistry, UT Southwestern Medical Center, Dallas, TX

Autosomal recessive primary microcephaly (MCPH) is a developmental disorder resulting in the reduction of cranial circumference due to reduced development of the central nervous system, and the greatest impact on the cerebral cortex. Six genes have been linked to MCPH. Four of these encode centrosomal proteins, implicating a centrosomal mechanism underlying early neuronal development. Spindle orientation plays a key role in the process of asymmetric cell division of neural precursors, and is, in part, centrosome dependent. Studies of mutations in two MCPH gene homologues in *Drosophila* and *Disco* (homologue of *CENP-D*), did not show reduced brain size, suggesting different requirements for centrosomal proteins in these two systems. A homologue search for *Drosophila* cnn revealed two mammalian genes: Cyclin Dependent Kinase 5 Regulatory Associated protein 2 (*CDK5RAP2*) and Myomegalin. An in vivo rescue assay is being used to determine functional homology among these genes with MCPH gene homologues in *Drosophila* and *Disco*.

**MTOC Reorientation in Macrophages**

E. W. Y. Eng, A. Bettio, J. Ibrahim, R. E. Harrison; Department of Life Sciences, University of Toronto at Scarborough, Scarborough, ON, Canada

The microtubule organizing center (MTOC) plays many important roles in cells, including microtubule nucleation, organelle positioning, cell division, as well as in cell polarization during T cell activation and the migration of fibroblasts in wounded monolayers. Recently, we have observed that the MTOC in macrophages reorients during the process of phagocytosis. The MTOC movement is initiated shortly after particle binding and continues after the particle is ingested. Key cytoskeletal and signalling elements that have been previously implicated in MTOC reorientation in other cells were investigated in RAW 264.7 macrophages using transfection, immunofluorescence, live imaging, and frustation phagocytosis assays. It was found that the reorientation of the MTOC towards the phagocytic site of IgG-sheep red blood cells (sRBCs) in macrophages requires an intact microtubule and actin network. In addition, signalling elements that have been previously implicated in MTOC reorientation in other cells were investigated in RAW 264.7 macrophages using transfection, immunofluorescence, live imaging, and frustrated phagocytosis assays. It was found that the reorientation of the MTOC towards the phagocytic site of IgG-sheep red blood cells (sRBCs) in macrophages requires an intact microtubule and actin network. In addition, signalling molecules, such as cdc42 and phosphatidylinositol 3-kinase (PI3K), and the microtubule motor, dynein, all appear to contribute to MTOC reorientation in macrophages. More extensive studies are currently underway to determine the role of MTOC reorientation during phagocytosis in macrophages.

**The a and β Subunits of G, Family Heterotrimeric G Proteins Are Both Required but Function Independently to Regulate Centrosome Reorientation**

E. S. Folker, G. G. Gundersen; Anatomy and Cell Biology, Columbia University, New York, NY

Centrosome reorientation to a position at the leading edge of motile cells is among the first steps in preparation for directed cell migration. In serum starved fibroblasts, lysophosphatidic acid (LPA) stimulates centrosome reorientation via two Cdc42 regulated processes: actin dependent nuclear movement away from the leading edge and microtubule dependent maintenance of the centrosome at the cell centroid (centrosome centration) (Gomes et al., Cell, 2005). We explored the possibility that heterotrimeric G proteins were involved in centrosome reorientation given their role in spindle positioning during asymmetric cell divisions in invertebrates. Pertussis toxin (PTX), an inhibitor of G i/o family heterotrimeric G proteins, blocked centrosome reorientation by inhibiting both nuclear movement and centrosome centration. PTX prevented activation of Cdc42 GTP by LPA, yet constitutively active Cdc42 did not overcome PTX inhibition, suggesting roles for G i/o proteins both upstream and downstream of Cdc42. Experiments to perturb G protein signaling using G ao, βARK, and LGN/mPins indicated that the G and Gβγ subunits of G, regulate different facets of centrosome reorganization. Gao and the C-terminus of βARK both inhibit reorientation by blocking nuclear movement. Both reagents bind and sequester Gβγ indicating that Gβγ activity regulates nuclear movement. Expression of LGN/mPins, a protein with C-terminal GoLoco domains that bind Gao and release Gβγ, and N-terminal TPR domains that interact with other proteins, was sufficient to induce both nuclear movement and centrosome centration in the absence of LPA resulting in centrosome reorientation. The C-terminal GoLoco domains alone induced only nuclear movement, suggesting that the TPR domains are essential for linking Gao to microtubules to regulate centrosome centration. These data support a model where LPA receptor activation releases Gβγ to initiate nuclear movement. LGN/mPins then binds Gao, preventing Gβγ reassociation, maintaining Gβγ activity. Additionally LGN/mPins serves as a bridge between Gao and the microtubules regulating centrosome centration.
Vinculin is a major component of cell adhesion sites anchoring actin filaments to the adhesion plaque. The protein consists of five alpha-helical bundle domains (Vd1-Vd5), which perform an uniform gradient. In this study we propose that ablation of the centrosome will result in random migration of the structurally polarized cells as opposed to a directed migration. HL60 cells were in a uniform concentration (non-gradient) of chemoattractants have the ability to polarize and move. Previous studies have show n that microtubules control the polarity of neutrophils in such a cDNA with sequence identity to the coding region of IK1. The IK blocker clotrimazole significantly inhibited swelling-activated K+ currents, and currents were inhibited by transfection with a opening of 50 pS K+-permeable channels, suggesting the involvement of intermediate conductance (IK) channels. Consistent with I K expression, we isolated from rat liver and HTC cells a hepatocytes, the molecular characteristics of the channels involved in volume regulation have not been determined. We found that hypotonic exposure of HTC rat hepatoma cells evoked the restoration of cell volume in the continued presence of osmotic stimuli is essential, particularly in liver, which swells in response to nutrient uptake. Responses to swelling involve the Ca2+-dependent activation of K+ channels, which promote electrolyte and fluid efflux to drive volume recovery. Although several classes of Ca2+-activated K+ channels have been detected in hepatocytes, the molecular characteristics of the channels involved in volume regulation have not been determined. We found that hypotonic exposure of HTC rat hepatoma cells evoked the opening of 50 pS K+-permeable channels, suggesting the involvement of intermediate conductance (IK) channels. Consistent with IK expression, we isolated from rat liver and HTC cells a cDNA with sequence identity to the coding region of IK1. The IK blocker clotrimazole significantly inhibited swelling-activated K+ currents, and currents were inhibited by transfection with a dominant interfering mutant of IK1. Clotrimazole also inhibited volume recovery. By contrast, neither the small conductance K+ channel blocker apamin nor the large conductance K+ channel blocker tetraethylammonium chloride affected swelling-activated K+ currents. Because IK1 can be regulated by products of phosphatidylinositol kinases, which are produced in lipid rafts, we sought to determine whether IK1 and lipid rafts undergo volume-sensitive association. In HTC cells transfected with a GFP fusion of IK1, there was a time dependent increase in colocalization between IK1 and a lipid raft marker, ganglioside GM1, on the plasma membrane, which subsequently decreased with volume recovery. Treatment of cells with filipin abolished plasma membrane GM1 localization and altered the plasma membrane signal of IK from discrete patches to continuous. Filipin also led to a loss of sustained volume recovery after hypotonic exposure. Collectively, these findings support the hypothesis that IK1 regulates compensatory responses to hepatocellular swelling, and that suggestion of cell volume involves coordination of lipid raft signaling and IK function.

Centrosome Ablation in Neutrophils Affects Cell Polarity and Migration
N. M. Wakida, J. Xu, L. Z. Shi, E. L. Botvinick, A. Dvornikov, M. W. Berns, H. R. Bourne; Beckman Laser Institute, University of California, Irvine, Irvine, CA, Departments of Cellular and Molecular Pharmacology and Medicine and Cardiovascular Res. Institute, University of California, San Francisco, San Francisco, CA, Department of Bioengineering, University of California, San Diego, San Diego, CA
Pathways for initiation and regulation of neutrophil polarization and chemotaxis in response to chemoattractants are of considerable interest. Numerous studies have been undertaken to elucidate the interactions between cytoskeletal elements (actin, myosin, microtubules), various Rho proteins, and other regulatory factors that control the migration of single cells. Neutrophils in a uniform concentration (non-gradient) of chemoattractants have the ability to polarize and move. Previous studies have shown that microtubules control the polarity of neutrophils in such a way that microtubules are required for cell polarization and chemotaxis. In this study we propose that ablation of the centrosome will result in random migration of the structurally polarized cells as opposed to a directed migration. HL60 cells were differentiated to a granulocytic morphology by treatment with DMSO allowing for studies on polarization and chemotaxis. Transient transfections by electroporation with GFP-Clip170 or β-arrestin were used to label the centrosome of the differentiated cells. (Xu et al., 2005) Cells were allowed to recover and attach to fibronectin plated coverslips for 1-2 hours before laser targeting. A uniform chemoattractant was added immediately after exposure of femtosecond laser pulses to specific regions of the cell. 10 of 10 cells in which laser pulses were directed at the centrosome region failed to polarize, 5 of 5 control cells where the laser was targeted to a random region in the cytoplasm exhibited neither a change in polarization nor directed movement. These results indicate that the centrosome plays a significant role in cell polarization and subsequent cell migration.

Association of the Ca2+-activated K+ Channel IK1 with Lipid Rafts Is Required for Hepatocellular Volume Regulation
E. Barfod, A. L. Moore, M. W. Roe, S. D. Lidoňsky; Pharmacology, University of Vermont, Burlington, VT, Medicine, University of Vermont, Burlington, VT
Restoration of cell volume in the continued presence of osmotic stimuli is essential, particularly in liver, which swells in response to nutrient uptake. Responses to swelling involve the Ca2+-dependent activation of K+ channels, which promote electrolyte and fluid efflux to drive volume recovery. Although several classes of Ca2+-activated K+ channels have been detected in hepatocytes, the molecular characteristics of the channels involved in volume regulation have not been determined. We found that hypotonic exposure of HTC rat hepatoma cells evoked the opening of 50 pS K+-permeable channels, suggesting the involvement of intermediate conductance (IK) channels. Consistent with IK expression, we isolated from rat liver and HTC cells a cDNA with sequence identity to the coding region of IK1. The IK blocker clotrimazole significantly inhibited swelling-activated K+ currents, and currents were inhibited by transfection with a dominant interfering mutant of IK1. Clotrimazole also inhibited volume recovery. By contrast, neither the small conductance K+ channel blocker apamin nor the large conductance K+ channel blocker tetraethylammonium chloride affected swelling-activated K+ currents. Because IK1 can be regulated by products of phosphatidylinositol kinases, which are produced in lipid rafts, we sought to determine whether IK1 and lipid rafts undergo volume-sensitive association. In HTC cells transfected with a GFP fusion of IK1, there was a time dependent increase in colocalization between IK1 and a lipid raft marker, ganglioside GM1, on the plasma membrane, which subsequently decreased with volume recovery. Treatment of cells with filipin abolished plasma membrane GM1 localization and altered the plasma membrane signal of IK from discrete patches to continuous. Filipin also led to a loss of sustained volume recovery after hypotonic exposure. Collectively, these findings support the hypothesis that IK1 regulates compensatory responses to hepatocellular swelling, and that suggestion of cell volume involves coordination of lipid raft signaling and IK function.
release intramembranous bonds and allow vinculin activation. Acidic phospholipids bind to Vδ4 and contribute to the regulation of vinculin-ligand interactions in competition with actin filaments. While conformational changes in the vinculin head upon binding of vinculin-binding-site (VBS) peptides are known, and a model for actin filament binding to Vδ4 has been suggested based on cryo-electron microscopy data, alterations in the Vδ4 structure induced by phospholipids remain largely uncharacterized. We studied the Vδ4 structure by electron paramagnetic resonance spectroscopy (EPR) employing single and double cysteine mutants which were site-specifically labeled with a commonly used paramagnetic spin label (Mnt). Peptide-derivatized proteins were tested for binding-induced activity. EPR analyses identified the interaction surface of the Vδ4 helical bundle with PtdSer-vesicles and the depth of penetration into the vesicle surface. In contrast to predictions based on the crystal structure of Vδ5, which suggested unfurling of the helical bundle, vesicle binding is accompanied by a movement separating helices H2 and H3 of Vδ5, with conservation of the remaining structure, to generate a new interaction surface with the lipid bilayer. The structural changes observed provide a rational for the strongly reduced binding of acidic phospholipids to the tail of metavinculin, a splice variant with an amino acid insert affecting this precise region.

CD98hc Activates Integrin Signals at the Embryo-Maternal Interface
M. Kabir-Salmani,1,2 M. Fukuda,3 M. Kanai-Azuma,4 K. Sugihara,1 M. Iwashita1, Basic Science, National Institute for Genetic Engineering and Biotechnology, Tehran, Iran (Islamic Republic of), 1The Department of Obstetrics and Gynaecology, Kyorin University School of Medicine, Tokyo, Japan, 2Gycochemistry Program, Cancer Research Center, Burnham Institute, La Jolla, CA, 2Anatomy, Kyorin University School of Medicine, Tokyo, Japan

CD98 heavy chain is an actin-associated type II plasma membrane protein highly expressed in human tumors and placenta, implicated as functional contributor to cell motility. Since αβ3 integrin serves as a dominant integrin of the focal adhesions of invasive extravillous trophoblasts, we investigated the potential role of CD98 and mechanisms by which it may promote αβ3 integrin activation. Immunocytochemistry revealed that CD98hc is co-localized with integrin αβ3, phospho-FAK, vinculin and with phospho-FAK in focal adhesions. Co-immunoprecipitation demonstrated a strong association between CD98hc and its transmembrane domain with β integrin. When serum-starved CD98 negative cells were stably transfected for CD98hc, crosslinking of CD98 enhanced activation of αβ3 integrin inside-out and outside-in signals, cell adhesion, and migration. Similar events occurred when these cells were transfected with a mutant of irrelevant type II membrane protein in which the transmembrane domain had been replaced with that of CD98hc. The CD98-induced effects were inhibited in knock down trophoblastic cells and upon treatment with specific inhibitors of CD99, αβ3 integrin, phosphoinositide 3-OH kinase (PI3-K) and RhoA. Our results suggest a novel role of CD98hc at the embryo-maternal interface. The association of CD98hc transmembrane domain with β integrin provides a new target for cancer therapy and assisted reproductive technology.

Rap1 Regulates a Feed Forward Signaling Pathway Required for β1-integrin-dependent Phagocytosis of Collagen
P. D. Arora,1 K. Burridge,2 P. A. Marignani,3 M. R. Philips,4 J. A. Cooper,5 C. A. McCulloch1, CHIR Group in Matrix Dynamics, University of Toronto, Toronto, ON, Canada, 1Department of Cell Biology, University of North Carolina, Chapel Hill, NC, 3Department of Biochemistry and Molecular Biology, Dalhousie University, Halifax, NS, Canada, 4Department of Medicine, New York University, New York, NY, 2Fred Hutchinson Cancer Research Center, Seattle, WA

Collagen phagocytosis is a crucial, αβ3 integrin-dependent process that mediates extracellular matrix remodeling by fibroblasts. We have shown previously that gelsolin is required for Rac1 activation in the initial binding step of collagen phagocytosis. Objective: To define the roles of the Ras related GTPase, Rap1, and the GTP exchange factor Vav2, in regulation of Rac1 during collagen phagocytosis. Methods: Cultured mouse fibroblasts were incubated with collagen beads to ligate alpha2 beta1 integrins. Cells were transfected with plasmids expressing small GTPase regulatory proteins and studied by confocal microscopy, immunoblotting and Rac1 activation assays. Results: Collagen bead binding required Rac activation but not cdc42 or RhoA. Rac activity was also increased following collagen bead binding. Accordingly, we focused on the upstream regulation of Rac in the collagen binding step of phagocytosis. Collagen bead binding promoted phosphorylation of Vav2 at Y172. Cells transfected with constitutively active Vav2 and Rap1 exhibited Rac activation and enhanced collagen bead binding while dominant-negative Vav2 and Rap1 blocked Rac activity and bead binding. Recruitment of active rac to bound collagen required active Vav2. Immunoprecipitation studies showed interactions between constitutively endogenous Vav2 and active Rap1. Transfection with dominant negative Rap1, with or without co-transfection with constitutively active Vav2, inhibited collagen bead binding. In contrast, cells co-transfected with constitutively active Rap1 and constitutively active Vav2, exhibited enhanced collagen bead binding. In cells transfected with constitutively active, but not dominant negative Rap1, incubation with collagen beads promoted translocation of constitutively active Vav2 to collagen bead binding sites. Conclusion: Rap1 interacts with constitutively active Vav2 to localize Vav2 activity to integrins and to enhance collagen binding by activating Rac.

Restoration of Dystrobrevin to the mdx Sarcolemma Does Not Attenuate Muscular Dystrophy
M. E. Adams, Y. Tesch, J. M. Percival, D. E. Albrecht, K. Anderson, S. C. Froehner; Physiology and Biophysics, University of Washington, Seattle, WA

Restoration of dystrobrevin to the mdx sarcolemma does not significantly reduce the muscular dystrophy phenotype of these animals. We conclude that dystrobrevin, even when expressed at normal levels, cannot rescue the muscular dystrophy of dystrobrevin-null mice. Synaptic integrity is significantly reduced in dystrobrevin-null mdx mice, and expression of either dystrobrevin isoform prevented the muscular dystrophy normally observed in the dystrobrevin null mouse and restored centrally nucleated fiber counts to levels similar to controls. On the mdx background that lacks dystrophin, only the palmitoylated form of dystrobrevin was present on the sarcolemma. The non-palmitoylated form did not accumulate at the sarcolemma. The palmitoylated form of dystrobrevin was able to restore α-syntrophin to the sarcolemma, however, nNOS remained absent. This suggests that nNOS requires dystrophin as well as syntrophin for proper localization. Furthermore, counts of centrally nucleated fibers showed that the presence of the dystrobrevin and syntrophin on the sarcolemma of mdx mice did not significantly reduce the muscular dystrophy phenotype of these animals. We conclude that dystrobrevin, even when directed to the sarcolemma, is not sufficient to restore a functional protein complex capable of preventing muscular degeneration.

A Novel Role of the Septins during the Spore Membrane Morphogenesis in Schizosaccharomyces pombe
M. Onishi,1 T. Koga,1 A. Hirata,2 H. Tachikawa,3 T. Nakamura,2 H. Asakawa,2 J. Bähler,2 J. Wu,3 C. Shimoda,1 J. Pringle,1 Y. Fukui1, Graduate School of Agriculture & Life Science, University of Tokyo, Tokyo, Japan, 1Department of Integrated Biosciences, Graduate School of Frontier Science, University of Tokyo, Chiba, Japan, 2Department of Biology, Graduate School of Science, Osaka City University, Osaka, Japan, 3Wellcome Trust Sanger Institute, Hinxton, Cambridge, United Kingdom, 4Department of Molecular, Cellular, and Developmental Biology, Yale University, New Haven, CT, 5Department of Genetics, Stanford University, Stanford, CA

Septins are a family of conserved, filament-forming proteins that has been shown to play roles in diverse cellular events in various organisms. We propose a novel role of the septins in the spore membrane morphogenesis of the fission yeast Schizosaccharomyces pombe. The S. pombe accomplishes gametogenesis by two tightly linked processes, meiosis and spore-envelope formation. At prometaphase of meiosis II, membrane vesicles begin to fuse at the cytoplasmic surfaces of the spindle-pole bodies to form the forespore membranes (FSMs), which then extend to form the spore membrane surrounding each haploid nucleus and associated cytoplasm. Formation of the FSMs is an interesting model for the de novo synthesis of biological membranes. In particular, understanding how the FSM extends and closes to form a sac might provide general insights into the mechanisms of membrane formation. The S. pombe genome encodes seven septins. As their possible roles in sporulation have not been examined in detail. We found that deletion of spm2, spm3, spm6, or spm7, but not of the others, dramatically affected sporulation formation. The orientation at the beginning of FSM extension was frequently abnormal, resulting in the formation of aberrant numbers of spores per ascus as some FSMs failed to enclose nuclei. The spore morphology is affected interdependently to a horseshoe-like assemblage along each FSM, which extended to form a ring in the end. We also found that Spm2p and Spm7p bound to the phosphoinositides PtdIns(4P) and PtdIns(5P) in vitro, and that PtdIns(4P) was enriched in the FSM. Introduction of a mutation in the phosphoinositide-binding region of Spm2p abolished the association of the septin assemblage with the FSM in vivo. We suggest that the septin assemblage contributes to the proper orientation of FSM extension by interacting with PtdIns(4P) in the FSM. Biochemical analyses of the sporulation-specific septin complex will be also presented.

Characterization of TIMP, the Potential Regulatory Subunit of Protein Phosphatase 1 in Human Endothelial Cells
I. Czirka,1,2 G. Oláh,1 C. Csortos,1,2 A. D. Verin; 1Department of Medicine, University of Chicago, Chicago, IL, 2Department of Medical Chemistry, University of Debrecen, Debrecen, Hungary
Reversible phosphorylation of numerous cytoskeletal proteins has a crucial role in the maintenance of appropriate alignment of the cytoskeleton. We have shown earlier that protein phosphatase 1c (PP1c), the catalytic subunit of myosin phosphatase (MP), associates with microfilaments and directly is involved in endothelial cell (EC) contractility and barrier regulation through the dephosphorylation of myosin light chain. In the present work we studied TIMAP, a potential regulatory subunit of PP1. It is highly abundant in EC and it was described as a membrane associated protein. Indeed, using an anti-peptide polyclonal antibody by immunofluorescence (IF) staining we observed TIMAP being enriched in a membrane in human pulmonary arterial EC (HPAEC) but also in the cytosol, mostly around the nucleus. We showed protein-protein interaction in HPAEC between TIMAP and PP1c by immunoprecipitation. Moreover, in pull-down assay using bacterially expressed recombinant GST-TIMAP we found for the first time that PP1c delta isoform binds to TIMAP with higher affinity then the alpha isoform. Thrombin (20 nM) treatment evoked increased IF staining of TIMAP at the membrane. In parallel, we detected enrichment of moesin, a member of the ERM family, as well as phospho-moesin at the cell membrane. These results suggest that TIMAP may take PP1 activity to the cell-membrane where it can participate in ECM driven membrane dynamics. Supported by NIH grants HL067307, HL58064, and OTKA grant T043133

288 Chromium Picolinate Displays Membrane Phospholipid and Actin Cytoskeleton Protective Effects Against Hyperinsulinemia-Induced Insulin Resistance in 3T3-L1 Adipocytes E. M. Horvath, J. S. Elmedina; Cellular and Integrative Physiology, Indiana University School of Medicine, Indianapolis, IN Analyses reveal that membrane phosphatidylcholines 4,5-bisphosphate (PIP2) and cortical filamentous actin (F-actin) are diminished by chronic insulin exposure and this loss contributes to insulin-induced insulin resistance in fat and skeletal muscle. Here we tested whether chromium picolinate (CrPic) could improve insulin sensitivity in 3T3-L1 adipocytes rendered insulin resistant by hyperinsulinemia (12 h, 5 nM), as accumulating evidence suggests that CrPic may alleviate high glucose and lipid abnormalities in diabetes. Insulin’s acute (30 min, 100 nM) effect on GLUT4-regulated glucose transport was diminished in hyperinsulinemic adipocytes. Concomitant with the insulin-resistant state, plasma membrane PIP2 and F-actin were decreased in hyperinsulinemic cells. We describe if CrPic could correct the insulin resistant state, cells were cultured in the absence or presence of CrPic. Insulin-regulated glucose transport improved in CrPic-treated hyperinsulinemic adipocytes and this was paralleled by an increase in plasma membrane PIP2; immunofluorescent detection and cortical F-actin polymerization. As study has demonstrated that CrPic improves insulin responsiveness by decreasing plasma membrane cholesterol, we next sought to assess potential cholesterol/PIP2 interaction. Labeling of cholesterol/caveolin-1-enriched membrane microdomains revealed a clear PIP2 co-localization in these regions. Furthermore, this juxtaposed nature of caveolin-1 and PIP2 intensifies in hyperinsulinemic cells and it appears as though CrPic treatment may remove PIP2 from the cholesterol-enriched caveolae microdomains. Immunofluorescent labeling also showed a clear co-localization of actin and caveolin-1 in these domains, which was diminished in hyperinsulinemic cells. Interestingly, treatment of resistant cells with CrPic restored the presence of actin/caveolin-1 structures. Our results support a novel paradigm in which plasma membrane lipid abnormalities induced by hyperinsulinemia impair regulation of the glucose transport system by insulin. Concomitant glucose membrane remodeling that occurs in response to CrPic favors insulin-regulated glucose transport. We propose that CrPic corrects plasma membrane abnormalities associated with insulin resistance.

289 Identification and Characterization of a Cardiac-specific Isoform of Alpha-spectrin Y. Zhang, W. G. Resnek, C. Lee, D. H. Catin, W. R. Randall, R. J. Bloch, J. A. Ursitti; Physiology, University of Maryland, Baltimore, MD, Pharmacological and Experimental Therapeutics, University of Maryland, Baltimore, MD, Medical Biotechnology Center, University of Maryland, Baltimore, MD Spectrin is a large, flexible protein that functions to stabilize membranes and organize proteins and lipids into microdomains in intracellular organelles and at the plasma membrane. Alternative splicing occurs in spectrins, and yet it is not clear if the small variations in structure caused by alternative splicing alter the functions of spectrin. Three splice variants have been identified previously for α-spectrin. Here we describe a new alternative splice variant: a 21 amino acid sequence in motif 21. This new splice variant (cardi+) is only expressed in significant amounts in cardiac muscle and occurs within the high affinity nucleation site for binding of all-spectrins to β-spectrin. Long-range RT-PCR demonstrates that the insert is expressed randomly in heart tissue. This indicates that the expression of the cardi+ insert is not dependent on the presence or absence of the other alternatively spliced sequences. In vitro studies of recombinant all-spectrin polypeptide complexes reveal two alternative splice variants of α-spectrin and significant differences in affinity for the complementary site on β-spectrin with values of -1 nM for both, as measured by surface plasmon resonance (SPR) in a Biacore 3000. Remarkably, however, the αβ-cardi+ form shows significantly higher levels of binding than the αβ-cardi- form, both by SPR and blot overlay. This suggests that the 21-amino acid insert prevents some of the αβ-cardi- form from interacting with ββ-spectrin, even in assays requiring minutes to hours to complete. Small constructs expressing the αβ-cardi- sequence are insoluble in solution and aggregate in COS cells, consistent with the possibility that this insert removes a significant portion of the protein from the population that can bind β subunits. We are continuing our studies of this unique splice variant of cardiac α-spectrin to determine its specific function in heart.

290 Tropomodulin Is Required for Anterior Lens Fiber Cell Organization and Lens Focusing R. Nowak, R. S. Fischer, J. R. Knues, V. M. Fowler; Cell Biology, Scripps Research Institute, La Jolla, CA, Ophthalmology and Pathology, Rush Medical College, Chicago, IL Tropomodulin (Tmod) caps the pointed ends of actin filaments in the lens fiber cell plasma membrane skeleton and is proposed to regulate lens fiber cell elongation and morphogenesis. To understand the role of Tmod and actin filament capping in the lens, we have studied the optical properties and fiber cell membrane organization in lenses from normal mice and in lenses lacking Tmod1. Immunoblotting and immunofluorescence staining show that both Tmod1 and Tmod3 isoforms are expressed in cortical but not nuclear fiber cells of mouse lenses. Biochemical fractionation of lens cortical fiber cells by immunoblotting demonstrates that Tmod1 is predominantly associated with fiber cell membranes whereas Tmod3 is cytoplasmic. Immunofluorescence staining and confocal microscopy of cryosections of P14 lenses also demonstrates that Tmod1 is enriched on lateral membranes of fiber cells, whereas Tmod3 is cytoplasmic. In lenses lacking Tmod1, Tmod3 protein levels are unchanged, and Tmod3 remains in the cytoplasm and does not become enriched on fiber cell membranes, suggesting that membrane-associated actin-actin interactions may be stabilized in the absence of Tmod1. Scanning electron microscopy of lenses lacking Tmod1 shows a decrease in membrane protrusion complexity along the long axis of cortical fiber cells when compared to wild-type, indicating that cell-cell and/or membrane stability is decreased in the absence of Tmod1. H & E staining of semi-thin sections of lenses lacking Tmod1 demonstrates defects in anterior fiber cell layer organization and packing relative to wild-type lenses. Cataracts do not form in the absence of Tmod1, but laser scan analysis reveals decreased lens optical quality as indicated by increased back focal length and back focal length variability relative to wild-type lenses. We conclude that Tmod1 function is required for normal anterior fiber cell interactions and layer organization, which determines lens optical quality and normal lens focusing function.

291 F-Actin Componentalisates the Plasma Membrane to Support Polarized Membrane Growth during Drosophila Cellularization A. Sokol, E. Wieschaus; Molecular Biology, Princeton University, Princeton, NJ, Molecular Biology, HHMI/Princeton University, Princeton, NJ In Drosophila, apical-basal blastic cell boundaries are formed by a thin sheet of F-actin that is a modification of the landmarks of a polarized epithelium. Surface labeling of ingressing furrows during cellularization previously suggested that new membrane insert at discrete domains along the plasma membrane and so could contribute to the generation of apical/basal polarity (Lecuit and Wieschaus, 2000). Using confocal microscopy to follow multiple membrane probes in fixed and living fly embryos, we now show that the actin/myosin-2 furrow canal at the basal tip of the ingressing furrow indeed comprises a membrane domain that is distinct from the adjacent, growing, apical/lateral plasma membrane. Contrary to prior models that named cell-cell junctions at the interface between these domains as possible barriers to lateral diffusion, our analysis of maternal/vgycogenic β-catenin mutants demonstrates that the membrane domains are maintained even in the absence of junctions. Instead, we find that a myristoylated, natively-disordered protein Nullo, that binds PH(3,4,5)P2, in vitro and concentrates at the cell-cell junction region in vivo, defines and/or maintains these discrete plasma membrane domains. Nullo drives the local accumulation of cortical F-actin, and when F-actin is disrupted in either null mutants or with cytochalasin-D, components of the apical/lateral plasma membrane invade the furrow canal domain. Mixing between the domains precedes the regression of some furrows, and that persists, the cell-cell junctions disperse throughout the membrane. Thus, Nullo compartmentalizes the plasma membrane via cortical F-actin to support membrane growth and to cluster polarity cues such as cell-cell junctions. Intriguingly, the interaction of Nullo with PH(3,4,5)P2 suggests that specific phosphoinositides may also contribute to plasma membrane compartmentalization during the establishment of this embryonic epithelium.

292 Probing the Fluid Environment at and Near the Cell Surface by Rotating Laser Trapped Microspheres E. Botvinick, H. Rubinstein-Dunlop, M. Berns; Beckman Laser Institute (UCI), Irvine, CA, Department of Physics/Centre for Biophotonics and Laser Science, The University of Queensland, Brisbane, Australia
A microscope system has been developed to apply ultra-localized fluid shear to sub regions of a cell’s surface. Spherical vaterite crystals are rotated near the cell surface by applying optical torques with circularly polarized light. Measurement of crystal rotation rate and changes in circular polarity as light exits the crystal allows measurement of fluid apparent viscosity near the crystal surface. The fluid flow field is generally confined to the length scale of the crystal (a few microns) allowing ultra-fine viscosity measurements. The fluid environment near the cell surface can be mapped out as a crystal approaches the cell surface and begins to interact with the glycoalyx and with the plasma membrane. The effects of the glycoalyx on the fluid environment outside the cell were measured for a set of controls including serum starvation and heparinase III treatment. It was found that degradation of the glycoalyx suppressed (with respect to normally cultured cells) the increase in apparent viscosity observed as a crystal is brought towards the cell from a sufficiently distal location. The rotating crystals are also used to apply physiological-magnitude shear to local regions of the cell surface. Using apparent viscosity as an indicator of the flow-field’s proximity to the plasma membrane or glycoalyx, it is possible to selectively apply fluid shear to the glycoalyx. In this way fluid shear mechanotransduction of the glycoalyx can be measured independently from that of the plasma membrane.

293 Modulation of Free PI(4,5)P2 Levels In vivo by MARCKS
J. E. Sable, 1 G. Di Paolo, 1 M. P. Sheetz; 1 Biological Sciences, Columbia University, New York, NY, 1Department of Pathology, Columbia University Medical Center, New York, NY

Phosphatidylinositol-3',4',5'-trisphosphates (PI(4,5,5)P3) have important roles in many cellular processes but how cytoplasmic PI(4,5)P2 levels are regulated is still relatively unknown. Myristylated alanine-rich protein kinase C substrate (MARCKS) is an abundant cellular protein that strongly binds PI(4,5)P2 in vitro and may be responsible for regulation of PI(4,5)P2 levels in vivo by localized sequestration/release mechanisms. We find that over-expression of MARCKS decreases membrane-lysosome adhesion, but increased PI(2,3)P2 synthesis via PI(4,5)P2 Inhibits prevents this decrease. We have also attempted to test MARCS +/- MEFs using optical tweezers but failed to obtain tethers due to presumably high membrane tension. Phosphorylation of MARCKS by PKC activation dramatically decreases its affinity for PI(4,5)P2 and the plasma membrane, restores normal membrane tension and causes increased recruitment of PLC-PIP2-GFP to the plasma membrane as shown by TIRF microscopy. In primary MARCKS +/- cells, biochemical analyses show a significant increase in the rate of turnover of PI(2,3)P2 and PI(4,5)P2 versus wild-type. MARCKS +/- cells also show a significant increase in the rate of labeling of PI(2,3)P2 (but not PI(4,5)P2) in vivo in in vitro experiments with liposomes and γ-ATP. These cells also have altered actin morphology (radial arrays of filopodia-like structures) and exhibit uncoordinated protrusions and retractions during cell spreading. We have also shown that MARCKS protein migrates towards EGF gradients in cells, which could provide localized increases of PI(2,3)P2 to the leading edge of the lamellipodia. Therefore, we suggest that MARCKS is critical to regulation of free PI(4,5)P2 levels and intracellular actin cytoskeleton dynamics by functioning as a critical reservoir of phosphoinositides at the plasma membrane.

294 Phosphatidylinositol-3’-OH-Kinase Coordinates Cdc42 and Rac GTPases by a Signal Transition and Integrates FcγR Signals during Phagocytosis
P. J. BeenMiller, 1 A. Hoppel, 1 A. Swanson; 1 Cellular and Molecular Biology, University of Michigan, Ann Arbor, MI, 2Microbiology and Immunology, University of Michigan, Ann Arbor, MI

Fc receptor (FcγR)-mediated phagocytosis of large particles (>3 μm diameter) by macrophages requires the activity of phosphatidylinositol-3',4',5'-trisphosphate (PI(4,5,5)P3) in the phagosome membrane. Macrophages treated with inhibitors of PI(3)K inhibit actin polymerization and pseudopod extension but fail to close phagosomes. The relationship between PI(3)K activity and the regulation of the Rho-family GTPases Cdc42, Rac1 and Rac2, essential regulators of the actin cytoskeleton and phagocyte oxidase complex, during phagocytosis has not been examined. We hypothesized that PI(3)K activity initiates a signal transition at the phagosome that coordinates the deactivation of one set of GTPases (including Rac1 and Cdc42) with the activation of a second set of GTPases (including Rac2). To determine how PI(3)K coordinates the activity of these GTPases during phagocytosis, we examined the coordinated GTP-changes that occurred during the transition from Cdc42, Rac1 and Rac2 to Cdc42, Rac1 and Rac2. In Cdc42, Rac1 and Rac2, we measured the increase in Cdc42 and Rac2 GTPase activity and decrease of Rac1 GTPase activity. In Cdc42, Rac1 and Rac2, we measured the increase in Cdc42 and Rac2 GTPase activity and decrease of Rac1 GTPase activity. These results suggest that PI(3)K-dependent Cdc42 GAP activity is required to initiate the signal transition, and that PI(3)K activity integrates FcγR signals during phagocytosis.

295 Coordination of Microtubules and the Actin Cytoskeleton Is Important during Ruffle Formation in Macrophages
P. C. Patel, R. Harrison; Department of Life Sciences, University of Toronto at Scarborough Campus, Toronto, ON, Canada

The exposure of cells to a variety of external signals causes rapid changes in plasma membrane morphology. Treatment of macrophages phorbol myristate acetate (PMA) rapidly induces the formation of conspicuous membrane ruffles, which can be visualized by phase and DIC microscopy as waves arising at the leading edge of lamellipodia that move centripetally towards the main cell body. Although ruffles have been studied in the context of macroopinocytosis for decades, ruffle formation and the mechanisms leading to their formation remains largely unknown. It is known that membrane ruffle formation, is highly dependent on the actin cytoskeleton but it remains unclear to what degree microtubules contribute to this process. We studied the interaction between microtubules and the actin cytoskeleton in ruffle formation. The treatment of macrophages with cytochalasin D, an F-actin-depolymerizing reagent, inhibited the process of ruffle formation and macroinocytosis, which was visualized by immunofluorescence microscopy, live DIC analysis and SEM. The role of the microtubule cytoskeleton in ruffle formation was tested using 10μm of nocodazole to disrupt microtubule polymerization. We found that MT depolymerization impaired membrane ruffles, which was reversed following nocodazole washout. Interestingly, treatment of macrophages with the microtubule stabilizing drug taxol resulted in ruffle formation in the absence of phorbol ester activation of PKC. These results were confirmed by live imaging, immunofluorescence and SEM. These findings suggest that coordination of the actin cytoskeleton and microtubules is important for the ruffle formation. Thus it appears that ruffle formation is a microtubule-dependent process and is likely facilitated by the actin reorganization.

296 Intracellular Trafficking in Activated Macrophages
M. G. Binker, R. E. Harrison; UTSC, Toronto, ON, Canada

Classically, macrophage activation is a process developed in response to different inflammatory and or infectious conditions. Several stimuli including Interferon-gamma (IFN-γ) and Lipopolysaccharides (LPS) are known to activate macrophages. As a consequence of this novel process, resting macrophages undergo several changes including microtubule cytoskeleton reorganization. The specific function of this change is unclear. Using acetylated-α-tubulin as a marker, we found a significant increase in the stabilization of microtubules when resting RAW 264.7 cells were activated through both IFN-γ and LPS alone or in combination. By confocal microscopy, an intimate contact was observed between these acetylated-microtubules and vesicles of the endocytic pathway characterized by the presence of Rab5 and Rab7 on its membranes. Moreover, Rab7-Interacting Lysosomal Protein (RILP) was present in large vesicles colocalizing with “the core” formed by these stable microtubules. We also noticed a sizeable difference in phagocytosis in activated macrophages. Based on our results, we hypothesize a differential trafficking between the cellular cortex and the microtubule organizing center (MTOC) when macrophages are activated.

297 Microtubule Dynamics and Microtubule-based Motors Contribute to the Formation of a Specialized Endocytic Compartment in Cells Infected with Salmonella Typhimurium
T. Dam, T. A. Schroer; Biology, The Johns Hopkins University, Baltimore, MD

Upon entering the host cell, the intracellular pathogen Salmonella typhimurium traffics through the endocytic pathway until it reaches a late endocytic compartment known as the Salmonella-containing vacuole (SCV). Bacterial-effectors proteins are then delivered into and through the SCV membrane. Acting in ways that are not yet fully established, these effector proteins cause dramatic changes in the structure and dynamic behavior of this late endosome-derived-derived. Interaction with other organelles is altered and the structure extends elongated, interconnected membranous tubules known as Salmonella-induced filaments (SIFs). SIF formation is known to be microtubule dependent. We have used fluorescent protein (FP) technology to image SIF formation in living HeLa cells. We observe SIFs to be extremely dynamic structures that can extend, branch, and rapidly retract. Low doses of taxol or nocodazole, conditions that suggest microtubule dynamics do not cause loss or rearrangement of the microtubule cytoskeleton, interfere with SIF formation, suggesting that dynamic microtubules play a role in tubule extension. The plus end-directed, microtubule-based motor, kinesin-2, is also required for normal SIF formation. These findings suggest that SIF formation is driven by the combination of kinesin-2 dependent movement of membrane tubules along microtubules and the association of these membranes with the ends of growing microtubules.
Epithelial Cytoskeletal and Cell Surface Response to Pathogenic Fungi

M. Sabanero,1 G. Sandoval-Bernal,2 A. Perez,2 G. Barbosa-Sabanero,3 K. Barbosa-Sabanero,3 V. Tsutsui Fujiyoshi,3 1Instituto de Investigación en Biología Experimental, Universidad de Guanajuato, Guanajuato, Mexico, 2Facultad de Medicina, Universidad Nacional Autónoma de México, México, México, Mexico, 3Instituto de Investigaciones Médicas, Universidad de Guanajuato, Guanajuato, Mexico, 4Patología Experimental, Centro de Investigación y de Estudios Avanzados - IPN, México, Mexico

Changes in the organization of the cell cytoskeleton during the interaction with the microbial and other organisms are complex and varied, and much still remains to be elucidated, specially in terms of the molecules that signal and bring about the reorganizations that are often observed. In this work, we developed a cell culture model of infection of polarized epithelia cultured yeasts of Sporothrix schenckii (S.s) on fibroblasts monolayer and examining changes in cellular morphology and organization of cytoskeleton induced by S. s. infection. The results show that the yeasts of S.s are physically associates with epithelial surface, the adhesion of yeast are time depend i.e. 5h - 31%, 24h - 47%. We monitored changes induced by S.s infection in the organization of cytoskeleton by immunofluorescence with beta tubulin antibodies. We observed that after infection the microtubules (MT) distribution are dramatically altered. Tubulin is visible as small dots or a few MT. Both the dots and end of MT are associated with the cortex membrane. Long time (48h-72h) infection on epithelial cells results in displastic changes in cellular morphology with alterations of monolayer continuity and cell - cell junctions. SEM revealed budding and blebs on epithelial cell surface during the infection by S.s yeast. These results suggest that the interaction of the pathogen with host cell generate an uptake signals that are able to alter the host cytoskeletal and cell surface. It is possible that pathogens induce modulation of different host cell pathways in order to evade host defenses and to faster their own proliferation. Preliminary results indicate that four glycoproteins are involved in the adhesion of pathogens to epithelial cells. The work was supported by the Universidad de Guanajuato. (Grant No. 18 to MSL)

Characterization of Membrane-associated APC Pools in Motile versus Non-Motile Epithelial Cells

K. A. Siemers,1 H. Y. Caro-Gonzalez,2 W. J. Nelson,2,3 A. I. M. Barth; 1Molecular and Cellular Physiology, Stanford School of Medicine, Stanford, CA, 2Department of Biological Sciences, Stanford University, Stanford, CA

The adenomatous polyposis coli (APC) protein has an important role in directed cell migration and localizes to the tip of extending membranes in response to growth factor or integrin-mediated signals. Here we used a biochemical approach to analyze the association of APC and its binding partners with membranes in motile and non-motile epithelial cells. In non-polarized motile Madin Darby Canine kidney (MDCK) epithelial cells, homogenized under conditions that disrupt the microtubule cytoskeleton, the majority of APC and its binding partners Asef and β-catenin were recovered in the membrane fraction whereas tubulin was cytosolic. To further analyze the different cytosolic and membrane-associated APC pool we used a self-forming iodixanol density gradient. APC was enriched in two membrane fractions: a lower density membrane fraction that co-distributes with E-cadherin and a higher density membrane fraction that co-distributes with Asef, IQGAP and Par-3. In polarized non-motile MDCK epithelial cells the majority of APC was enriched in the lower density membrane fraction with E-cadherin. Disruption of cell-cell adhesion causes a shift of APC from this lower density “E-cadherin”-membrane fraction into the higher density “IQGAP/Asef”-membrane fraction. These results indicate that APC complexes that distribute in these higher density fractions may have a role in cell motility.

Deciphering the Relationship between Bik1p (CLIP-170) Localization and Function in Yeast

F. Caudron, A. Andrieux, D. Job, C. Boscheron; INSERM, Grenoble, France

We have previously demonstrated impairment of Bik1p localization at microtubule ends in yeast cells expressing Glu tubulin, with resulting defects in spindle motion. Here, in Glu tubulin cells Bik1 deletion further suppressed Bik’s localization at microtubule ends, where it became undetectable. However, Bik1 deleted Glu tubulin clones were fully viable, which was surprising since a double Bik1 deletion was lethal and since Bik1p function is thought to be intimately related to association with microtubule ends. We provide evidence for an unexpected conservation of dynactin localization at microtubule ends in Bik1 deleted Glu tubulin clones. Surprisingly, additional deletion of the kinesin Kip2p was still compatible with cell viability despite suppression of both dynactin association with microtubule ends and detectable interactions of astral microtubules with the cell cortex. In Bik1/Kip2p deleted Glu tubulin spindles, spindle positioning was achieved through a new mechanism in which the spindle elongated in the mother cell and was orientated through apparent geometrical constraints. Thus, Bik1p can mediate both dynactin positioning at microtubule ends and cell division without detectably accumulating at microtubule ends.

Characterization of a Novel Protein, Linking Membrane and Microtubules, “CLIP-76”

G. T. Ugrinova, A. J. Martin, H. Y. Goodson; Chemistry and Biochemistry, University of Notre Dame, Notre Dame, IN

The microtubule cytoskeleton plays a central role in cell organization and membrane traffic in higher eukaryotes. Cytoplasmatic linker proteins (CLIPs) have been implicated in both membrane-microtubule interactions and regulation of microtubule dynamics. We are studying two vertebrate-specific proteins related to CLIP-170. One of them, CLIP15-59 localizes to the Golgi apparatus and is involved in the control of early endosome/TGN transport. (JCB, 156(4), 631-642, 2002). We are presently focusing on the second protein, CLIP76. At least two alternatively spliced isoforms of CLIP76 exist. Both contain four ankyrin-like repeats at the N-terminus. One is widely expressed and has three CAP GLY motifs, while a second (CLIP76T) has two CAP GLY motifs and may be tissue-specific. Serial deletion mutants of CLIP76 have been placed into mammalian and bacterial expression vectors to allow characterization of its domains in vivo and in vitro. Full-length CLIP76 localizes to the endoplasmic reticulum (ER) and alters ER morphology at high expression levels. Detailed serial deletion analysis of CLIP76 showed that the information necessary for ER targeting resides within a domain containing the second CAP GLY motif and the serine-rich region. Overexpression of mutants containing only the CAP GLY motifs strongly perturbs ER and ER-Golgi intermediate compartment (ERGIC) morphology, causing strong colocalization with microtubules. Preliminary data show that VSVG transport between ER and Golgi is inhibited in cells expressing these mutants. These data suggest a role for CLIP76 in membrane transport, specifically ER-Golgi transport. Ongoing studies will further investigate the effects of CLIP76 mutations on their fragments on membrane transport in vivo and on microtubule assembly in vitro.

In Vitro Model Systems for Studying Tissue Impedance

J. P. Frampton,1 M. R. Hynd,2 A. Gupta,2 C. Bjornsson,2 G. Lin,2 B. Roysam,2 W. Turner;2 SUNY Albany, Albany, NY, 1Wadsworth Center, Albany, NY, 2Rensselaer Polytechnic Institute, Troy, NY

Mammalian cell culture typically is performed on planar substrates. While such strategies allow observations of individual cells that are difficult to make in vivo and have provided information on dynamic cellular processes, cells cultured in two-dimensions behave differently from cells in their native three-dimensional (3-D) environments. Functionalized alginate scaffolds were used to make culture systems for 3-D systems. Astroglia and neurons were used. Tissue impedance spectroscopy and biochemistry were used to describe organization of 3-D tissue constructs. Impedance spectroscopy provides a real time method for assessing organization in living cultures. Immunocytochemistry and 3-D imaging, and image analysis permit mapping of cells within scaffolds. We will correlate impedance spectroscopy and image analysis data to determine how cell density, cell type, and changes in cell morphology contribute to tissue impedance spectra. These data can be used to test computer-generated models for predicting changes in cell and tissue organization following tissue damage or responses to infection or disease. Alginate was functionalized by covalent attachment of a GRDGR peptide using aqueous carbodiimide chemistry. 3-D hydrogel constructs were created by suspending cells at various densities in alginate solutions. Alginate was polymerized by exposure of gel solutions to 200 mM CaCl2 through MilliPore tissue culture inserts. Hydrogels were polymerized on planar microelectrode arrays and the thickness of the 3-D construct was controlled by fixing the total volume of the cell-alginate mixture. Cell densities were varied from 1000 cells/μl to >20,000 cells/μl, thus approaching estimates of cell densities in the brain. Computer reconstructions of cell distribution in the in vitro 3-D constructs were created and compared to similar reconstructions of brain tissue where astrocytes, microglia, neurons, and vascular elements are mapped. Work was supported by the Nanobiotechnology Center (NBTC), an STC program of the NSF under Agreement Number ECS-9876771, CenSyS (NSF), NIH, NS044287, and CNCT (EB002030).
Tumor Cell Motility in 3D Matrices: Parsing the Roles of Proteolysis, Adhesion, and Mechanics
M. H. Zaman, D. Lauffenburger, P. Matsudaira; Biomedical Engineering, University of Texas at Austin, Austin, TX, Bioengineering, MIT, Cambridge, MA, Biology, Whitehead Institute, Cambridge, MA

Cell migration on 2D surfaces is governed by a balance between counter-acting tractive and adhesion forces. While receptor-ligand interactions and signaling through adhesion complexes have been studied in detail in a 2D context, the critical biochemical and biophysical parameters that affect cell migration in 3D matrices have not been quantitatively investigated. Using a combination of high-resolution and high-throughput imaging, rheological measurements and novel computational modeling, we demonstrate that in addition to adhesion and tractive forces, matrix stiffness is a key factor that influences cell movement in 3D. Our 3D migration assays with varying concentrations of the matrix, fibronectin and integrin activity shows that the migration speed of DU-145 human prostate carcinoma cells is a balance between tractive and adhesion forces. Unlike the 2D systems, where migration is a balance between adhesion ligand concentration and integrin activity, we note that in 3D systems, matrix stiffness and structure plays an equally important role, along with adhesion and integrin expression, in regulating motility. These novel observations have also been predicted by a recent force-based computational model of cell movement in a 3D matrix (Zaman et al., Biophys. J. [2005]). Additionally, 3D motility through an extra-cellular environment of pore size much smaller than cellular dimensions does depend on proteolytic activity as broad-spectrum MMP inhibitors limit the migration of DU-145 cells and also HT-1080 fibroswroma cells. Our hybrid approach, combining high-resolution experimental and computational techniques demonstrate an original discovery of a novel set of balances of cell and matrix properties that govern the ability of tumor cells to migrate in 3D environments. Reference: Zaman et al, Proc. Natl. Acad. Sci. USA. 2006, 103; 10889-10894. Zaman et al, Biophysical Journal, 2005. 89; 1389-1397.

Probing the Role of Extracellular Matrix Composition and Tensional Homeostasis in Single Mammary Epithelial Cells by Atomic Force Microscopy
J. Alcaraz, C. Nelson, V. Spencer, R. Xu, H. Mori, C. Bustamante, M. Bissell; Cell and Molecular Biology, Lawrence Berkeley National Laboratory, Berkeley, CA, Physics and Cell and Molecular Biology, Howard Hughes Medical Institute and University of California, Berkeley, CA

The extracellular matrix (ECM) has profound influence on cellular phenotype. Although the mechanism by which ECM integrates form and function are largely unknown, recent findings suggest that ECM may control cellular phenotype by modulating intracellular tension as part of a mechanical homeostasis mechanism. To dissect how ECM regulates endogenous tension in relation to function, we cultured single mammary epithelial cells on top of gels with different composition but similar stiffness comparable to what normal cells experience in vivo. Using atomic force microscopy we measured how single cells store and dissipate mechanical energy, processes that are related to intracellular tension and structural disorder, respectively. We found that ECM composition rather than gel stiffness or cell shape per se controls intracellular tension. Functional differentiation, assessed by β-casem protein expression, was modulated by tension in a biphasic manner. Moderate levels of tension, mediated by binding of β1-containing integrin to the basement membrane protein laminin, correlated with β-casem expression and enhancement of β-casem protein. In contrast, β-casem was down-regulated by conditions that elicited either low or high mechanical tension. Intriguingly the structural disorder remained essentially stable for all substrata except basement membrane ECM gels, even after blocking binding of β1 and of-and containing integrins to laminin, thereby suggesting that structural disorder is regulated by non-integrin laminin receptors. Our findings indicate that ECM integrates cell shape, intracellular tension, and structural disorder through different receptors, and suggest that these signals contribute to cell function in fundamentally different ways. Specifically our data suggest that a moderate level of tension, transduced by β1-containing integrins, is necessary for functional differentiation.

The Use of Surface Protein Micropatterning for Directing Neural Cell Growth on a Novel Biomimetic Surface
M. R. Hynd, J. F. Frampton, N. M. Dowell-Mesfin, J. N. Turner, W. Shan; Department of Health, Wadsworth Center, Albany, NY, Department of Biomedical Sciences, SUNY at Albany, Albany, NY

Critical to the development of patterned neural networks is the ability to control the spatial localization of molecules on biocompatible materials. Hydrogels are a class of synthetic, non-toxic, hydrophilic polymers well-suited for use in biomedical applications. Here we describe a method for patterning of hydrogel surfaces to control and direct neural cell growth and attachment. A novel approach was used to create streptavidin-functionalized hydrogel surfaces capable of binding biotin-labelled molecules. Hydrogels were formed by co-polymerization of an aqueous solution of acrylamide, poly(ethylene glycol) diacrylate and streptavidin-acrylamide. Microcontact printing (µCP) was used to pattern the biotinylated proteins, laminin and fibronectin, and the laminin epitope (biotin-IKVAV), onto hydrogel surfaces. Proteins were patterned using PDMS stamps with patterns corresponding to either 10 μm-wide relief structures and 90 μm gap spacings or orthogonal 2 μm-wide lines connecting 15 μm diameter nodes, with a repeat spacing of 150 μm. As a biological assay, LRM55 astroglia and primary rat hippocampal neurons were plated on patterned hydrogels. LRM55 cells were found to selectively adhere to regions patterned with biotin-conjugated proteins. After 24 hours, LRM55 cells were well spread along the patterned regions and exhibited process-bearing morphologies. Primary rat hippocampal neurons on patterned hydrogels were found to attach predominantly to the 15 μm nodal regions of the stamped grid pattern, with few cells attaching to the orthogonal 2 μm-wide lines. Neurons were found to self-organize into networks by 10 days and develop functionally active synapses as measured by uptake of the dye, FM 1-43FX. Neurons survived on peptide-modified hydrogel surfaces for at least 4 weeks. Results from this study suggest that hydrogel surfaces can be patterned with multiple proteins to direct cell growth and attachment. This work was supported in part by the Nanobiotechnology Center (NBTC), an STC Program of the National Science Foundation under Agreement No. ECS-9676771.

Adhesion and Proliferation of Primary Hepatocytes on Synthetic Peptides
N. Takahashi, Y. Kikkawa, M. Nomizu; Tokyo Univ. of Pharm. and Life Sci., Hachioji, Japan

Liver transplantation is a curative treatment for hepatic dysfunction such as cirrhotic liver and hepatocellular carcinoma. However, it is limited by severe shortage of donors. Therefore, a bioartificial liver is expected to provide the critical hepatic functions. Design of effective biomaterial for hepatic adhesion is important for development of a bioartificial liver. Previously, we have identified 20 cell adhesive sequences in the mouse laminin-111, a multifunctional glycoprotein in basement membranes, using 673 synthetic peptides. Here, we screened hepatocyte-adhesive peptides using the 20 cell adhesive peptides to apply as a biomaterial for development of bioartificial liver. Rat hepatocytes were isolated by two-steps collagenase perfusion and used for cell adhesion assay. When we tested the 20 synthetic peptides in a hepatocyte adhesion assay, only two peptides, A13 (RQVFGQAYIYIK, mouse laminin α1 chain residues 121-133) and C16 (KADFITYYRLK, mouse laminin γ1 chain residues 139-150) exhibited the activities in a dose-dependent manner. The morphology of hepatocytes on the A13- and C16-coated plates was similar. Further, we tested inhibitory effects of EDTA and heparin on cell adhesion activity of the peptides to characterize the cellular ligands for the peptides. Both EDTA and heparin inhibited the adhesion of the hepatocytes to the peptides, suggesting that the cellular interaction was dependent on a divalent cation and potentially interact with heparin/heparan sulfate proteoglycans. We also evaluated the effect of the A13 and C16 peptides on proliferation of hepatocytes. The C16 peptide promoted DNA synthesis in hepatocytes but A13 did not affect, suggesting that the cellular effect of the peptides was different. These results suggest that the A13 and C16 peptides could control the cell attachment and proliferation of hepatocytes. The peptides have a potential to maintain hepatic function in long-term culture and may be useful for development of bioartificial liver as a biomaterial.

Fibronectin Heparin III Binding Domain (III4-5 Repeats) Is Involved in Fibronectin Fibrillogenesis
A. Maqueda, J. V. Mooyan, D. M. Peters, A. Garcia-Pardo; Immunology, Centro de Investigaciones Biologicas, CSIC, Madrid, Spain, Department of Pathology and Laboratory Medicine, University of Wisconsin, Madison, WI

Fibronectin (Fn) is an important component of the extracellular matrix, from where it regulates cell adhesion and migration, growth, and differentiation. Fn matrix assembly involves interactions among various regions of the molecule, which contribute to elastogen and stabilization of the fibrils. We previously showed that the heparin II domain of Fn (repeats III12-14) is involved in Fn fibrillogenesis (Bultmann et al., J. Biol. Chem. 273: 2601, 1998). Because of the functional similarities between Fn heparin-binding domains II and III (repeats III4-5), we have now studied whether the heparin III region participates in Fn fibrillogenesis. The recombinant fragment FNI11-5 blocked Fn fibril formation and 121-Fn incorporation into fibroblast cell layers, as effectively as the amino-terminal domain of 20 kDa fragment, a well known competitor in these assays. Binding assays using a biosensor revealed that FNI11-5 bound to Fn and to the amino-terminal receptors of 70 kDa and 29 kDa. FNI11-5 also bound to itself, indicating that the fragment containing sequences in FNI11-5, KLDAPT(II)2 site and WTPPRA...TGYRL...TGLTR (HBP/III5 site) (Mooyan et al., J. Biol. Chem. 274: 135, 1999), were involved in these interactions and in the matrix inhibitory effect, we mutated specific amino acids in the II and II5 sites and studied their functional effect. While mutations on the II site had no effect, mutating the first two arginine residues in HBP/III5 abolished the ability of FNI11-5 to bind to itself, Fn or 70 kDa. In contrast, the last two arginine residues in HBP/III5 were required for the matrix inhibitory effect.
activity of FNIII4-5, and for blocking 125I-29 kDa incorporation into cell layers. Altogether these results established that IIIA-5 repeats constitute a novel Fn region involved in self-association and Fn fibrogenesis, and that both functions require different arginine residues in the HBP/III5 sequence.

308 The Homogeneous Mutant Collagen in Brit/Mov Compound Mice Is Associated with a Milder Osteogenesis Imperfecta Phenotype Than Occurs in Heterozygous Brit/+ Mice, Despite Increased Matrix Insufficiency Due to the Mov13 Null Allele

T. E. Uveges,1 J. A. Meganck,1 E. L. H. Daley,1 S. A. Goldstein,1 J. C. Marin1; 1BEMB, NIH/NICHD, Bethesda, MD, 2Ortho Res Lab, University of Michigan, Ann Arbor, MI

The Brit mouse (Brit/+), a model for dominant-negative type IV osteogenesis imperfecta (OI), has a glycine substitution (G349C) in one col1a1 allele and a heterogeneous population of collagen forms, with 0, 1 or 2 mutant α1(I) chains. Surprisingly, mice homozygous (Britl/Britl) for this dominant mutation have a milder phenotype, with growth, BMD, and femoral geometry and mechanical properties intermediate between wt and Britl/+.

Britl/Britl synthesize homogenous collagen with only mutant α1(I) chains (Forlino, 2005 EJHG 13(S1):61-65:C12), suggesting that heterogeneity of type I collagen may be an essential factor in OI severity. To examine collagen homogeneity by an alternative route; we crossed Britl/+ with Mov13/+ mice, which have a null col1a1 allele. Analyses of the offspring indicate that Britl/Mov mice also have a milder phenotype than Britl/+ mice. Britl/Mov, like Britl/Britl, has normal perinatal survival vs 30% lethality in Britl/+.

On skeletal staining, Britl/Mov and Mov13/+ do not have the in vitro rib fractures of Britl/+.

Growth curves of Britl/Mov and Mov13/+ are intermediate between wt and Britl/+.

At 2 months of age, Britl/Mov and Mov13/+ dermal collagen fibril diameters were significantly smaller than Britl/+ or wt fibrils. Britl/Mov fevms have normal BMD and the same geometric adaptations found in Mov13/+ (increased cross-sectional area and cortical thickness) rather than the improved material properties found in Britl/Britl. Britl/Mov fevms also have improved mechanical properties (energy to failure and brittleness) compared to Britl/+. Since Britl/Mov femoral geometry and mechanics resemble Mov13/+, we cannot rule out the possibility that the type I collagen insufficiency associated with the mov13 allele is disorganizing the matrix in a way that masks the weakening effect of the structurally abnormal collagen. However, the data on Britl/Mov and Britl/Britl are most consistent with the interpretation that a homogeneous population of mutant collagen is associated with a milder OI phenotype.

309 Annexin V / Collagen Interactions Regulate Mineralization of Growth Plate Chondrocytes

H. Kim, T. Kirsch; University of Maryland, Baltimore, MD

Mineralization of growth plate cartilage is crucial for normal bone formation. Therefore, an understanding of the mechanisms regulating mineralization is important. We have shown that an annexin (II, V and VI) form Ca2+ channels in growth plate chondrocytes enabling the initiation of mineralization. In addition, binding of annexin V to type I, II, and X collagen stimulates annexin V Ca2+ channel activities. In this study, we hypothesized that type II or type I collagen matrix stimulates mineralization of growth plate chondrocytes via binding and activating annexin V Ca2+ channels. To test this hypothesis, we treated growth plate chondrocytes with vitamin C to stimulate mineralization events in the absence or presence of dihydroxyproline, which inhibits collagen fibril formation, and measured intracellular Ca2+ concentration (Ca2+), alkaline phosphatase activity and the degree of mineralization. On the other hand, we cultured growth plate chondrocytes on type I or II collagen coated dishes. Vitamin C stimulated type II and X collagen synthesis, alkaline phosphatase activity and mineralization of growth plate chondrocytes, whereas dehydroxyproline inhibited the stimulation of these events in vitamin C-treated cells. Vitamin C also led to an increase of [Ca2+]i in growth plate chondrocytes, whereas dehydroxyproline inhibited this increase. Flow cytometric analysis and cell attachment assays revealed that ~ 40% of annexin V were located on the outer membrane surface and that cell attachment of growth plate chondrocytes to type II and type I collagen was inhibited with annexin V specific antibodies. On the other hand, culturing growth plate chondrocytes on type I or II collagen coated dishes stimulated their phosphatase activity and the degree of mineralization compared to cells cultured on culture dishes. In conclusion, our findings reveal that type I and II collagen via binding to annexin V stimulate annexin-mediated Ca2+ influx, alkaline phosphatase activity and mineralization of growth plate chondrocytes.

310 Localization of Pdlim2 at Cell-Matrix Adhesion Sites Requires an Intact Actin Cytoskeleton and Rho Activity

A. Gatesman-Ammer, B. M. Helfer, D. C. Flynn, S. M. Frisch; Mary Babb Randolph Cancer Center, West Virginia University, Morgantown, WV

The homogeneous mutant collagen in Britl/Mov compound mice is associated with a milder osteogenesis imperfecta phenotype than occurs in heterozygous Britl/+ mice, despite increased matrix insufficiency due to the Mov13 null allele.

Pdlim2 cDNA, encoding a protein containing an N-terminal PDZ motif and a C-terminal LIM domain, was previously identified in a rat eye iridocorneal angle cDNA library. It is highly expressed in the corneal epithelium and is associated with α-granules, filamin A, myosin VI, and MYH9.

In the present study, we further explore its potential involvement in cell adhesion, motility, migration, and actin cytoskeleton in Human Corneal Limbal and Epithelial cells (HCL) by Total Internal Reflection Fluorescence Microscopy (TIRFM).

The results showed that GFP-Pdlim2 was specifically localized to cell-matrix adhesion and actin attachment sites at the periphery of cells grown on fibronectin. Cell controls transfected with GFP only did not acquire any specific TIRF signals. Cytochalasin D treatment completely obliterated Pdlim2-associated structures at the cell periphery, while treatment with C3, a Rho family inhibitor, changed the distribution of Pdlim2 from cell adhesion sites to lamellipodia. Immunofluorescence showed co-localization of Pdlim2 with actin cortical filaments and phospho-S19 myosin light chain regulatory chain (MLC II) at the cell periphery. We also identified active Rho, Pdlim2, phospho-S19 MLC II, and β1 integrin in protein complexes isolated by Rhoptenkin RBD affinity chromatography.

Consistent with these findings, immunofluorescence of corneal whole mounts detected Pdlim2 protein only in the corneal epithelium in association with actin cytoskeletal structures. These findings demonstrate that localization of Pdlim2 at cell adhesion sites requires an intact actin cytoskeleton and Rho activity, and suggest that Pdlim2 plays a role in corneal epithelial cell adhesion and migration.

311 Caspase-2 Regulates Cell-Matrix Adhesion

B. M. Helfer, A. Gatesman-Ammer, D. C. Flynn, S. M. Frisch; Mary Babb Randolph Cancer Center, West Virginia University, Morgantown, WV

Caspase-2 plays important roles in DNA damage-induced, detachment-induced, and heat shock-induced apoptosis. Additional biologic functions are likely; while the developmental phenotype of caspase-2 knockout mice is normal, it is often the case that the same gene knockout examined in different mouse strains has varying effects. Here, we demonstrate that caspase-2 has additional roles in the cell beyond apoptosis. Caspase-2 promotes cell-matrix adhesion and protects the fidelity of cytoskeleton as well as affecting cell motility. Mechanisms for the regulation of cytoskeleton by caspase-2 are being explored and will have important ramifications for normal and tumor cell behavior.

312 Laminin 411 Expression and Localization in Human Erythromegakaryocytic Cell Lines and Blood Platelets

S. Ingerup,1 T. Geberthow,2 E. Junoren,1 M. Pook,1 M. Meiesar,1 T. Mainets,1 M. Patartoy,2 1Institute of Molecular and Cell Biology, University of Tartu, Tartu, Estonia, 2Department of Odontology, Karolinska Institute, Stockholm, Sweden, 3Institute of General and Molecular Pathology, University of Tartu, Tartu, Estonia

Laminins are a family of heterotrimeric proteins with cell adhesive and signaling properties. Laminin 411 (α4β1γ1) is a major laminin isoform of blood vessels and also found in platelets, monocytes, lymphocytes and neutrophils, and mediates their adhesion via α6β1 and αMβ2 integrins. We have explored the synthesis and presence of laminin 411 in erythromegakaryocytic HEL and DAMI cells. In HEL cells, transcripts for α4, β1 and γ1 laminin chains were detected by RT-PCR. Metabolic labeling of HEL cells and immunoprecipitation of lysate with anti-β1 and γ1 chain mAbs revealed corresponding laminin subunits in precipitate. Immunofluorescence flow cytometry demonstrated reactivity of mAbs to laminin β1 and γ1 chains with permeablized cells. Confocal microscopy studies on HEL and DAMI cells have demonstrated laminin localization in cytoplasm being assembled mainly in membrane skeleton area. Abovementioned facts suggest that blood platelet laminin originates from bone marrow megakaryocytes. We have shown also that human platelets contain and following activation secrete laminin 411. The mAbs to laminin α4 chain give positive staining in resting and glass-activated human platelets as well as in bone marrow megakaryocytes predominantly to granules but also the overall cytoplasm reactivity is noticeable. However, fibrinogen matrix-activated platelets expose positive staining of laminin in the center of the cell. Rearrangements upon activation are typical to other platelet α-granule adhesive proteins which accumulate in the cell center when α-granules coalesce in the cytoplasm and fuse with the open canalicular system. We used sucrose density-gradient centrifugation to separate α-granules to reveal subcellular localization of laminin. Laminin 411 was present in the high-density fraction, which was paralleled by thrombospandin and fibrinogen, two marker proteins of α-granules, indicating association of laminin with these structures. Synthesis and expression of laminin molecules by platelets suggest a role of laminin in hemopoiesis and platelet physiology.

313 Structural Analysis of the Plakin Domain of Bullous Pemphigoid Antigen1 (BPAG1) Shows That Plakins Are Related to Spectrins

J. J. Jefferson,1 L. Shapiro,2 R. K. Liem1; 1Pathology and Cell Biology, Columbia University, New York, NY, 2Biochemistry and Molecular Biophysics, Columbia University, New York, NY

Bullous Pemphigoid Antigen1 (BPAG1) is a member of the plakin family of proteins and was first identified as an autoantigen in patients with the skin blistering disease, bullous pemphigoid. Homozygous deletions in the BPAG1 gene result in sensory neuron authentication disorder resulting in severe loss of coordination, as well as skin fragility. The plakins are multi-domain containing proteins and each domain has been shown to have specific interaction partners, including microtubules, actin filaments and intermediate filaments, as well as junctional complexes. A common feature of the plakins is the so-called plakin domain, which serves as an important platform for interactions with protein complexes found in specialized cell junctions, such as desmosomes and hemidesmosomes. This domain has been predicted to consist of a series of alpha-helical bundles that fold into a globular domain near the N-terminus of the plakins. We have determined the crystal structure of a tetrameric alpha-helical bundle domain of BPAG1. The structure was solved by SAD phasing from a selenomethionine-substituted protein crystal at 3.0 angstroms resolution. The crystal structure shows that this protease resistant fragment consists of a pair of spectrin repeats, made up of triple helical bundles that are gently curved and wrapped around each other in a left handed supercoil and connected by an alpha-helical linker region. Based on this structure and the conservation of key residues that are important for the folding and stability of spectrin repeats, as well as domain prediction algorithms, we propose that despite the absence of clear sequence similarity, the plakin domain of BPAG1, as well as all other plakins, consists of two pairs of spectrin repeats interrupted by a putative SH3 domain placing the plakins in the spectrin superfamily.

314 Canine Myosin Is Labelled with Palmitic Acid

C. S. Ricard, A. Mukherjee; Ophthalmology, Saint Louis University, St Louis, MO

Objective: Myosin has been associated with primary open angle glaucoma. Normal and pathological functions of myosin remain to be elucidated. MDCK express myosin, making them a useful cell model to study myosin. The sequence of canine myosin bears close similarity with the human myosin sequence. MDCK are a well-characterized canine polarized cell line. Analysis of lipid rafts, protein trafficking to apical versus basolateral membranes, and studies in viral infection have been performed in MDCK cells. Methods: MDCK cells were confirmed as uninfected canine cells by multiple PCR at each of these time points. Type 1 collagen mRNA levels from the testes of CTGF transgenic mice were shown to be elevated at least 2-10-fold as compared to non-transgenic littermates. These results are consistent with histological examination of testes from CTGF and non-transgenic littermates using RT-PCR.

315 Integrin and Growth Factor Mediated Signaling in Erhythroproisis

S. Eshghi,1 M. G. Vogegeanz,2 R. O. Hynes,3 L. G. Griffith,4 H. F. Lodish2; 1Biological Engineering, MIT/Whitehead Institute, Cambridge, MA, 2Department of Cell Biology, Harvard Medical School, Boston, MA, 3Center for Cancer Research, MIT, Cambridge, MA, 4Biological Engineering, MIT, Cambridge, MA

Objective: The adapter protein SH2-B, which binds to the activated form of the nerve growth factor (NGF) receptor TrkA, has been implicated in neuronal differentiation as well as in the survival and motility of sympathetic neurons. SH2-B enhances NGF-induced neurite outgrowth in pre-neuronal PC12 cells, while a dominant negative mutant of SH2-B lacking an intact SH2 domain required for

316 The Contribution of Connective Tissue Growth Factor (ctgf, CCN2) to Fibroblast Biology

L. Kennedy1, S. Liu,2 X. Shi,2, W. Chen,1 D. E. Carter,1 K. M. Lyons,4 C. M. Black,2 D. J. Abraham1, A. Leake1; 1CHR Group in Skeletal Development and Remodeling, University of Western Ontario, London, ON, Canada, 2Physiology, Center for Rheumatology, University College London (Royal Free Campus), London, United Kingdom, 3Biological Engineering, University College London (Royal Free Campus), London, United Kingdom

Regulation of cell behavior by both growth factor and integrin-mediated signaling is a common theme in many diverse systems. Intracellular signaling initiated by binding of erhythropein to its receptor has long been understood to be the major pathway governing erythroid development but the role of signals originating from the extracellular matrix in this system has been less rigorously studied. Here we present evidence that signaling initiated by binding of fibronectin to αⅣβ1 integrins on the surface of erythroid progenitor cells is necessary for proper erythroid proliferation. Furthermore our data suggest that a two-stage model for erythroid development, where an early Epo-dependent, integrin-independent phase is followed by an Epo-independent, integrin-dependent phase. Using flow cytometry, fetal liver erythroid progenitors were separated at four distinct stages of development based on expression of cell surface antigen. CD71 and Ter119. This system allowed us to show that αⅣβ1 integrins are developmentally regulated during erythropoiesis and that these integrins mediate adhesion to specific domains of fibronectin. An in vitro differentiation assay indicated that αⅣβ1 integrins are necessary for terminal erythroid proliferation but only after an early Epo-dependent phase. This work not only supports the view that normal erythroid development is achieved through signaling pathways initiated by αⅣβ1 integrin in addition to the erythropein receptor but also provides new insight to the more general integration of signals from growth factor and environmental cues in development.

317 Connective Tissue Growth Factor (CTGF) Stimulates Type I Collagen mRNA Synthesis In Vivo

Z. Zhou, P. A. Harding; Zoology, Miami University, Oxford, OH

Connective tissue growth factor (CTGF/CN2) is a member of the CCN family of proteins whose biological properties include cellular proliferation, adhesion, extracellular matrix production, migration, and is implicated in fibrosis. The goals of this study are to understand the biological actions of CTGF/CN2 using a transgenic mouse model. Transgenic mice were generated using a pIRES-EGFP expression vector using a bicistronic mRNA containing both human CTGF cDNA and enhanced green fluorescent protein (EGFP) coding sequences under the regulation of the cytomegalovirus immediate-early (CMV-IE) promoter. Immunohistochemical examination of testes from 8-week CTGF transgenic and non-transgenic littermates using an anti-human CTGF C-terminal peptide antibody exhibited recombinant human CTGF expression in both the interstitium and sperm in testes from CTGF transgenic mice. In contrast, no immunoreactive CTGF was observed in the testes from non-transgenic littermates. Quantitative real time RT-PCR was employed to determine the TGFβ1 mRNA levels testes from CTGF transgenic and non-transgenic littermates at 2, 4, 6, and 8 weeks of age. Results demonstrated no significant differences in the TGFβ1 mRNA levels between CTGF transgenic and non-transgenic mice. Similarly, RT-PCR was taken to investigate the expression levels of type 1 collagen mRNA at each of these time points. Type 1 collagen mRNA levels from the testes of CTGF transgenic mice were elevated at least 2-10-fold as compared to non-transgenic littermates. These results are consistent with histological examination of testes from CTGF transgenic and non-transgenic littermates using Masson-Trichrome in which collagen was observed within the interstitium of testes from CTGF transgenic mice. However, no collagen was detectable in the interstitium of testes from non-transgenic mice. Taken together, we have generated a model to examine testicular fibrosis using a CTGF transgenic mouse model in which recombinant human CTGF is expressed in the testis.

318 The Adapter Protein SH2-B Regulates a Subset of Nerve Growth Factor-induced Gene Expression and Neuronal Invasiveness

L. Chen, Ryunan, National Institute of Medical Science, Tsing Hua University, Hsinchu, Taiwan

The adapter protein SH2-B, which binds to the activated form of the nerve growth factor (NGF) receptor TrkA, has been implicated in neuronal differentiation as well as in the survival of sympathetic neurons. SH2-B enhances NGF-induced neurite outgrowth in pre-neuronal PC12 cells, while a dominant negative mutant of SH2-B lacking an intact SH2 domain required for recruitment to TrkA, SH2-B(R555E), blocks it. SH2-B undergoes nucleocytoplasmic shuttling suggests that SH2-B may regulate the expression of genes that determine neuronal
differentiation. We used Affymetrix gene array analysis to compare gene expression profiles of NGF-treated and control cells expressing GFP, GFP-SH2-Bj or GFP-SH2-Bjl (R555E). Multiple NGF-responsive genes were upregulated by SH2-Bjl but not SH2-Bjl (R555E), including genes encoding urokinase plasminogen activator receptor (uPAR), matrix metalloproteinase 3 and 10 (MMP3 and MMP10). In addition, NGF-induced activation of MMP3 and/or 10 was increased in cells expressing GFP-SH2-Bjl but reduced in cells expressing SH2-Bjl (R555E) compared to control cells. uPAR, MMP3 and MMP10 regulate intracellular signaling and the interaction between the cell and extracellular matrix (ECM), which is continuously regulated during differentiation. uPAR has been shown to be required for neuronal differentiation of PC12 cells. MMP3 has been shown to maintain growth cone invasiveness, which is important for neurite outgrowth, in PC12 cells. Consistent with SH2-Bjl upregulating MMP3 and MMP10 and stimulating their function, overexpression of SH2-Bjl enhanced NGF-induced invasiveness of PC12 cells growing on Matrigel. NGF-induced invasiveness was reduced by an inhibitor of MMP, tissue inhibitor of MMP2 (TIMP2). Thus, the increased invasiveness in SH2-Bjl overexpressing cells is likely a result of increased secretion of MMP3 and MMP10, which degrade the ECM and allow differentiating cells to penetrate the Matrigel. Taken together, these results suggest that SH2-Bjl enhances NGF-induced gene expression of uPAR, MMP3 and MMP10. We also identify a new function of SH-B in neuronal invasiveness.

Identification of Src and Fak as Key Intermediates in Integrin and Trk Activated Signaling Pathways in the Stimulation of Neurite Growth in Adult NGF-Responsive DRG Neurons

B. A. Tucker, M. Rahimtula, K. M. Mearrow, Memorial University of Newfoundland, St. John's, NF, Canada

Axonal regeneration is predominantly influenced by factors located in the neuron's extracellular environment, and includes neurotrophins, such as NGF, and adhesion molecules, such as laminin. As we have previously reported, the provision of both NGF and laminin to adult NGF-responsive DRG neurons results in optimal levels of neurite growth not achievable by either factor alone. In this study, we were interested in determining the key points of collaboration between laminin and NGF induced neurite growth. Pharmacological inhibition of specific signaling components were performed, and early neurite growth and signalling analysis was conducted. Adult NGF-responsive DRG neurons were treated with NGF, laminin, or laminin plus NGF for 10 min, 1 hr, or 6 hrs, and subsequently analysed. Our results indicate that inhibition of either Src or Fak activity attenuates both PI 3-K/Akt and MEK/ MAPK signalling pathways induced by laminin and/or NGF. Furthermore, inhibition of Akt blocks observed neurite growth; however, inhibition of MEK/MAPK has no significant effect. We have also shown that neither PI 3-K nor MEK/MAPK exert any influence on one another. Together, these results indicate, for the first time, that Src and Fak are key points of collaboration between NGF and laminin induced neurite growth in NGF-responsive adult DRG neurons.

Quantitative Differential Sulfation Pattern of Chondroitin Regulates Axonal Guidance

Y. Katagiri,1 H. Wang,1 T. McCooam,1 Z. Yu,1 F. Tan,1 E. Unsworth,1 P. Goldsmith,2 Y. Wang,4 A. Symes,4 H. M. Geller1; 1Developmental Neurobiology Section, NHLBI, NIH, Bethesda, MD, 2Pathology Core, NHLBI, NIH, Bethesda, MD, 3NCl, Bethesda, MD, 4USUHS, Bethesda, MD

Glycosaminoglycan (GAG) side chains endow extracellular matrix proteoglycans with an unparalleled diversity of biological regulatory properties based upon the length, composition, and charge distribution of the polysaccharide chain. A “sulfation code” hypothesis has been proposed in heparan sulfates which states that distinct patterns of sulfation along the polysaccharide chain regulated by distinct sulfotransferases encode information required for substrate binding and growth regulation. Here we provide evidence that this sulfation code in the GAG chains of chondroitin sulfate (CS) is a critical determinant of axonal guidance and neuronal growth. 4-sulfate-enriched CS-A, but not 6-sulfate-enriched CS-C, exhibits a strong negative guidance cue to mouse cerebellar granule neurons and activates RhoA, indicating that the pattern of sulfation and the net charge of the GAG chains is the molecular determinant of growth inhibition. Even partial removal of 4-sulfate from CS-A completely abolishes growth inhibition. In astrocyte-neuron co-cultures, 4-sulfated CS and chondroitin 4-sulfotransferase 1 (C4ST1) are rapidly and substantially increased upon induction of reactive astrocytes, resulting in impaired neurite growth. Parallel increase in 4-sulfated CS is observed following spinal cord injury in mice. Depletion of astrocyte C4ST1 by siRNA restores axonal growth in culture, and its overexpression renders astrocytes far less permissive for neuronal growth. These findings demonstrate the importance of the sulfation code of CS for neuronal growth regulation, and suggest that inhibition of 4-sulfation is a potential therapeutic target for intervention in central nervous system injury.

Neurite Outgrowth Is Enhanced by Laminin-mediated Downregulation of the Low Affinity Neurotrophin Receptor p75NTR

S. L. Rankin, C. S. Guy, M. Rahimtula, K. M. Mearrow, Basic Medical Sciences, Memorial University, St. John's, NF, Canada

It is recognized that the extracellular matrix (ECM) is a key factor in promoting axonal regeneration, coordinate regulating growth in conjunction with trophic signals provided by the neurotrophins, including nerve growth factor (NGF). Laminin (LN) significantly contributes to the composition of the ECM, and represents a potent inducer of neurite outgrowth in vitro. While LN-mediated mechanisms leading to enhanced growth are not defined, they likely represent a complex interplay between enhancement of permissive cues, and downregulation of those which are inhibitory. The current study investigated potential interactions between the LN and NGF-mediated signaling pathways. Differentiated PC12 cells were exposed to either neutral (poly-lysine) or permissive (LN) substrates in the presence or absence of NGF. Qualitative analysis revealed that neurite outgrowth stimulated by NGF is enhanced on a LN substrate. Western blot analysis of pertinent signal transduction components revealed both enhanced phosphorylation of early signaling intermediates and a concomitant downregulation of p75NTR, the low affinity NGF receptor. This downregulation seems to be associated with a LN-induced upregulation of PTEN, and resulted in a PURPIND decrease in Rho activity. p75NTR is a key activator of Rho signaling, which is inhibitory to neurite outgrowth. Furthermore, p75NTR is well documented for its role as the transducing element for inhibitory myelin-derived signals. These novel results demonstrate the importance of the sulfation code of CS for neuronal growth regulation, and suggest that inhibition of 4-sulfation is a potential therapeutic target for intervention in central nervous system injury.

The Role of Latent TGF-β Binding Proteins in Secretion of the TGF-β-Superfamily Ligand Myostatin

S. B. Anderson,1 A. L. Goldber,1 M. Whitman1; 1Developmental Biology, Harvard School of Dental Medicine, Boston, MA, 2Cell Biology, Harvard Medical School, Boston, MA

Myostatin is a TGF-β Superfamily ligand that negatively regulates skeletal muscle mass. Myostatin is cleaved from a proform into a mature ligand that is capable of signaling through TGF-β Superfamily receptors. Latent TGF-β Binding Proteins (LTBPs) have been shown to assist in proper folding and secretion of the canonical TGF-β ligands, but until this time a role for LTBPs in maturation of non-canonical TGF-β Superfamily ligands has not been demonstrated. In order to better understand the events surrounding myostatin maturation, we have investigated the interactions between myostatin and LTBPs. We demonstrate by co-immunoprecipitation that the proform of myostatin interacts with all four known LTBPs, LTPB 1-4. Of the four LTBPs, LTPB3 specifically interacts with a dimerized and glycosylated proform of myostatin, suggesting that LTPB3 interacts with properly folded and secreted myostatin. When LTBPs and myostatin are co-expressed in 293T cells, the newly synthesized myostatin accumulates in its proform within the extracellular matrix. Evidence will be presented about whether similar regulation of myostatin maturation occurs in adult mouse muscle.

Quantitative Studies of EGFR System Autocortic Induced Cell Signaling and Response

E. J. Joslin,1 B. S. Hendricks,1 H. Kim,1 N. Kumar,1 L. K. Oprekosko,1 H. S. Wiley2; 1Biological Engineering Division, MIT, Cambridge, MA, 2Research Technology Center, Pfizer, Cambridge, MA, 3Pacific Northwest National Lab, Richland, WA

Dysregulation of the epidermal growth factor receptor (EGFR) family and their cognate ligands has been implicated in several types of cancer. We aim to test the hypothesis that varying the rate of extracellular autocrine ligand release will yield important changes in signaling dynamics and cell behavior. We also aim to quantify the difference between autocrine and exogenous stimulation. High and low release rates of EGF are achieved experimentally using chimeric transmembrane EGF ligand precursor retrovirally transfected into a human mammary epithelial cell line. The high ligand release can be down-modulated upon addition of a metalloprotease inhibitor. We have developed a computational model in combination with our experimentally measured EGF stimulation. High and low release rates of EGF are achieved experimentally using chimeric transmembrane EGF ligand precursor retrovirally transfected into a human mammary epithelial cell line. HGF Stimulation Causes c-Met to Phosphorylate the MUC1 Cytoplasmic Tail and Facilitates Endocytosis and Nuclear Localization

P. K. Singh, R. L. Cerny, M. A. Hollingsworth; 1Eppley Institute for Research in Cancer and Allied Diseases, UNMC, Omaha, NE, 2University of Nebraska-Lincoln, Lincoln, NE

MCF10A cells, did not exhibit high levels of Erk phosphorylation. Thus, TGF-β treatment was associated with a high sustained level of Erk phosphorylation/activation which contrasted with low levels of phospho-Erk in the normal MCF10A acini. In addition, an increase in vimentin expression, a marker of EMT, was also observed in TGF-β treated acini. TGF-β treatment also impaired acinus formation from primary mouse mammary epithelial cells. Again the result was the formation of loose assemblies of non-polarized cells; and again lumen formation failed and vimentin expression was induced. However, the assemblies had a smaller mean diameter than the normal acini and, in contrast to the MCF10A cells, did not exhibit high levels of Erk phosphorylation. Thus, TGF-β treatment impairs acinus formation from two different mammary epithelial cell types by a mechanism that is probably not dependent on triggering deregulated growth factor-Erk MAP kinase signaling.

The Inhibitor of VEGF-Receptors Tyrosine Kinase PTK-787/ZK-222584 Blocks the Invasive Potential of Adult T-Cell Leukemia Cells through the Endothelium

L. E. Haddad, M. D. Migliori, J. H. Hruban, H. A. El-Khoury, Y. Kfouri, L. S. Atweh, D. H. The, O. Hermine, M. E. reciprocal co-immunoprecipitations followed by western blotting. Recombinant human c-Met protein catalyzed in vitro phosphorylation of tyrosine in the YHYP motif of the a 66-residue MUC1CT as detected by tandem mass spectrometry. Stimulation of pancreatic adenocarcinoma cells with HGF, a ligand for c-Met, enhanced the incorporation of 32P in MUC1CT, and enhanced phosphorylation at tyrosine in the YHYP motif as determined by analysis with site specific phospho-enhanced clathrin-mediated endocytosis of MUC1CT and its nuclear localization, as determined by real-time confocal imaging of C-terminally GTP-tagged MUC1. There was faster turnover of MUC1 under stimulation with HGF, and overexpression of MUC1 facilitated faster turnover of c-Met in S2-013 cells. These results indicate that c-Met, serving as a kinase for MUC1, phosphorylates MUC1CT and promotes the endocytic trafficking-mediated nuclear localization of MUC1 and subsequent turnover of MUC1CT and c-Met during HGF stimulation. Given that MUC1 and Met are overexpressed in pancreatic adenocarcinoma, further studies of MUC1 and Met signaling should provide additional insight into the mechanisms that regulate invasion and metastasis of pancreatic cancer.

Differential Signaling Response of Constitutively Active IL2R-EGFR Chimera

J. O. Hunttoo, A. Kramer; Dept. of Cell and Tissue Biology, UCSF, San Francisco, CA

endothelial cells through the junctional complexes comprising tight junctions, adherens junctions, and gap junctions. All these structures may play a crucial role in maintaining the integrity of the endothelium and initiating angiogenesis and communicating with endothelial cells through gap junctions. This results in induction of endothelial-derived metalloproteinases, sub-endothelial basement membrane degradation

Metastasis, a pivotal step in cancer, is the colonization of selective, secondary organ sites by dissemination of tumor cells from their primary location by their extravasation through the endothelium.

Treatment Impairs the Formation of Mammary Epithelial Acini

S. M. McCarthy; Conway Institute, Dublin, Ireland

Epithelial-mesenchymal transition (EMT) is a process that involves the loss of epithelial cell polarity due to the disappearance of cell-cell junctions and the gain of a mesenchymal phenotype. Transforming growth factor β (TGF-β) is known to initiate and maintain EMT in a variety of biological systems and may promote associated tumor cell invasion and metastasis. It was of interest therefore to observe the effects of exogenous TGFβ treatment on the formation of 3-D mammary epithelial cell acini both using MCF10A cells and primary mouse mammary epithelial cells. MCF10A cells are an immortalized but non-transformed human mammary epithelial cell line. When cultured in the presence of a laminin-rich extracellular matrix, MCF10A cells form 3D acinar structures. TGFβ treatment disrupted MCF10A acinus formation. The treatment resulted in the formation of loosely associated assemblies of cells. The cells failed to polarize, the forming acini not to their lumina and interestingly, the cells probably failed to exit the cell cycle; preliminary results suggest that TGFβ treatment was associated with a high sustained level of Erk phosphorylation/activation which contrasted with low levels of phospho-Erk in the normal MCF10A acini. In addition, an increase in vimentin expression, a marker of EMT, was also observed in TGFβ treated acini. TGFβ treatment also impaired acinus formation from primary mouse mammary epithelial cells. Again the result was the formation of loose assemblies of non-polarized cells; and again lumen formation failed and vimentin expression was induced. However, the assemblies had a smaller mean diameter than the normal acini and, in contrast to the MCF10A cells, did not exhibit high levels of Erk phosphorylation. Thus, TGFβ treatment impairs acinus formation from two different mammary epithelial cell types by a mechanism that is probably not dependent on triggering deregulated growth factor-Erk MAP kinase signaling.

Patterning of Multiple Cell Lineages from a Single Stem Cell Population

Given that MUC1 and Met are overexpressed in pancreatic adenocarcinoma, further studies of MUC1 and Met signaling should provide additional insight into the mechanisms that regulate invasion and metastasis of pancreatic cancer.

Differential Signaling Response of Constitutively Active IL2R-EGFR Chimera

J. O. Hunttoo, A. Kramer; Dept. of Cell and Tissue Biology, UCSF, San Francisco, CA

endothelial cells through the junctional complexes comprising tight junctions, adherens junctions, and gap junctions. All these structures may play a crucial role in maintaining the integrity of the endothelium and initiating angiogenesis and communicating with endothelial cells through gap junctions. This results in induction of endothelial-derived metalloproteinases, sub-endothelial basement membrane degradation followed by endothelial cell retraction allowing neoplastic lymphocytes extravasation. This local and transient effect is dependent on the paracrine interaction through local production of functional angiogenic factors such as VEGF (vascular endothelial growth factor) by tumor cells and on the direct hetero-cellular communication between tumor cells and endothelial cells through the junctional complexes comprising tight junctions, adherens junctions, and gap junctions. All these structures may play a crucial role in maintaining the integrity of the endothelium’s barrier. We explored the effects of the specific tyrosine kinase inhibitor of VEGF receptors, PTK-787/ZK-222584 (PTK/ZK), and anti VEGF antibodies on ATL cell extravasation. Both agents inhibit ATL-induced in vitro angiogenesis. ATL-derived cell free supernatant induced a rapid and sharp increase in the phosphorylation of FAK and ERK and a moderate increase in AKT phosphorylation. Both PTK/ZK and anti-VEGF antibodies reduced FAK phosphorylation in a dose dependent manner but had no effect on AKT and ERK phosphorylation. Finally, blocking of VEGF signaling by PTK/ZK or anti-VEGF antibodies significantly attenuates ATL cell extravasation. These results demonstrate the central role of VEGF signaling in ATL cell extravasation and support the potential use of PTK/ZK in the treatment of ATL and other hematological malignancies with angiogenic, invasive and metastatic properties.
Integrin (α6β4) Regulation of mTOR and Breast Carcinoma Survival

W. Yin, H. Kim, J. Chung; Biochemistry, Louisiana State University HSC-S, Shreveport, LA

During malignant transformation, the rich environment filled with growth factors and extracellular matrix is rapidly lost. In their absence, normal epithelial cells undergo anoikis, a programmed cell death. Therefore, it is highly important for carcinoma cells to maintain their survival and induce angiogenesis in tumor-micro environment. Our previous findings implicate a critical role of integrin α6β4 in the survival of breast carcinoma cells by maintaining cap-dependent translation of angiogenic/survival factor, VEGF under serum starvation via activation of the mTOR. Clearly, VEGF is only the ‘tip of the iceberg’ and, most likely, α6β4 stimulates the translation of other mRNAs that contribute to breast carcinoma survival. In addition, the mechanisms by which this integrin activates mTOR remain elusive. We have found that α6β4 activates mTOR in cooperation with its signaling partner β-Arg in Akt and Ras dependent manner. Activated mTOR mediates α6β4 dependent breast carcinoma survival under stress conditions that mimic tumor micro-environment because downregulation of mTOR expression by shRNA or inhibition of mTOR activity via rapamycin blocks α6β4 dependent carcinoma survival. α6β4 to mTOR signaling enhances translation initiation of pro-survival and anti-apoptotic mRNAs that ultimately contribute carcinoma survival in vivo and progression. Considering that translational control is understudied, but important regulator of progression, our studies will provide the novel paradigm of integrin regulation of translation initiation that plays a pivotal role in cancer progression.

Mechanotransduction through Transmembrane Syndecans

R. Bellin, 1 J. Kubick, 2 A. Kamien, 1 M. Frigault, 1 B. Keil, 1 P. LeDuc 1, 2 1Department of Biology, Holy Cross College, Worcester, MA, 2Department of Mechanical Engineering, Carnegie Mellon University, Pittsburgh, PA

Mechanotransduction studies over the past decade have focused primarily on integrins as the molecular initiation point of the signaling process. Although much has been learned about the role of integrins in the cellular response to physical strain, there is reasonable evidence to suggest that other transmembrane proteins may also play a similar signaling role. In our recent studies we have discovered that syndecans, a class of heparan sulfate transmembrane proteins, serve as integrin-independent conduits of mechanical strain. To conduct these studies, we developed a method to produce syndecan-specific cell adhesion by conjugating syndecan ectodomain-specific antibodies to the surface of polydimethylsiloxane (PDMS) membranes. We subjected cultured cells on these membranes to controlled mechanical deformation through the use of our PreCS (Pressure-driven Cell-Stretching) mechanical strain device. Assays of these cells after stretching demonstrate a statistically significant increase in ERK phosphorylation in comparison to non-stretched controls. In addition, treatment of cells with actin cytoskeletal disruptive drugs before stretching results in a statistically significant reduction in the level of ERK phosphorylation in comparison to non-treated stretched cells. This finding indicates a potential role for the cytoskeleton in syndecan-based mechanical signaling. Overall, these results open the door for new areas of exploration in the field of mechanotransduction and inform us of a novel cellular role for transmembrane syndecan proteins.

Breast Epithelial Cells Adjust Their Response to 3D Density by Regulating Cellular Contractility through Filamin-β1 Integrin Interactions

S. Gehler, 1 D. A. Calderwood, 2 P. J. Keeley, 1 1Pharmacology, University of Wisconsin, Madison, WI, 2Pharmacology, University of Wisconsin School of Medicine, New Haven, CT

Breast epithelial cells cultured in a compliant, low density three-dimensional collagen matrix, but not in high density 3D collagen gels that can not be contracted, undergo ductal morphogenesis and recapitulate differentiated structures seen in vivo. The mechanisms by which breast epithelial cells detect changes in the physical properties of the extracellular matrix (ECM) and translate that information into biological signals are not clearly understood. We propose that interactions between β1 integrin and the actin-binding protein, filamin A, are part of the mechanism by which cells respond to the mechanical properties of the ECM, thus leading to changes in myosin-mediated contractility and tubule formation of breast epithelial cells. First, T47D breast epithelial cells expressing filamin A shRNA exhibit reduced contractility and have disrupted tubulogenesis in low density collagen gels. Conversely, increasing endogenous filamin A expression using FLPiP (filamin interacting protein) shRNA increased cell contractility while blocking tubule formation. These findings suggest an intermediate level of filamin A expression regulates cell contractility and tubule formation. Second, filamin A-β1 integrin interactions are enhanced in cells cultured in a floating, high density collagen gel relative to a more compliant, low density gel. These enhanced filamin-β1 integrin interactions correspond to a disruption in tubule formation. Consistent with this finding, cells expressing a β1(V787,791I) integrin mutant that exhibits enhanced filamin A-β1 integrin interactions undergone increased contractility, yet disrupted tubulogenesis, in low density collagen gels. However, tubulogenesis could be rescued by culturing these cells in dense collagen gels. These results suggest that cellular phenotype is regulated by the degree of cellular contractility in response to the compliance of the ECM. Regulation of filamin A binding to β1 integrin may serve as a mechanosensitive complex that is important for breast epithelial cells to respond to the mechanical properties of the ECM.

Extracellular Matrix Dependent Survival and Apoptosis Resistance in the 3rd Dimension

J. C. Friedland, 1 J. N. Lakins, 2 M. Nuth, 2 V. M. Weaver, 1 1Radiation Oncology, University of Pennsylvania, Philadelphia, PA, 2Institute for Medicine and Engineering, University of Pennsylvania, Philadelphia, PA

Apoptosis resistance is acquired by epithelial tissues during malignant transformation and metastasis and plays a key role in the development of drug resistance. Cells exist within a 3D tissue and cell-cell and cell-extracellular matrix (ECM) interactions regulate cell behavior. Previous studies have demonstrated that cell shape is a critical determinant of cell life and death, with increased cell spreading favoring cell survival. However, we previously showed that MECS survive when grown in a compliant matrix to form 3D polarized structures, and these MECS do not spread. Additionally, MECS acquire resistance to chemical and receptor-dependent apoptotic stimuli when grown in a compliant matrix, similar to terminal-ductal-lobular units in vivo. Therefore, we have been examining how cell context could influence cell survival and apoptosis resistance, which is dependent upon laminin ligated α6β4 integrin activation of Rac to activate Pak1 and NFκB. We also found that the apoptosis resistant phenotype could be enhanced if the MECS acini were embedded within a highly compliant 3D ECM, but antagonized by interaction with a rigid 2D ECM. Because we determined that ECM stiffness increases Rho but represses Rac activity, and ectopic expression of V14Rho or N17Rac perturbs apoptosis resistance in acini, we asked if matrix compliance would regulate acini survival by modulating the ratio of Rac and Rho activity. Consistently, expression of active V12Rac, which concentrated at regions of cell-cell interaction, induced apoptosis in MECS on a rigid 2D matrix, where Rho activity is elevated. Interestingly, inhibiting Rho in disorganized tumors, which have high Rho, leads to the formation of organized tumor structures that are extremely resistant to exogenous death cues. Our data indicate that the 3rd dimension and tissue organization are critical for Rac-dependent survival. Importantly, we are exploring whether tissue architecture could alter Rac function by differentially regulating expression for localization of Rac targets.

Requirement of Substratum Rigidity in β1 Integrin Activation and Clustering to Activate FAKβ39 Phosphorylation

W. Wei, 1 W. Chiu, 1 C. Wang, 1 M. Shen, 1 M. Tang 1, 2 1The Institute of Basic Medical Sciences, National Cheng Kung University, Tainan, Taiwan, 2Department of Physiology, National Cheng Kung University, Tainan, Taiwan

Previous study in our lab showed that FAKβ39 phosphorylation level was decreased due to low rigidity when MDCK cells were cultured on collagen gel, whereas other phosphorylation levels of FAK (407, 577, 861, and 925) remained elevated. We also found that β1 integrin activation was suppressed under low substratum rigidity. To examine whether low substratum rigidity
Differentiation of small intestine. Hensin. Preliminary investigations of small intestine with integrin antibodies to integrin β1 gene inactivation (cre-lox technology) suggest the crucial role of integrin β1 mediated hensin polymerization in the differentiation of small intestine.

Integrin β1 Activation Leads to Extracellular Matrix Assembly of Hensin, a Rabbit Isoform of Brain Tumor Suppressor Protein DMBT1 S. Vijayakumar, Q. Al-Awqati; Dept. of Medicine (Nephrology), Columbia University Medical Center, New York, NY Hensin is an extracellular matrix (ECM) protein that mediates the terminal differentiation of an intercalated cell line derived from rabbit kidney. ECM hensin induced actin cytoskeleton remodeling and columnar differentiation of Madin Darby Canine Kidney (MDCK) cells cultured on rigid substratum. The direct interaction of hensin with activated integrin β1 integrin was colocalized with lipid raft in cells cultured on rigid but not on soft substratum. Taken together, our data demonstrate that substratum rigidity is required for integrin activation and clustering that are mediated by lipid raft.

Suppression of Laminin-5 Synthesis Alters Cell Cycle Progression, Rb Phosphorylation, and PI3K Signaling M. M. Buschmann, H. Waechter, K. S. Matlin; Department of Surgery, University of Cincinnati, Cincinnati, OH Normal epithelial cells rely on spatial cues from the extracellular matrix to proliferate, migrate, and survive. Inappropriate expression of the laminin family of extracellular matrix proteins has been observed in several cancers; connected with increased invasion, metastasis, and angiogenesis (Pattaro et al., Semin Cancer Biol. 12, 197-207, 2002). We have shown that the laminin isoform, laminin 5 (LNS) is necessary for proliferation in normal, nontransformed, Madin Darby Canine Kidney (MDCK) epithelial cells, as loss of LNS expression by siRNA-mediated knockdown results in cell cycle arrest (Mak et al., Mol Biol Cell. 17, 3664-3677, 2006). To identify the mechanism of proliferation control by LNS, we have examined Cyclin/Cdk complexes required for G1/S cell cycle progression and upstream signaling events following LNS suppression. Flow cytometry data demonstrates that LNS suppression results in G1 arrest. In addition, CyclinD1/Cdk4 complexes assemble and accumulate in the nucleus. Surprisingly, these complexes appear to be inactive because Rb remains hypo-phosphorylated. Upstream of the cell cycle, the activity of ERK1/2, which regulates Cyclin D1 expression, remains unaltered. This suggests that cell cycle arrest following LNS suppression is not due to changes in the ERK1/2 pathway. Interestingly, LNS suppression results in a marked decrease in PI3K phosphorylation. Despite this decrease in PI3K phosphorylation, phosphorylation of Akt at Thr308 and Ser473 is significantly increased. PI3K is required for this increase in Akt activation, however, as treatment with PI3K inhibitor, LY294002, inhibits Akt activation following LNS suppression. In conclusion, suppression of LNS synthesis in MDCK cells appears to arrest proliferation by inhibiting Rb phosphorylation, even though CyclinD1/Cdk4 complexes assemble, and alters upstream PI3K signaling.

Transcriptional Repression of N-cadherin in Differentiated Prostate Carcinomas W. B. Bair,1 N. Alexander,2 M. Jaramillo,1 D. I. Simon,3 R. L. Heimark1; 1University of Arizona, Tucson, AZ, 2Vanderbilt University, Nashville, TN, 3Brigham and Women's Hospital, Harvard Medical School, Boston, MA N-cadherin is essential for cell-cell adhesion during development and has been found to be upregulated in many carcinomas. In prostate carcinogenesis, N-cadherin upregulation is associated with a loss of E-cadherin. The switch from E-cadherin to N-cadherin in metastatic cells contributes to cancer progression through detachment of cells and inhibition of apoptosis. Studies have shown the repression of E-cadherin involves genetic and epigenetic mechanisms and is an important step in metastasis. However, the mechanism of epithelial-restricted patterns of N-cadherin gene expression is less well known and may involve activators and repressors limiting expression to epithelial cells. To determine the cis-regulatory elements involved in the regulation of the N-cadherin, we cloned ~4 kb of the N-cadherin gene including the 5' upstream regulatory region, the first exon and 3 kb of the first intron. The transcriptional activity of the proximal N-cadherin promoter (nts ~860-20) was assessed in N-cadherin-expressing and nonexpressing carcinoma cells, and promoter activity was seen in both. Previous studies in our lab indicated that the first intron (nts +2627) of the N-cadherin gene is important from regulating N-cadherin transcription in N-cadherin expressing cells. Addition of the first intron can inhibit activity of the proximal promoter as measured by luciferase assays in carcinoma cells that do not express N-cadherin. We identified a negative response element located in the N-cadherin first intron and sequence analysis of the intron yielded a forkhead binding site for the putative tumor suppressor FoxP1. EMSAs have demonstrated that FoxP1 can bind to this sequence and mutation of this sequence alters the binding motif in repressing basal levels of N-cadherin transcription by different cell type-specific mechanisms, and support the hypothesis that FoxP1 sequesters negative regulators of transcription, thereby suppressing N-cadherin gene expression. Supported by a NIH Grants CA56666 and CA092123-18.

Collagen I Promotes Metastasis in Pancreatic Cancer by Up Regulating N-cadherin Expression via JNK Y. Shintani, K. R. Johnson, M. J. Wheelock; Oral Biology, University of Nebraska Medical Center, Omaha, NE Pancreatic cancer is characterized by excessive deposition of type I collagen. This led us to ask whether interactions with type I collagen would up-regulate N-cadherin expression in pancreatic cancer cells, which would be predicted to increase the metastatic potential of these cells. BxPC-3 human pancreatic cancer cells respond to collagen I, but not other matrices, by up-regulating mesenchymal markers, including N-cadherin, fibronectin, and vimentin. A modified transwell assay showed that cells were more motile on collagen I-coated transwell dishes as compared to fibronectin coated transwell dishes. To clarify the role of N-cadherin expression in cell motility, we generated 3 cell lines: mock infected cells (neomycin resistance gene), N-cadherin knockdown cells, and N-cadherin over-expressing cells. Collagen mediated cell motility was inhibited by N-cadherin knockdown, whereas it was increased by N-cadherin overexpression. We transplanted these cells into the pancreas of nude mice. Examination of the abdominal cavities 8 weeks later revealed that N-cadherin over-expressing cells formed significantly more metastases to the peritoneum than did the other cell lines. Histological examination demonstrated micro-metastases in the lung of 7 of 10 mice receiving injections of N-cadherin over-expressing cells, whereas no metastases were observed in mice that received mock- or N-cadherin knockdown cells. Inhibiting JNK with chemical inhibitors or siRNA abrogated all collagen I-induced changes. We show that JNK1 is activated in response to collagen I, which increases tumorigenesis by up regulating N-cadherin expression and increasing motility via phosphorylation of paxillin. Furthermore, inhibition of JNK1 prevented invasion and metastasis in the mouse model for pancreatic cancer. Thus, inhibiting collagen-I mediated signals, or preventing downstream activities of N-cadherin or JNK1 prevent metastasis of pancreatic cancer cells. These data strongly suggest that blocking signaling between tumor stroma and tumor cells has the potential to impact treatment for pancreatic cancer.

Modulation of E- and N-cadherin Levels in Oral Squamous Cells Reveals N-cadherin Specific Increases in Invasion-related Signaling Pathways K. R. Lawson,1 J. N. Myers,2 M. J. Wheelock,3 K. R. Johnson1; 1Oral Biology, University of Nebraska Medical Center, Omaha, NE, 2Head and Neck Surgery, MD Anderson Cancer Center, Houston, TX
We have previously demonstrated that overexpression of the mesenchymal protein N-cadherin inversely correlates with E-cadherin expression in oral squamous cells, and that overexpression of N-cadherin in breast cancer cells can supersede E-cadherin function, increasing both motility and invasion even in the presence of E-cadherin. To better define the mechanism by which the gain of N-cadherin, but not loss of E-cadherin, can confer increased invasiveness and motility to oral squamous cells, we have transduced a series of retroviral vectors into two independently-derived human oral squamous carcinoma lines, Tu167 and UM-SCC-1, in order to modulate levels of E- or N-cadherin expression. The overexpression of N-cadherin in both Tu167 and SCC-1 cells substantially increased invasiveness compared to both control cells and E-cadherin-depleted cells. Although SCC-1 cells displayed a marked increase in motility upon N-cadherin expression, Tu167 cell motility was unaffected. In Tu167 cells, N-cadherin overexpression, but not E-cadherin loss, increased the expression of matrix-metalloproteinase-9 in a manner dependent upon phosphatidylinositol 3-kinase (PI3 kinase) activity. Treatment of N-cadherin-expressing Tu167 cells with various growth factors (including fibroblast growth factor) did not amplify this effect. To identify the regions of N-cadherin protein that modulate invasion and motility, Tu167 and SCC-1 cell lines were transduced to express chimera cadherin molecules in which the extracellular or cytoplasmic domains of E- and N-cadherin were reciprocally substituted. Overexpression of an E-N chimera (containing the cytoplasmic domain of N-cadherin) substantially increased invasiveness, whereas expression of an N-E chimera (containing the N-cadherin extracellular domain) preferentially increased motility. These results suggest that N-cadherin modulates both the motility and invasiveness of oral cell lines via specific signaling mechanisms that are independent from those arising as a consequence E-cadherin loss.

R-cadherin Expression Induces Myoblast Transformation: Role in Rhabdomyosarcomagenesis

C. Gauthier-Rouvière; CRBM, CNRS, Montpellier, France

Cadherins are a family of transmembrane glycoproteins that mediate Ca2+-dependent homophilic cell-cell adhesion and play a crucial role in proliferation, differentiation and cell transformation. The goal of this study is to understand the role of R-cadherin found in rhabdomyosarcomas (RMS), tumors of skeletal muscle origin, while it is absent in normal myoblasts. We show that R-cadherin expression in C2C12 myoblasts results in inhibition of myogenesis induction and of myoblast fusion and impairs their cell cycle exit when cultured in differentiation medium. Furthermore, R-cadherin expression elicits myoblast transformation as shown by anchorage-independent growth in soft agar and in vivo tumor formation assays. In contrast, inhibition of R-cadherin expression using RNA interference inhibits growth in soft agar of RD cell line and its tumorigenicity in mice. In addition, expression of R-cadherin results in decreased expression of endogenous N- and E-cadherin. The analysis of the nature of R-cadherin-mediated signals shows that R-cadherin-dependent adhesion increases Rac1 activity. Dominant negative forms of Rac1 inhibit R-cadherin-mediated signaling and transformation. Together, these data suggest that R-cadherin expression inhibits myogenesis and induces myoblast transformation through Rac1 activation.

M-cadherin Activates Rac1 GT-Pase through the Rho-GEF Trio during Myoblast Fusion

S. Charrasse, F. Comunale, M. Fortier, E. Portales-Casamar, A. Debant, C. Gauthier-Rouvière; CNRS, Montpellier, France

Cadherins are transmembrane glycoproteins that mediate Ca2+-dependent homophilic cell-cell adhesion and play crucial role during skeletal myogenesis. M-cadherin is required for myoblast fusion into myotubes, but its mechanisms of action remain unknown. The goal of this study was cast some light on the nature of the M-cadherin-mediated signals involved in myoblast fusion into myotubes. We found that the Rac1 GT-Pase activity is increased at the time of myoblast fusion and it is required for this process. Moreover, we showed that M-cadherin-dependent adhesion activates Rac1 and demonstrated the formation of a multistepic complex containing M-cadherin, the Rho-GEF Trio and Rac1 at the onset of myoblast fusion. Interestingly, Trio knockdown efficiently blocked both the increase in Rac1-GTP levels, observed after M-cadherin-dependent contact formation, and myoblast fusion. We conclude that M-cadherin-dependent adhesion can activate Rac1 via the Rho-GEF Trio at the time of myoblast fusion.

Association of N-cadherin with Lipid Rafts/Caveolae Is Required for Tyrosine Phosphorylation of N-cadherin by Src Family Kinases during Transendothelial Migration of Melanoma Cells

J. Qi, J. Wang, C. Siu; BBDMR and Department of Biochemistry, University of Toronto, Toronto, ON, Canada, Shandong Academy of Medical Sciences, Shandong University, Jinan, China

Activation of Src family kinases (SFKs) results in tyrosine phosphorylation of N-cadherin and dissociation of β-catenin in a co-culture system where melanoma cells are seeded on top of an endothelial monolayer. The question remains how N-cadherin is sequestered in the heterotypic contact. Here we report that N-cadherin became associated with the caveolin-enriched membrane (CEM) during transendothelial migration (TEM) of melanoma cells. The SFK inhibitor PP2 failed to block the association of N-cadherin with CEM during co-culture, although it abolished endothelial monolayer. The question remains how N-cadherin is sequestered in the heterotypic contact. Here we report that N-cadherin became associated with the caveolin-enriched membrane (CEM) during transendothelial migration (TEM) of melanoma cells. The SFK inhibitor PP2 failed to block the association of N-cadherin with CEM during co-culture, although it abolished tyrosine phosphorylation of N-cadherin and inhibited dissociation of β-catenin in the CEM. It is likely that N-cadherin becomes associated with the CEM first, where it is phosphorylated by the activated SFKs. Further studies show that disruption of the CEM using filipin or caveolin-1 siRNA abolished tyrosine phosphorylation of N-cadherin and inhibited transmigration of melanoma cells. Expression of an active Src led to tyrosine phosphorylation of N-cadherin in the CEM and a reduced level of β-catenin association. On the other hand, β-catenin was tyrosine-phosphorylated in the Non-CEM but showed no change in its association with N-cadherin. Together, the data suggest that lipid rafts/caveolae provide a platform for tyrosine phosphorylation of N-cadherin by SFKs and stabilization of the N-cadherin association in the absence of β-catenin, leading to the concomitant activation of the β-catenin signaling cascade during TEM of melanoma cells. (Supported by the Canadian Institutes of Health Research.)
Cadherin Proteins Regulate Cell Adhesion and Morphogenesis in Drosophila Egg Development

J. Zartman, N. Yakoby, C. Brislow, T. Schüpbach, S. Shvartsman; 1Lewis Sigler Institute and Department of Chemical Engineering, Princeton University, Princeton, NJ, 2Howard Hughes Medical Institute and Department of Molecular Biology, Princeton University, Princeton, NJ.

During Drosophila oogenesis, a two-dimensional follicular epithelium gives rise to an elaborate three-dimensional eggshell (1). Eggshell morphogenesis critically depends on patterning of the follicle cells, but the connection between signaling pathways, pattern formation, and eggshell morphogenesis is not well understood. As important components of morphogenesis, cadherin proteins have been proposed to regulate cell-cell adhesion, cell migration, and epithelial polarity and integrity (2). Recently we have identified the non-classical cadherin, Cad74A, as a key molecule that bridges epithelial patterning and morphogenetic dynamics in this system. Starting in mid-oogenesis, cad74A is expressed in all the columnar cells except for two dorsal lateral patches, in the border cells, and later in the future operculum domain. We have established that this pattern is partially controlled by the EGFR and BMP pathways and that Cad74A is involved in multiple aspects of egg development. We will present several lines of evidence showing that these spatially distinct expression domains are essential for proper formation of several chorion structures. Females homozygous for a disrupted allele of cad74A exhibit severe defects in late egg development, including the loss of dorsal appendages and a collapsed eggshell. Milder eggshell phenotypes include shorter and thinner dorsal appendages, a missing ventral collar, and a less structured micropleue. Based on these results, we propose that Cad74A provides an important link between signaling pathways, pattern formation, and the structuring of the Drosophila eggshell. 1. C. A. Berg, Trends in Genetics 21, 346 (2005). 2. U. Tepass, Curr Opin Cell Biol 11, 540 (Oct, 1999).

Chicken Protocadherin-1 Functions to Localize Neural Crest Cells to the Dorsal Root Ganglia during PNS Formation

J. Bononi, R. Bradley; Cell Biology and Neuroscience, Montana State University, Bozeman, MT

In vertebrates, neural crest cells emerge from the dorsal neural tube and migrate along well-defined pathways to form a wide variety of tissues, including the majority of the peripheral nervous system (PNS). The cell adhesion molecules that mediate cell-cell interactions during neural crest cell migration and subsequent re-aggregation to form the PNS are not well understood but likely include members of the cadherin family. To identify cadherins involved in PNS formation we screened an embryonic chicken dorsal root ganglia (DRG) library for protocadherin subfamily members, resulting in the isolation of chicken protocadherin-1 (cPcdh1). In the trunk, cPcdh1 is expressed in migrating neural crest cells and in the DRG, sympathetic ganglia (SG) and Schwann cells along the ventral branch (VB). Within the DRG, cPcdh1 is initially restricted to the perimeter, where neural crest cells first cease migration and remain in an undifferentiated and mitotically active state. This expression pattern suggested a role for cPcdh1 in mediating migration arrest and cell adhesion at the DRG perimeter. To test this, we utilized in ovo electroporation to disrupt cPcdh1 function in neural crest cells. Results indicate that when full-length cPcdh1 is over-expressed in neural crest cells, the majority of ectopically expressing cells cease migrating at the perimeter of the DRG. In contrast, when cPcdh1 function is inhibited, using a dominant-negative cPcdh1 construct, a greater percentage of ectopically expressing neural crest cells localize to the SG and VB, at the expense of the DRG. Furthermore, those cells that still target to the DRG, when cPcdh1 function is inhibited, no longer localize to the perimeter, but are instead dispersed throughout the DRG. These results suggest that cPcdh1-mediated cell adhesion plays an important role in neural crest cell migration to localize newly arrived cells at the DRG perimeter where they remain mitotically active and undifferentiated.

N-cadherin Directs Drosophila Reorganization and Lamellipodia Dynamics in Migrating Sheets of Smooth Muscle Cells

P. I. B. Sabatini, M. Zhang, M. P. Bendeck, B. L. Langille; Laboratory Medicine and Pathobiology, University of Toronto, Toronto, ON, Canada, 2Toronto General Hospital, Toronto, ON, Canada

In cells migrating at wound edges, anterior activation of integrins induces Cdc42-dependent reorientation of the microtubule-organizing center (MTOC) and initiates actin polymerization towards the direction of migration (Etienne-Manneville and Hall, Cell 106:489, 2001). Classical cadherins, which regulate cell-cell adhesion, localize to the posterior-lateral regions of cells at wound edges and one such cadherin (N-cadherin) can modulate Cdc42 activity; therefore, we hypothesized that N-cadherin directs cell polarity in wound edge cells. Treatment with an N-cadherin blocking antibody suppressed wound-induced Cdc42 activation, slowed migration and impaired the polarization of the MTOC to the anterior side of the nucleus. N-cadherin was also blocked by calcium chelation with EGTA, to disrupt calcium-dependent adherens junctions, and it was restored after EGTA washout. Interestingly, retrograde flow in lamellipodia of cholesterol rich membrane domains (labeled with FITC-conjugated cholera toxin B subunit) was completely immobilized by N-cadherin ligation with antibody. This retrograde flow of membrane rafts was also arrested by treatment with cytochalasin B to disrupt actin microfilaments; however, this was not due to the much faster retrograde flow of lamellipodial actin (4.0 versus 1.2 μm/min for rafts) since actin retrograde flow persisted after treatment with anti-N-cadherin antibody. Also, N-cadherin-GFP clusters in the lamellipodia were transported retrogradely with the cell membrane; therefore, regulation of retrograde flow may modulate the delivery and retention of this cadherin adhesion molecule at the cell anterior.

Dynamic Microtubules Regulate the Local Concentration of E-cadherin at Cell-Cell Contacts

S. J. Siebhen, A. D. Patterson, S. M. Crampton, A. M. Shewan, C. Fergason, A. Khambhatia, R. G. Parton, A. S. Yap; Division of Molecular Cell Biology, Institute for Molecular Bioscience, The University of Queensland, St. Lucia, Queensland, Australia, 2School for Biomedical Science, The University of Queensland, St. Lucia, Queensland, Australia, 3Centre for Microscopy and Microanalysis, The University of Queensland, St. Lucia, Queensland, Australia, 4MGC Department of Cell Biology and Genetics, Erasmus Medical Center, Rotterdam, The Netherlands

Classical cadherins are a family of membrane receptors that mediate cell-cell adhesion in mammalian organisms. During embryogenesis cadherins act as key determinants of tissue organisation and patterning as well as being responsible for normal tissue architectural integrity. In the adult it is becoming increasingly clear that cadherin receptor activity, and ensuing adhesion, is an extremely dynamic process coordinated by localised membrane signalling processes. Thus, acting to regulate the complex relationship between the cadherin and the actin cytoskeleton. In contrast the potential link between cadherins and microtubules has been less extensively investigated. We now identify a pool of microtubules that extend radially into cell-cell contacts and are inhibited by manoeuvres that block the dynamic activity of microtubule plus ends, including low concentrations of nocodazole and expression of a CLIP-170 mutant. Blocking dynamic microtubules perturbed the ability of cells to concentrate and accumulate E-cadherin at cell-cell contacts, as assessed both by quantitative immunofluorescence microscopy and FRAP analysis, but did not affect either transport of E-cadherin to the plasma membrane, nor the amount of E-cadherin expressed at the cell surface. This indicated that dynamic microtubules allow cells to concentrate E-cadherin at cell-cell contacts by regulating the regional distribution of E-cadherin once it reaches the cell surface. Importantly, dynamic microtubules were necessary for Myosin II to accumulate and be activated at cadherin adhesive contacts, a localised mechanism that supports the focal accumulation of E-cadherin. We propose that this population of microtubules represents a novel form of cadherin-microtubule cooperation, where cadherin adhesions recruit dynamic microtubules that, in turn, support the local concentration of cadherin molecules by regulating Myosin II activity at cell-cell contacts.

Single-Molecule Analysis of Cadherin-mediated Cell Adhesion

D. Wirtz, P. Panorchan; Chemical and Biomolecular Engineering, Johns Hopkins University, Baltimore, MD

Cadherins are ubiquitous cell surface molecules that are expressed in virtually all solid tissues and localize at sites of cell-cell contact. Cadherins form a large and diverse family of adhesion molecules which play a crucial role in a multitude of cellular processes, including cell-cell adhesion, motility, and cell sorting in maturing organs and tissues, presumably because of their different binding capacity and specificity. Here, we develop a method that probes the biochemical and biophysical properties of the binding interactions between cadherins expressed on the surface of living cells, at the single-molecule level. Single-molecule force spectroscopy reveals that cadherins, N-cadherin, E-cadherin, and VE-cadherin, form bonds that display adhesion specificity, and a pronounced difference in adhesion force, reactive compliance, and bond lifetime. Moreover, their potentials of interaction, derived from force-spectroscopy measurements, are qualitatively different when comparing the single-barrier energy potential for the dissociation of an N-cadherin/N-cadherin bond with the double-barrier energy potential for an E-cadherin/E-cadherin bond. Together these results suggest that N-cadherin and E-cadherin molecules form homophilic bonds between juxtaposed cells that have significantly different kinetic and micromechanical properties.
Inhibition of Cyclin Dependent Kinase 5 (Cdk5) Regulates E-cadherin Degradation and Trafficking in Madin-Darby Canine Kidney (MDCK) Epithelial Cells

S. S. Saravanamanuthi, C. Y. Gao, P. S. Zelena; Laboratory of Molecular and Developmental Biology (LMDB), National Eye Institute (NEI), National Institutes of Health (NIH), Bethesda, MD

E-cadherin is essential for epithelial cell polarity and cell-cell adhesion. Dynamic trafficking of E-cadherin to and from the cell surface modulates its levels within adherens junctions, thereby providing a mechanism for regulating cell adhesion. Previous work from this laboratory has shown that Cdk5, a protein kinase with known trafficking functions in neurons, is also involved in regulating cell-cell adhesion in epithelial cells of the lens and cornea. This work examines the role of Cdk5 in E-cadherin-dependent adhesion in MDCK cells, a widely used epithelial cell model. To investigate the effect of Cdk5 inhibition on E-cadherin-dependent adhesion, cells were plated on microwells plated that had been coated with E-cadherin ectodomain and adherent cells were measured after incubating in the presence or absence of the Cdk5 inhibitor, olomoucine (15μM). Inhibition of Cdk5 activity reduced E-cadherin based cell-cell adhesion by approximately 50%. To study the potential role of Cdk5 in E-cadherin degradation and/or trafficking, the surface localized E-cadherin in a confluent monolayer of cells was biotinylated using cell impermeable cleavable sulpho-NHS-Ss biotin reagent. After 6h incubation in the presence or absence of olomoucine, the cells were lysed and the remaining biotinylated E-cadherin was determined by affinity chromatography on neutravidin-coated beads followed by immunoblotting for E-cadherin. The total biotin-labeled E-cadherin remaining in the olomoucine-treated samples was reduced in the untreated controls (17% as compared to 47%, p<0.001). To assess what fraction of the remaining E-cadherin had been internalized by endocytosis for recycling, surface biotin was stripped by cleaving the disulfide link prior to cell lysis. The inhibition of Cdk5 activity increased the internal pool approximately 4-fold and decreased the surface membrane-associated pool by 14-fold as compared to the untreated control. Thus, Cdk5 activity affects both degradation and endocytic recycling of E-cadherin to regulate epithelial cell-cell adhesion.

Nuclear Translocation of the Cleaved Cytoplasmic Domain of E-cadherin

E. C. Ferber, Y. Fujita; MRC Laboratory for Molecular Cell Biology and Cell Biology Unit, London, United Kingdom

E-cadherin is the most crucial membrane protein for the formation of tight and compact cell-cell adhesions in epithelial cells. In addition to this structural role, E-cadherin has been shown to be involved in several signalling pathways including cell proliferation, differentiation, and cell survival. However the molecular mechanisms of E-cadherin-mediated signalling are largely unknown. Presenilin-1/G-secretase induces proteolytic cleavage of various membrane proteins including E-cadherin. For many of such membrane proteins, the resulting intracellular domain fragments have been reported to localise to the nucleus and have signalling functions. Upon cleavage of E-cadherin by presenilin-1, the whole cytoplasmic fragment (designated as E-cad/CTF2) is released into the cytoplasm. In this study, a possible signalling role for E-cad/CTF2 is investigated. Firstly, in HEK293 cells we found that E-cad/CTF2 is ubiquitinated and translocated to the nucleus, when co-expressed with p120-catenin, a cadherin binding protein. To clarify the functional role of the p120-induced ubiquitination of E-cad/CTF2, we performed a yeast 2-hybrid screen and identified Ret Finger Protein (RFP) as a binding partner for p120. RFP is a RING-finger type E3-ubiquitin-ligase, and it enhances ubiquitination and nuclear localisation of E-Cad/CTF2. In the nucleus, E-Cad/CTF2 binds indirectly but specifically to DNA. Furthermore, its association with DNA is enhanced by p120. Thus we have revealed a molecular mechanism for the nuclear translocation of E-cad/CTF2. The functional role of E-cad/CTF2 in the nucleus is currently being investigated.

Alternative Pathways of E-cadherin Degradation

R. B. Troyanovsky, O. Lazar, S. M. Troyanovsky; Dermatology, Washington University Medical School, St. Louis, MO, 2Microbiology and Immunology, Emory University, Atlanta, GA

Internalization, recycling and degradation of the cell-cell adhesion receptor E-cadherin maintain the dynamics of intercellular contacts in epithelial cells. We studied cadherin internalization and its rate of degradation in control epithelial A-431 cells and after the inactivation of clathrin-based endocytosis by clathrin small interfering RNAs. The lifetime of the endogenous or myc-tagged E-cadherin appeared to be approximately 8 h. Inactivation of clathrin-based endocytosis blocked cadherin recycling nearly completely. However, it failed to change the cadherin lifetime and the overall amount of this protein on the cell surface. This observation suggested that in addition to clathrin-dependent cadherin recycling, there are alternative clathrin-independent mechanisms that maintain cadherin surface expression. To evaluate those mechanisms, we determined the lifetime of different cadherin mutants in control and clathrin-depleted cells. Point mutations of the extracellular cadherin region inactivating any cadherin calcium-binding site or a truncation of the intracellular cadherin region (Ser844-Asp882) abolishing its binding to beta-catenin slightly decreased cadherin lifetime. The lifetime reduction of calcium-site cadherin mutants became very dramatic in clathrin-depleted cells. Mutants of this group, however, were completely stabilized in both control and clathrin-depleted cells by deletion of the p120-binding site (Asp760-Leu771). Behavior of the cadherin-binding site mutant was very different: (i) clathrin depletion normalized its lifetime and increased its surface expression; (ii) it was even further destabilized by deletion of p120-binding region. These data suggest that clathrin-based recycling competes with the p120-dependent degradation pathway. The latter mechanism is able to selectively recruit for degradation proteins with abnormalities in calcium-binding sites. In contrast, the clathrin-dependent pathway may select for degradation the E-cadherin that bears abnormalities in the intracellular region.

Characterization of Pannexin Family Members and Their Potential Role as Gap Junction Proteins

S. Penuela, Q. Shao, X. Gong, C. S. Lounsbury, J. Manias, D. Bai, D. W. Laird; Department of Anatomy and Cell Biology, University of Western Ontario, London, ON, Canada

Pannexins are among the many families of gap junction proteins (pannexins) that are proposed to play a role in gap junctional intercellular communication (GJIC). There are three pannexins in the murine genome, namely Panx1, Panx2 and Panx3. In this study, we characterized their expression, subcellular localization and potential function in GJIC. RT-PCR products of murine RNA were cloned to generate carboxyl terminus-GFP-tagged and untagged expression constructs of Panx1 and Panx3 coding sequences. Synthetic peptides derived from motifs specific for each pannexin were used to successfully generate polyclonal antibodies. Immunofluorescent labeling of untagged and GFP-tagged Panx1- and Panx3- transfected NRK and N2A cells, revealed cell surface localization of Panx1 and Panx3, except when Panx3 was tagged with GFP as this caused Panx3 to be restricted to the endoplasmic reticulum. Western blots of untagged Panx1- and Panx3- expressing cells showed that both pannexins exhibited a molecular weight of approximately 44-47 kDa. Interestingly, recent functional assays suggest that N2A cells expressing untagged Panx1 protein are capable of passing Lucifer yellow dye and demonstrate robust electrical coupling. However, Panx1-based functional coupling was greatly reduced when tagged with GFP and only negligible functional coupling was detected in cells expressing either untagged or tagged Panx3. Preliminary immunofluorescent labeling results from an endogenous pannexin survey of over 14 different cell lines revealed specific cell surface labeling for both pannexins in MDCK cells while pannexins were not detectable in the majority of the cell lines tested. Our in vitro studies suggest that in mammalian cells, Panx1 is a functionally competent gap junction protein while, at present, Panx3 on its own fails to meet the functional criteria expected of a gap junction protein. Ongoing in vivo studies are expected to elucidate the physiological functions of pannexins and further assess their potential roles in GJIC.

Projection Structure at 7Å Resolution and Initial 3D Map of a Human Connexin26

A. Oshima,1 K. Tanii,1 Y. Hiroaki,1 Y. Fujioyshi,1 G. E. Sosinsky; 2Department of Biophysics, Faculty of Science, Kyoto University, Kyoto, Japan, 3National Center for Microscopy and Imaging Research, Department of Neurosciences, University of California San Diego, La Jolla, CA

Projection Structure at 7Å Resolution and Initial 3D Map of a Human Connexin26

2006 ASCB Annual Meeting Abstracts

Connexin26 (Cx26) is the second smallest member of the family of gap junction (GJ) proteins. Here, we report the projection and the initial 3D maps of Cx26 at 7Å and 20Å resolutions, respectively, of a mutant human Cx26 (8C26M34A). We over-expressed a hexahistidine tagged hCx26M34A using baculovirus recombinant expression system. Detergent solubilized and purified hemichannels were reconstituted into the synthetic lipid (DOPC) to produce two-dimensional crystallized with the unit cell parameters of a = b = 108.4Å, gamma = 90.0°. Analysis of cryoelectron microscopy (cryoEM) images of these crystals using the ALLSPACE program, indicated that these crystals have the phase relationships of p22,2 symmetry. Four untilted images were processed and merged at 7Å resolution, where the overall phase residual proved to be 23.3°. The projection map displays hexameric channels each of which shows a weak but significant density in the channel pore. While crystallizations were done with hemichannel preparations, the 3D map revealed that two hemichannels had re- docked at their extracellular surfaces into the full intercellular channel. Thin section micrographs supported the re-docked structure and also revealed that this crystal form contained two sets of symmetry related intercellular channels and three lipid bilayers. New features observed in this 3D map include a new prominent density inside the channel pore suggesting that the GJ is physically closed and significant protrusions at the cytoplasmic surfaces. The transmembrane domain structure is consistent with the previous structural work (Fleshman et al. Mol. Cell 15 (2004) 879). A full 3D structure determination at higher resolution is currently in progress.
Influence of Connexin Isoform Stoichiometry and/or Arrangements on Channel Permeability of Second Messengers

D. Locke,1 W. Ayad,4 C. Bevans,2 A. L. Harris 1; 1Pharmacology and Physiology, New Jersey Medical School, UMDNJ, Newark, NJ, 2Department of Structural Biology, Max Planck Institute for Biophysics, Frankfurt, Germany

Heteromeric Cx26/Cx32 hemichannels are selectively permeable to cAMP, cGMP and inositol phosphates, whereas the corresponding homomeric hemichannels are not (JBC 273:2808 and 281:16727; ECR 298:643). This selectivity changes with aggregate isoform ratio. The permeability of cAMP and inositol phosphates is not accounted for by these means, suggesting that the radial arrangement of isoforms, rather than stoichiometry, plays the crucial role. To extend the analysis to include other second messengers, we employed a combination of pH and aminosulfonates, which are known to modulate protein conformation and/or permeability. Using high-resolution AFM tomography, we found that the presence of protonated aminosulfonates led to a significant reduction in the number of open channels, which could be attributed to a decrease in the radius of the aqueous pore. Furthermore, we observed that the selectivity of the hemichannel for cAMP and inositol phosphates was dependent on the isoform ratio. Together, these findings suggest that the radial arrangement of isoforms plays a critical role in determining the selectivity of the hemichannel for second messengers.
361 Associations of Different Connexin Channels with Different Lipids
D. Locke, A. L. Harris; Pharmacology and Physiology, New Jersey Medical School, UMDNJ, Newark, NJ
Paired connexin hemichannels form aqueous intercellular pores that compose gap junction plaques in vertebrates. Unpaired hemichannels also exist in plasma membrane, providing separate biological functions. For other channels, the lipid environment provides not just a structural framework, but also the means to modulate channel structure and/or function. Unfortunately, the importance of these interactions for connexin channels is not well understood. It is difficult to define the role of different lipids for connexin channel function in native membranes without dynamically disrupting lipid-lipid or lipid-protein interactions, and/or the physical attributes of membrane and/or junctional plaque. Therefore, the studied roles of particular lipids in connexin channel function (here, Cx26 and/or Cx32) was studied ex vivo using unilamellar liposomes, which affords substantial control over lipid environment(s). Activity of hemichannels was reported by their ability to mediate large osmolyte exchange across the liposome membrane. A complex relationship was observed between channel connexin composition, and the chemistry(ies) of glycerolphospholipid headgroup(s), membrane thickness and/or acyl chain length(s), and their degree of desaturation(s). For example, Cx32 hemichannels were inactive in L-α-phosphatidylglycerol membranes, but active in glypil-PC membranes, which was highly charged, a positively-charged derivative. Channel activity was restored in PC (uncharged) membranes by addition of charged phospholipids, such as L-α-phosphatidylethanolamine, L-α-phosphatidylcholine, L-α-phosphatidic acid or L-α-phosphatidylserine (all negative), but not other uncharged phospholipids, such as L-α-phosphatidylinositol, unless cholesterol was present. Previous work suggested that the ‘lipid’ composition of junctional plaques differs from the surrounding plasma membrane. Electrospray ionization-mass spectrometry was used to analyze mono/di/tri-acylglycerol and glycerophospholipid species in Cx26 and/or Cx32 plaques enriched from transfected HeLa cells. Lipids were identified that were unique to Cx26 or Cx32 plaques, common to both, and different from non-plaque membrane. There is an intimate involvement of specific lipids with different connexins that may contribute to, or reflect, modulations of channel structure and/or function. Supported by NIH grant GM36044

362 Cx30 Forms Heteromeric Channels with Cx26 and Cx32 during Adult Mouse Mammary Gland Development
D. Locke, 6 J. M. Samiei, 7 T. Stein, 7 J. Liu, 6 M. B. Hodgins, 6 B. Gusterson, 7 A. L. Harris; Pharmacology and Physiology, New Jersey Medical School, UMDNJ, Newark, NJ, 6 Squamous Cell Biology & Dermatology, Division of Cancer Sciences & Molecular Pathology, Faculty of Medicine, University of Glasgow, Glasgow, United Kingdom. 7 Gene Regulation & Mechanisms of Disease, Division of Cancer Sciences & Molecular Pathology, Faculty of Medicine, University of Glasgow, Glasgow, United Kingdom.
Oligonucleotide microarray analysis uniquely shows several connexin family members (gap junction proteins) are expressed by the secretary epithelium at different times during the developmental stage of pregnancy, lactation and involution in adult mammary gland. Specifically, Cx30 appears throughout the second half of pregnancy, but is lost within a day or two of pup birth, and is absent in virgin, early-pregnancy or involuting glands. This agrees, in part, with the expression profile for Cx26; however, Cx26 appears much earlier during pregnancy and persists until much later during lactation than Cx30. From mid-pregnancy into early lactation, Cx26 and Cx30 co-localize in junctional plaques between epithelial cells, forming hemichannels of mixed connexin content. Microarray analysis also reveals that Cx32, which is involved in the establishment of secretory regulation in most other exocrine glands, is developmentally restricted to parturition, so suggesting that specific modification of gap junction channel composition and/or intercellular communication pathways occurs at pup birth. Specifically, heteromeric channels of all pairwise combinations are formed when Cx26, Cx30 and Cx32 are expressed within the same cells. Of these hemichannels, Cx26/Cx30 pores are increasingly sensitive to closure by taurine, an osmolyte implicated in milk protein synthesis, with increasing Cx30 content. In contrast, physiological taurine concentrations have no effect on Cx26/Cx30 and Cx30/Cx32 channel activity. The next challenge will be to unravel how different connexin homomers and heteromers contribute to adult mammary gland development through their form, and their function. Such changes in connexin expression, channel composition and their chemical modulation are discussed in relation to the various stages of mammary gland development in the adult mouse.

363 Liver Vesicles Containing Connexin(Cx)32 Use Microtubule Motors to Traffic In Vitro
A. G. Fort, 6 N. G. Dandichi, 6 J. W. Murray, 6 A. W. Wolkoillo, 6 D. C. Spray; 6 Neuroscience, Albert Einstein College of Medicine, Bronx, NY.
Gap junctions consist of transmembrane channels formed by connexin proteins that are unique in allowing direct cytoplasmic communication. Vectorial trafficking of vesicles has been hypothesized to explain polarized and restricted gap junction expression within cells. However, most assays of cytoskeletal involvement in gap junction trafficking have been limited to examination of effects of microtubule and actin filament depolymerization. We have now investigated whether delivery of connexins to their final functional location is mediated by interaction of their cytoplasmic domains with microtubule motors, specifically kinesin. We concentrated on Cx32, the major gap junction protein in liver. We first demonstrated through immunoprecipitation experiments an interaction between Cx32 with kinesin and tubulin in liver lysates. We obtained identical results when we used vesicles isolated from rat and mouse liver by homogenizing in the presence of protease inhibitors, ultracentrifugation and chromatography. Surface plasmon resonance spectroscopy demonstrated a direct interaction between Cx32 and kinesin, and identified the binding site on Cx32, using synthetic peptides corresponding to cytoplasmic domains of Cx32 applied to covalently bound recombinant kinesin. The motility of anti-Cx32 antibloclotting antibodies was evaluated in HepG2 (Murray et al., Mol. Bio. Cell 11, 419, 2000). Vesicles were added to a bed of artificially polymerized rhodamine-labeled microtubules, and then labeled with anti-Cx32 antibody before motility assay was assayed upon addition of 1 mM ATP. On average, 5-10% of Cx32-vesicles in a field were motile; average vesicle velocity along the microtubules was 0.45 um/sec and was inhibited by 1 mM 5'-adenylylimido-diphosphate (AMP-PNP), a kinesin motor inhibitor, but not by 5 uM vanadate, a dynein motor inhibitor. Thus, trafficking of Cx32 in liver is demonstrated to be both microtubule and motor-dependent.

364 Slow Gating of Wild-type and C-terminus Truncated Connexin32 Channels
C. Peracchia, M. Salin, L. L. Peracchia; Pharmacology and Physiology, University of Rochester, Rochester, NY
Gap junction channels are gated by transmembrane voltage (V) and increased [Ca^{2+}] or [K^{+}] (rev. in Peracchia, 2004). There are two V_{j} sensitive gates: fast and slow. Slow V_{j} gate and chemical gate are probably the same (Bukauskas & Peracchia, 1997; Peracchia et al., 1999, 2000). Slow and fast V_{j} gates are in series and each hemichannel has both gates. The slow gate closes at negative side of V_{j} and is believed to be virtually inactive without uncouplers or connexin (Cx) mutations. In contrast, present data indicate otherwise. Oocytes expressing wild-type Cx32 were subjected to trains of -100 mV pulses (12 s duration) repeated every 30 s. At the pulse, current junctional dropped exponentially to a steady-state level after the initial peak. Both peak (PK) and steady-state (SS) junctional conductances (G_{j}) measured at each pulse, decreased exponentially by 50-60% (tau = 1.2 min). G_{j} of Cx32 dropped more dramatically, such that G_{j} of Cx32 increased from 0.4 to 0.6, indicating a drop in V_{j} sensitivity. Similar, but less striking effects were obtained with -60 mV pulses. During recovery, G_{j} measured by applying 20 mV pulses (2 s duration) at 30 s intervals slowly returned to initial values (tau = ~7 min). Reversal of V_{j} pulse polarity caused a slight and brief increase in G_{j} and decrease in G_{j}/G_{PK}. This suggests that V_{j}-dependent hemichannel reopening is faster than hemichannel closing. Similar, yet more dramatic results were obtained with COOH-termim truncated Cx32 (Cx32-D225), a mutant that lacks fast V_{j} gating. The data indicate that the slow gate of Cx32 is fast active in the absence of chemical uncouplers and mutations. There is evidence that calmodulin may be directly involved in the chemical/slow gating of Cx32, possibly by plugging the pore (Peracchia et al., 2000). Supported by NIH grant GM20113.

365 Androgen-regulated ERAD of Connexin32 and Its Assembly into Gap-Junctions
S. Mitra, S. Chakraborty, K. Johnson, P. P. Mehta; Biochemistry and Molecular Biology, University of Nebraska Medical Center, Omaha, NE
The physiological stimuli that control the assembly of connexins into gap junctions and their degradation remain poorly understood. Androgens are the key physiological regulators of the growth and differentiation of prostate epithelial cells. We hypothesized that they maintain the differentiated state of prostate epithelial cells by regulating gap junction assembly and disassembly. Hence, we investigated their effect on gap junctions composed of Cx32 in an androgen-responsive prostate cancer cell line, LNCaP. In LNCaP cells, androgens controlled the expression level of Cx32, and hence gap junction assembly, posttranslational. As assessed by pulse chase analysis of metabolically labeled Cx32, by transfection of Do-Red-Cx32 chimera, which remains trapped in the ER, and by inhibiting intra-Golgi transport with monensin, we found that in the absence of androgens, a major fraction of Cx32 was degraded from the ER in a proteasomal-inhibitor-sensitive manner, whereas in their presence, this fraction was rescued from degradation and formed gap junctions. In the absence of androgens, Cx32 accumulated as discrete puncta upon proteasomal inhibition. Cell fractionation assay showed that these puncta neither resided in the cytosolic fraction nor co-localized with ER/Golgi/ERGIC markers. Supported by NIH Grant GM36044.
**Regulation of Connexin43 Gap Junctions by Intracellular Calcium**

S. V. Thomas,1 M. M. Lurtz,2 C. Louis2; 1Biology, Georgia State University, Atlanta, GA, 2Cell Biology and Neuroscience, University of California, Riverside, CA

Connexin35 (Cx35) forms gap junctions in neurons in the retina and CNS, and has been shown to be regulated by protein kinase A (PKA) phosphorylation. In this study we asked: 1) Is the phosphorylation state of Cx35 regulated by light adaptation? 2) Which signaling pathways affect Cx35 phosphorylation? Dark-adapted, nighttime zebrafish were exposed to white light for 10 minutes, and the eyes excised and fixed. Sections were immunostained with a monoclonal antibody against Cx35 and one of two phospho-specific antibodies: one against Ser110-phosphorylated Cx35, the other against Ser276-phosphorylated Cx35. Also, excised eyecups from light-adapted, daytime zebrafish were superfused for 15 minutes with drugs affecting cAMP signaling pathways, and fixed and immunostained as described. Dark-adapted retinas showed sparse Cx35 phosphoSer110-like immunoreactivity (110P-IR) in the inner plexiform (synaptic) layer (IPL). The labeling was punctate and much of it co-localized with specific Cx35 labeling by the monoclonal antibody (mCx35-IR). 276P-IR was similar to 110P-IR, and nearly all of it co-localized with mCx35-IR. 10 minutes of light exposure resulted in a large increase in 110P-IR in the IPL; there was little change in 276P-IR. The mean intensity of phosphoSer110 puncta increased after light exposure; there was no change in phosphoSer276 puncta intensity. Daytime levels of 110P-IR and 276P-IR were similar to those after short-term light exposure, as was the mean phosphoSer110 puncta intensity. Mean phosphoSer276 puncta intensity was higher during the daytime than after light exposure. In light-adapted excised eyecups, superfusion with 20M Rp-8-cpt-CAMPS, a PKA inhibitor, reduced mean phosphoSer110 and phosphoSer276 puncta intensity. We conclude that white light stimulation triggers rapid phosphorylation events in zebrafish retina, including phosphorylation of Cx35. Inhibition of PKA activity suppresses phosphorylation, allowing for rapid dephosphorylation. This suggests that retinal light adaptation involves widespread phosphorylation of Cx35, which is known to reduce coupling through this gap junction.

**Beta-Adrenergic Regulation of Connexin43 Gap Junctions**

S. V. Thomas,1 M. M. Lurtz,2 C. Louis2; 1Biology, Georgia State University, Atlanta, GA, 2Cell Biology and Neuroscience, University of California, Riverside, CA

Connexin40 (Cx40) is the major connexin in the atria of the heart yet the possible regulation of Cx40 gap junction function by [Ca2+] is unknown. The goal of this study was to determine how [Ca2+] regulates Cx40-mediated cell-to-cell dye transfer in Cx40-transfected HeLa cells. Increasing [Ca2+] by inclusion of the ionophore ionomycin in the medium and elevating extracellular calcium ([Ca2+]), from 1.8 mM to 10 mM resulted in an elevation of [Ca2+], and affected an inhibition of Cx40-mediated cell-to-cell dye transfer ([IC50 of 850 ± 0.72 nM]. AlexaFluor 594 dye transferred to 9.6 ± 0.3 cells at resting [Ca2+] (~ 100 nM); when [Ca2+] was increased to ≥5 µM AlexaFluor 594 dye transfer decreased to 4.0 ± 0.3 cells. This [Ca2+]-mediated inhibition of Cx40 gap junctions was prevented by the calmodulin inhibitor calmidazolium; dye transferred to 9.0 ± 0.3 cells in the absence of calmidazolium and in the presence of calmidazolium the dye transfer was unchanged (9.0 ± 0.4 cells). The Ca2+-dependent inhibition did not appear to be protein kinase mediated because inclusion of the PKC inhibitor Bisindolylmaleimide I or the CaM Kinase inhibitor Lavendustin C were without effect on the ability of elevated [Ca2+] to inhibit Cx40-mediated cell-to-cell dye transfer. These data demonstrate that Cx40-containing gap junctions are inhibited by elevated [Ca2+], which is calmodulin dependent but not PKC or CaM Kinase dependent. Understanding the biochemical basis and the pathways involved in these interactions will provide insight into the regulation of Cx40 gap junctions when atrial [Ca2+] is elevated in conditions such as the ischemia that accompanies myocardial infarction. Supported by NIH grant EY-05684 and American Heart Association affiliate research award 0315176B.

**Functional Investigation of Prostate Specific G Protein-Coupled Offactory Receptor**

W. Zhang, E. Neuhaus, H. Hatt; Cell Physiology, Ruhr University Bochum, Bochum, Germany

Olfactory receptors (ORs) build the greatest superfamily of G-protein coupled receptors. They are expressed individually in the neurons in the olfactory epithelium where they detect volatile substances and react to odors in the olfactory epithelium, in the nasal cavity, and in other tissues, such as tests where they may play an important role in sperm development, chemotaxis and oocyte-sperm interaction. We cloned and functionally expressed a human OR, which was named prostate specific G-protein coupled receptor (PSGR) due to its reported expression in prostate epithelial cells. We employed Ca2+ imaging in HEK293 cells to identify ligands for the recombinant expressed receptor and characterized the molecular receptive field. As PSGR was found to be overexpressed in prostate cancer, we investigated whether the identified ligands also induce Ca2+ influx in a prostate cancer epithelial cell line (LNCaP). In addition to ligand stimulation Ca2+ increase, treatment of LNCaP cells resulted in a time dependent activation of members of the MAPK family. The ligand was also found to be a potent inhibitor of cell proliferation and an inducer of apoptosis. Similar results were obtained using primary prostate cancer cells from resection specimens. Together these results suggest that ligands for PSGR could be developed as novel therapeutic agents for the treatment of prostate cancer. In our study we will further try to find out which signal transduction mechanisms are involved in OR mediated Ca2+ influx in prostate epithelial cells.
Regulation of Anterograde Transport of G Protein-coupled Receptors by the N-Terminal at Multiple Intracellular Compartments

C. Dong, G. Wu; Pharmacology, LSU Health Sciences Center, New Orleans, LA

G protein-coupled receptors are a superfamily of cell-surface receptors that regulate a variety of cell functions. However, the molecular mechanisms underlying the targeting of receptors to their functional destination are poorly defined. Previous studies on the intrinsic structural determinants for export trafficking of G protein-coupled receptors have been mainly focused on the intracellular C-terminus of the receptors. In this report, we determined the role of the extracellular N-termini of α2-adrenergic receptors (α2-ARs) in the anterograde transport from the endoplasmic reticulum (ER) through the Golgi to the cell surface. The N-terminally truncated α2B-AR mutant is completely unable to target to the cell surface and activate downstream signaling. Single Met69 residue is absolutely essential for the export of α2B-AR from the ER, which is highly mediated through modulating correct α2B-AR folding in the ER. The Tyr-Ser motif, which is highly conserved in the membrane-proximal N-termini of all α2-AR subtypes, is required for the exit of α2A-AR and α2B-AR from the Golgi apparatus. Thus, the Tyr-Ser motif may represent a novel Tyr-based signal directing G protein-coupled receptor transport at the Golgi level. These data provide the first evidence indicating an essential role of the N-termini of G protein-coupled receptors in the export from distinct intracellular compartments along the secretory pathway.

Investigation of the Interaction between Olfactory Receptors and Multiple PDZ Domain Protein 1, MUPP1

R. Dooley, E. Neusahn, H. Hart; Cell Physiology, Ruhr University Bochum, Bochum, Germany

The unique ability of mammals to detect and discriminate between thousands of different odorant molecules is governed by the diverse array of olfactory receptors (ORs) found on the dendrites of olfactory sensory neurons in the nasal epithelium. ORs are 7-transmembrane-domain G-protein coupled receptors and comprise the largest gene superfamily in the mammalian genome. Odorant binding produces activation of specific G-proteins that in turn regulate the function of membrane bound enzymes such as adenyl cyclase. Interestingly, certain OR subtypes possess a classical PDZ (PSD-95, Discs large, ZO-1) domain binding motif in the C-terminal region of the receptor. It has previously been shown that PDZ proteins specifically recognize short peptide motifs in the C-terminus of their target proteins and more recently, they have also been shown to bind internal motifs within their interacting partner proteins. These domains have been established as sites for protein-protein interaction and play a central role in organizing diverse cell signalling assemblies. The objective of this work is to investigate the binding of various olfactory receptors with a multiple PDZ domain protein called MUPP1. We found that MUPP1 is expressed in the dendritic knobs of olfactory sensory neurons, where olfactory signal transduction takes place. Upon application of a mixture of 100 different odorant compounds, an increase of MUPP1 expression in the dendritic knobs was observed. In HEK (human embryonic kidney) cells, co-expression of MUPP1 with various ORs of such mutants are the Gly380Arg and Ala391Glu mutations. MUPP1 co-localizes with Rab4, a marker for the rapid recycling pathway, and with mannose-6-phosphate receptor, which traffics between the trans-Golgi network and endosomes, in RhoB Q63L expressing cells suggesting that CXCR2 is recycled through alternative pathways. These findings reinforce the idea that PDZ-domain containing proteins are important for the regulation of receptor sorting and may contribute to the olfactory signal transduction cascade.

RhoB Plays an Essential Role in CXCR2 Sorting Decisions

N. F. Neel,1,2 L. A. Lapierre, 3,2 J. R. Goldenring, 4,2 A. Richmond 1,2; 1Department of Cancer Biology, Vanderbilt University Medical School, Nashville, TN, 2Department of Veterans Affairs, Nashville, TN, 3Department of Surgery, Vanderbilt University Medical School, Nashville, TN, 4Department of Surgery and Department of Cell and Developmental Biology, Vanderbilt University Medical School, Nashville, TN.

The elucidation of the mechanisms that regulate the cellular responses mediated by chemokines is crucial for the identification of therapeutic targets. An important aspect of chemokine receptor function is the intracellular trafficking of these receptors. The CXCR2 chemokine receptor is a G protein-coupled receptor that undergoes clathrin-mediated endocytosis upon ligand binding. The trafficking of CXCR2 is critical for cells to maintain a proper chemotactic response. The mechanisms that regulate the recycling/degradation sorting decision are largely unknown. The small GTPase RhoB regulates the trafficking of the EGFR receptor. We sought to investigate whether RhoB regulates CXCR2 trafficking. In our studies, we utilized dominant negative (T19N) and GTPase-deficient activated (Q63L) RhoB mutants, as well as RhoB siRNA to investigate the role of RhoB in CXCR2 trafficking. Expression of both RhoB mutants and RhoB siRNA severely impaired CXCR2-mediated chemotaxis. Expression of RhoB T19N and RhoB siRNA impaired sorting of CXCR2 to the lysosome after 3 h CXCL8 stimulation and RhoB T19N impaired CXCL8-induced CXCR2 degradation. In cells expressing the RhoB Q63L mutant, CXCL8 stimulated CXCR2 recycling through the Rab11a perinuclear recycling compartment was impaired but CXCR2 degradation was not induced after 30 min of CXCL8 stimulation. CXCR2 co-localized with Rab4, a marker for the rapid recycling pathway, and with mannose-6-phosphate receptor, which traffics between the trans-Golgi network and endosomes, in RhoB Q63L expressing cells suggesting that CXCR2 is recycled through alternative pathways. These data suggest that RhoB plays a key role in CXCR2 recycling/degredation sorting decisions. Identification of the Domain in ErbB2 That Restricts Ligand-induced Degradation

F. Shen, Q. Lin, C. Childress, W. Yang; Weis Center for Research, Geisinger Clinic, Danville, PA

Ligand-induced receptor degradation is an important process for down-regulation of plasma membrane receptors. While epidermal growth factor receptor (EGFR) is rapidly internalized and degraded upon ligand stimulation, ErbB2, the closest member to EGFR in ErbB receptor family, is resistant in ligand-induced degradation. To understand the molecular mechanisms underlying the impairment of ErbB2, we attempted to determine structural factor in ErbB2 that restricts the degradation. By analysis of ligand-induced degradation of EGFR/ErbB2 chimeras, we have identified a region between amino acid residues F1030 and L1075 in ErbB2 as the domain that restricts the ligand-induced degradation. We designated this domain as the Blocking ErbB2 Degradation or the BED domain. Replacement of the BED domain in an EGFR/ErbB2 chimera with the corresponding region of EGFR changed this chimera from a non-degradable to a degradable receptor, indicating that the BED domain is the factor restricting the ligand-induced degradation of ErbB2. In addition, we found that a non-degradable EGFR/ErbB2 chimera was not defective in tyrosine phosphorylation, ubiquitination and interaction with c-Cbl, rather, was defective in ligand-induced internalization, suggesting that the endocytosis defect is the cause restricting the degradation of ErbB2, and that c-Cbl catalyzed mono-ubiquitination is not involved in the impairment in ligand-induced degradation of ErbB2.

Probing the Biophysical and Molecular Mechanism of Pathological Mutations in the Transmembrane Domain of Fibroblast Growth Factor Receptor 3

L. He, E. Li, S. O'Connor, J. Placone, K. Hristova; Johns Hopkins University, Baltimore, MD

Mutations in the transmembrane (TM) domains of receptor tyrosine kinases (RTKs) have been implicated in the induction of pathological phenotypes. These mutations are believed to stabilize the RTK dimers, leading to constitutive signaling. Examples include the β2-AR (Gly380Arg), the α2B-AR folding in the ER. The Tyr-Ser motif, which is highly conserved in the membrane-proximal N-termini of all α2-AR subtypes, is required for the exit of α2A-AR and α2B-AR from the Golgi apparatus. Thus, the Tyr-Ser motif may represent a novel Tyr-based signal directing G protein-coupled receptor transport at the Golgi level. These data provide the first evidence indicating an essential role of the N-termini of G protein-coupled receptors in the export from distinct intracellular compartments along the secretory pathway.

Metal-induced Inhibition of Estrogen-induced Apoptosis in Osteoclasts

K. Patel, A. K. Wilson; Biological Sciences, Benedictine University, Lisle, IL

Divalent metal cations have been demonstrated to be estrogenic on reproductive tissues. We have demonstrated that low-level cadmium exposure can act anti-estrogenically by interacting with ERα receptors to cause bone loss through a non-genomic secondary messenger pathway. It was hypothesized that other divalent metal cations might have similar anti-estrogenic effects on bone via ERα receptors. The ability of metal cations such as, cadmium(Cd²⁺), copper(Cu²⁺), tin(Sn⁴⁺) and chromium(Cr⁶⁺) to prevent estrogen-induced apoptosis of osteoclasts was measured in model lipid systems.
Intracellular Retention, Degradation, and Signaling of Glycosylation Deficient FGFR2 and Craniosynostosis Syndrome Associated FGFR2

E. Hatch, M. Hudson, M. Bothwell; Department of Orthodontics, University of Michigan, Ann Arbor, MI, Department of Physiology and Biophysics, University of Washington, Seattle, WA

FGFRs are known to play a critical role in a variety of fundamental processes including wound healing, angiogenesis and development of multiple organ systems. Mutations in the FGFR gene family have been linked to a series of syndromes (the craniosynostosis syndromes) whose primary phenotype involves aberrant development of the craniofacial skeleton. Craniosynostosis syndrome linked FGFR mutations have been shown to be gain of function in terms of receptor activation, and have been presumed to result in increased levels of FGFR signaling. Unfortunately, studies attempting to link expression of mutant FGFR's with changes in cellular phenotype have yielded conflicting results. In an effort to better understand the biochemical consequences of these mutations on receptor function, here we have investigated the effect of the FGFR2 mutation of Crouzon craniosynostosis syndrome on receptor trafficking, ubiquitination, degradation and signaling. We find that FGFR2-expressing diminished glycosylation, increased degradation and limited cellular sub-localization in the osteoblastic cell line, MC3T3-E1(C4). Additionally we show that trafficking and auto-activation of wild type FGFR2 is glycosylation dependent. Both FGFR2 and unglycosylated wild type FGFR2 signal through phospholipase-C-PLCγ in a ligand independent manner as well as exhibit dramatically increased binding to the adaptor protein, frα. These findings suggest that auto-active FGFR2 can signal from intracellular compartments. Based upon our results we propose that the functional signaling of craniosynostosis mutant, auto-active receptors is limited in some cell types by protective cellular responses such as increased trafficking to lysosomes and proteasomes for degradation.

Role of Ubiquitination in cMet Internalization

K. S. Hill, N. Li, A. Elfenink; Neuroscience and Cell Biology, University of Texas Medical Branch, Galveston, TX

Intracellular retention and degradation of the receptor tyrosine kinase cMet is often detected in metastatic cancers, correlating closely with tumor aggressiveness and poor patient prognosis. Hepatocyte growth factor (HGF) binding to cMet induces receptor phosphorylation and clathrin-dependent endocytosis. Subsequent lysosomal degradation of the internalized cMet terminates signaling. Thus clathrin-mediated cMet internalization is considered a key limiting step for termination of cMet signaling. Studies have shown that the direct binding of Cbl to cMet at Y1003 mediates cMet ubiquitination and receptor degradation. However the precise role of cMet ubiquitination on receptor internalization remains unclear. To determine the role of cMet ubiquitination on receptor internalization, two cMet mutants (Y1003F and P991S) deficient in receptor ubiquitination were generated using site-directed mutagenesis and stably expressed in cMet null (+/-) cells. Biochemical and confocal approaches will be used to examine these mutant cMet receptors for defects in endocytic trafficking and receptor signaling. If cMet ubiquitination is required for HGF dependent internalization, then cells expressing these mutants would be expected to have increased surface levels of cMet, exhibit a highly proliferative and motile phenotype and form metastatic tumors in vivo. These studies will be extended to determine whether ubiquitination of other endocytic components is important for cMet internalization, and the role of Cbl and additional ubiquitin ligases in this process. An increased understanding of the ubiquitin-dependent interactions important for the termination of cMet signaling could identify new therapeutic targets for treating metastatic cancers in which cMet signaling persists.

Cell Surface Biliverdin Reductase Regulates Innate Immunity

B. Wegiel, C. J. Baty, E. Ciszmadia, J. R. Scott, E. Kaczmarek, H. Bach, E. Otterbein; BIDMC Harvard Medical School, Boston, MA, University of Pittsburgh, Pittsburgh, PA, University of Texas Medical Branch, Galveston, TX

The pasteurella multocida variant strain (P. multocida) demonstrates that BVR is also present on the external plasma membrane in macrophages in vitro and in vivo in the lung and liver as show by total internal reflection fluorescence (TIRF) microscopy, immunoblotting, and flow cytometry (FACS). Surface cell BVR expression is greatly increased after endotoxin challenge. BVR as a surface protein functions not only to generate bilirubin, but also to initiate signaling by the P38A-PLCγ cascade. BVR directly interacts with p85α regulatory subunit of PI3K via increasing biliverdin-induced tyrosine kinase activity and thereby induces activation of PI3K-Akt signaling. Mutation of BVR on Tyr198 leads to the loss of biliverdin signaling and P38A-mediated production of IL-10. Furthermore, P3K-p85α- but not p85β- bone marrow-derived macrophages show impaired signaling of biliverdin. We also tested the hypothesis that the potent anti-inflammatory properties of biliverdin in models of endotoxic shock is due in part to BVR co-localization and interaction with Toll like receptor 4 (TLR4) in the cell membrane. Increased surface BVR expression resulted in decreased TLR4 activity and inhibition of LPS-induced TNF-α and IL-6 expression. Conversely, expression of BVR siRNA increased TLR4 expression and cytokine production, resulting in a loss of the anti-inflammatory effects of biliverdin. These findings demonstrate for the first time that BVR is expressed as a surface protein and directly modulates LPS induced TLR4-Myd88-NFkB and PI3K-Akt signaling. The physical interaction between BVR, which contains a TIR-like domain and TLR4 suggests that BVR is a novel adapter protein involved in negative regulation of LPS signaling. Additionally, the protective effects ascribed to heme oxygenase-1 may in part be explained by the action of BVR. Taken together the above findings elucidate a major new molecular mechanism for the natural regulation of innate immunity.

Characterization of P2X Receptors in Human Lung Mast Cells

C. Vial, P. Bradling; Cell Physiology and Pharmacology, University of Leicester, Leicester, United Kingdom

Mast cells are involved in both innate and acquired immunity and play a central role in the induction of allergic inflammation. A potential role for extracellular nucleotides on mast cells including chemotaxis, cytokine expression, apoptosis and histamine release has been reported. However, the identity of the P2 receptor subtypes involved in these physiological events remains unclear. In the present study, we investigated which functional P2X receptors were expressed by human lung mast cells (HLMC) and the human immature and mature mast cell lines, HMC-1 and LAD-2. Using a combination of RT-PCR and western blot techniques, we identified the presence of the P2X1, P2X2 and P2X3 receptor subtypes in these cells. We recorded P2X receptor currents from LAD-2 cells, using the perforated patch configuration and repetitive applications of ATP (100 μM) every 5 min evoked. The first ATP application evoked a rapidly activating (peak current -169±42 pA, time to peak 47±4 ms) and desensitizing inward current (24±4 /% of peak current remaining at 2s)(n=9). In contrast, subsequent ATP applications evoked slower activating (time to peak of the fourth ATP application: 625±52 ms, p<0.05 (n=9)) and desensitizing inward currents. Indeed, the percentage of peak current remaining at 2s for the second, third and fourth ATP applications were 57±5%, 68±4% and 72±4% respectively (p<0.001, n=9). This shows that the first initial fast ATP response plays a priming role in recruiting the more sustained current observed after subsequent ATP applications. The receptors involved are likely to be P2X1 and P2X3 receptors as P2X- receptor would require a higher concentration of ATP to be activated. Similar results were observed for human lung mast cells, indicating that the mature mast cell line LAD-2 is a good model to study P2X receptor functions in mast cells.

Demonstration of Specific Binding of TP508 to Receptors on Fibroblasts and Coronary Artery Endothelial Cells by Photo-Affinity Cross-Linking

J. S. Bergmann, Z. Dowdy, D. Carney; Biochemistry & Mol. Biology, University of Texas Medical Branch, Galveston, TX

TP508 (Chrysalin®) is a non-proteolytic synthetic peptide representing the portion of human thrombin originally identified as the fibroblast high-affinity receptor binding domain. TP508 is shown to accelerate revascularization and repair of animal tissues and is undergoing human clinical testing for healing of bone fractures and diabetic foot ulcers. In spite of these physiological effects, modified TP508 (125I-TP508S), couple the heterobifunctional, photoactivatable cross-linker (Sulfo-SANPAH), and cross-link and fourth ATP applications were 57±5%, 68±4% and 72±4% respectively (p<0.001, n=9). This shows that the first initial fast ATP response plays a priming role in recruiting the more activating (time to peak of the fourth ATP application: 625±52 ms, p<0.05 (n=9)) and desensitizing inward currents. Indeed, the percentage of peak current remaining at 2s for the second, third and fourth ATP applications were 57±5%, 68±4% and 72±4% respectively (p<0.001, n=9). This shows that the first initial fast ATP response plays a priming role in recruiting the more sustained current observed after subsequent ATP applications. The receptors involved are likely to be P2X1 and P2X3 receptors as P2X- receptor would require a higher concentration of ATP to be activated. Similar results were observed for human lung mast cells, indicating that the mature mast cell line LAD-2 is a good model to study P2X receptor functions in mast cells.

Characterization of P2X Receptors in Human Lung Mast Cells

C. Vial, P. Bradling; Cell Physiology and Pharmacology, University of Leicester, Leicester, United Kingdom

Mast cells are involved in both innate and acquired immunity and play a central role in the induction of allergic inflammation. A potential role for extracellular nucleotides on mast cells including chemotaxis, cytokine expression, apoptosis and histamine release has been reported. However, the identity of the P2 receptor subtypes involved in these physiological events remains unclear. In the present study, we investigated which functional P2X receptors were expressed by human lung mast cells (HLMC) and the human immature and mature mast cell lines, HMC-1 and LAD-2. Using a combination of RT-PCR and western blot techniques, we identified the presence of the P2X1, P2X2 and P2X3 receptor subtypes in these cells. We recorded P2X receptor currents from LAD-2 cells, using the perforated patch configuration and repetitive applications of ATP (100 μM) every 5 min evoked. The first ATP application evoked a rapidly activating (peak current -169±42 pA, time to peak 47±4 ms) and desensitizing inward current (24±4 /% of peak current remaining at 2s)(n=9). Indeed, the percentage of peak current remaining at 2s for the second, third and fourth ATP applications were 57±5%, 68±4% and 72±4% respectively (p<0.001, n=9). This shows that the first initial fast ATP response plays a priming role in recruiting the more sustained current observed after subsequent ATP applications. The receptors involved are likely to be P2X1 and P2X3 receptors as P2X- receptor would require a higher concentration of ATP to be activated. Similar results were observed for human lung mast cells, indicating that the mature mast cell line LAD-2 is a good model to study P2X receptor functions in mast cells.
show that PAR-1 migrates as a single band of ~42 kDa in these gels and that none of the \(^{125}\)I-TP508S complexes are recognized by the antibody to PAR-1. These results indicate that TP508 signals specifically binds to one or more receptors distinct from PAR-1. Ongoing characterization and sequencing will provide additional answers to help us understand how these molecules relate to TP508 signaling.

Role of Oxidative Stress on Angiotensin II-induced Stimulation of Cl-/HCO\(_3\)/Exchanger in Immortalized SHR Proximal Tubular Epithelial Cells

R. Pedrosa, P. Soares-da-silva; Institute of Pharmacology and Therapeutics, Faculty of Medicine University of Porto, Porto, Portugal

We have recently reported an increased activity and expression of the apical Cl-/HCO\(_3\) exchanger (SLC26A6) in immortalized proximal tubular epithelial cells from spontaneous hypertensive rat (SHR) when compared with their normotensive controls (Wistar Kyoto rat; WKY). We also had shown that SHR cells have an enhanced sensitivity to Ang II-induced stimulation of the Cl-\(\rightarrow\)HCO\(_3\) exchanger activity through the AT1 receptor. The present study was designed to evaluate, in immortalized proximal tubular epithelial cells from SHR and WKY rats, (1) the expression of AT1 receptors and (2) the involvement of oxidative stress, namely the H\(_2\)O\(_2\) and NADPH oxidase contribution on enhanced sensitivity to Ang II-induced stimulation of the Cl-/HCO\(_3\) exchanger activity through the AT1 receptor in SHR cells. The level of expression of AT1 in SHR cells was similar to that in WKY cells. However, the membrane expression of AT1 in WKY cells was greater than in SHR cells. The rate of H\(_2\)O\(_2\) production in SHR cells was found to 5-fold that in WKY cells. The addition of ascorbic acid (100 \(\mu\)M), an inhibitor of the NADPH oxidase pathway, in dextran-O\(_4\)-BSA (dextran-O\(_4\)-BSA is used to complex an oxidized lipoprotein)–infused SHR proximal tubular epithelial cells, during four days after seeding 1) reduced the extracellular levels of H\(_2\)O\(_2\) in both WKY and SHR cells, though the effect was markedly higher in SHR cells, 2) completely blocked the enhanced sensitivity of SHR cells to Ang II-mediated stimulation of the Cl-/HCO\(_3\) exchanger activity, but 3) did not change the AT1 expression in both WKY and SHR cells. It is concluded that the enhanced sensitivity to Ang II-induced stimulation of the Cl-/HCO\(_3\) exchanger activity through the AT1 receptor in SHR cells is associated with the higher H\(_2\)O\(_2\) generation, this being independent of differences on AT1 membrane expression. Supported by grant POCI/SUS/CEF/39207/2004 from Fundação para a Ciência e a Tecnologia (Portugal).

Examination of the Effects of Poly(Ethylene Glycerol) (PEG) Rich Matrices on the Transport of Multi Drug Resistance (MDR) and Multi Drug Resistance Associated Protein (MRP) Substrates Using the Caco-2 Cell Model

N. Santos-Roman, M. Licha, M. Torres-Lugo; Chemical Engineering Department, University of Puerto Rico, Mayaguez Campus, Aguadilla, PR

Poly(ethylene glycol) (PEG) is a linear or branched neutral polymer that is widely used in a variety of biological applications for its unique properties. Recently, it has been observed that cells that have been in contact with linear polyethylene glycol (PEG) exhibited an enhanced drug transport for known MRP and MDR substrates. Therefore, the main goal of this project is to characterize crosslinked PEG rich matrices and the investigation of their effect on the transport of known MDR and MRP substrates. Poly(ethylene glycol) hydrogels were synthesized via free radical polymerization using poly(ethylene glycol dimethacrylate N= 600, 1000) (PEGDMA) as the crosslinker and poly(ethylene glycol monomethacrylate N=200, 400, and 1000) as the backbone chain. The hydrogels were characterized by equilibrium swelling ratio, mesh size, partition coefficient, release of the model molecule fluorescein sodium salt, and cytotoxicity. As expected slight effects of increasing tethered chain and/or crosslinker length showed an increase in swelling behavior. This correlates well with mesh size data that showed similar effects, although to a lesser extent. However, no effect of tethered chain was found on partition coefficient. Fluorescein sodium salt (FLUO) release experiments indicated an anomalous behavior for most of the morphologies and relaxation controlled release for the larger tethered chains. Finally, transport of fluorescein sodium salt through Caco-2 cells in contact with 10 mg/mL polymer suspensions at 37 °C shows an enhanced transport of FLUO as the tethered chain increases with a maximum observed at the intermediate length. At 4 °C no polymer effect is observed, which suggests that the previous effects is due to active transport. Next steps include further investigation of the effects of PEG on transport of MDR substrates and on membrane fluidity.

Activation of PAF Receptor Leads to Endothelial Actin Rearrangement and Increased Vascular Permeability.

D. N. Predescu, I. Knezevic, S. Predescu, R. Narnau, M. Gorovoy, N. Knezevic, A. Malik; Pharmacology, University of Illinois, Chicago, IL

Although platelet activating factor (PAF) is one of the most potent vascular permeability modulator known to date, little is known about the molecular mechanisms linking its receptor activation to the cellular signal changes reported. To better understand the molecular determinants and signaling pathways leading from PAF-R to an increased vascular permeability, we decided to use cultured endothelial cells challenged with PAF as a model. We report that upon binding to its receptor PAF: i) activates small proteins of the Rho family (Rac1 and RhoA), ii) determine a shift of different pools of actin, promoting its phosphorylation, iii) induces the appearance of ruffles and filopodia, iv) opens the spaces between endothelial cells, causing formation of gaps in the monolayer, v) promotes via activated Rac actin nucleation that is phosphoinositide dependent. The activation of PAF-R promotes the phosphorylation of cSrc and PLCβ3 via Gαq; however the myosin is not phosphorylated. Therefore, we were able to demonstrate that one of the main signaling pathways leading from PAF-R to actin nucleation require the association of Rac1 with the receptor after its activation by Tiam1/land their translocation from cytosol to cellular membrane. The activated Rac1-Tiam1 complex induces the formation of new free actin barbed ends that finally supports the formation of actin filaments that stand behind the ruffles and filopodia. Hence, the induced polymerization of actin, via activated Rac1 and RhoA, and not the phosphorylation of cSrc is the main mechanism by which PAF induces changes in vascular permeability that are so fast and so well controlled. In conclusion our data provide evidence for the existence of a new signaling pathway involved in controlling the restrictiveness of endothelial barrier.

Familin-C Interacts with α1-Adrenergic Receptor and Modulates Its Effect on F-actin Reorganization through Balancing ERK1/2 and p38 MAPK Pathway

T. Zhang,1,2 Q. Xu,1 F. Chen,3 Z. Lu,1 Q. Han,1 Y. Zhang1; 1Institute of Vascular Medicine, Peking University Third Hospital and Key Laboratory of Molecular Cardiovascular Sciences, Ministry of Education, Beijing, China; 2Present address: NIMH, Bethesda, MD

α1-adrenergic receptors (α1-ARs) are G-protein-coupled receptors that couple to the Gq11 signaling pathway. All three α1-AR subtypes (α1A-, α1B-, and α1D-AR) respond to agonists in vascular smooth muscle contraction, cardiac hypertrophy quite differently. In addition, evidence has shown that α1A-AR is the most important and efficient subtype of α1-ARs. To look for new α1A-AR interacting non-G-proteins that may contribute to these differences among α1-ARs, we have identified filament-C C terminus (FlnC-CT, Ig repeat 24) as an α1A-AR C terminus binding partner in yeast cells. In the present study, we have further investigated their interactions and functions in HEK293A cells with or without stable α1A-AR expression. Immunofluorescence indicated that FlnC-CT (Ig repeats 19-24) co-localized with full length α1A-AR and affects subcellular localization, especially after AR activation with phenylephrine. Their direct binding was further confirmed by both Co-immunoprecipitation and FRET assays. Functional studies revealed that α1A-AR activation induced F-actin formation could be inhibited by FlnC-CT but not full-length FlnC (FlnC-F) overexpression. In addition, FlnC-F or FlnC-CT inhibited α1A-AR dependent ERK1/2 or p38 phosphorylation level differently: FlnC-F increased p38 while FlnC-CT increased ERK1/2. Blocking of ERK1/2 phosphorylation by PD98059 reversed FlnC-CT’s inhibition on α1A-AR activation induced F-actin formation. In contrast, blocking of p38 by SB203580 inhibited F-actin formation in FlnC-F overexpressed HEK293A cells. Our findings provided evidence for the first time of a direct interaction between α1A-AR and FlnC in mammalian cells. It showed that FlnC could modulate α1A-AR dependent F-actin reorganization through balancing ERK1/2 and p38 MAPK pathway. This data sheds new light on FlnC’s participation in and modulation of α1A-AR signaling pathway and provides new clues for studies on physiological functions of both α1A-AR and FlnC.

Microbead Analysis of Inhibitors of Lectin-Cell Binding

We model an inexpensive alternative to microarrays using derivatized microbeads to examine the binding of mannose-rich yeast (Saccharomyces cerevisiae) to Concanavalin A, in the presence of 30 different inhibitors. We developed a list of candidate inhibitors of immobilized Con A, in order of decreasing inhibitory activity, and multitissue being most effective, based on over 14,000 replicates. Saccharides were tested at 0.05 M concentration, the lowest sugar concentration found to provide reliable results. At lower concentrations of sugars, down to 0.017M, results were not reliable. This is the most extensive listing of saccharide inhibitors of immobilized Con A binding ever developed and we suggest that it should replace less expensive lists that have been in the literature for decades. Currently microarrays are being used in the development of carbohydrate drugs and diagnostic tests. We propose that microbeads can, in some cases, substitute for microarray technology. If, for example, our model yeast was a pathogen, our studies show that it binds via cell surface mannose residues and drugs to prevent binding could be developed using the inhibitors identified here. Microbeads could be also used in the development of diagnostic tests that identify the presence of organisms in blood samples, etc., in much the same way as microarrays are being used today (Supported by grants from NIH NIGMS SCORE, RISE, MARC programs, IQT program and the Joseph Drown Foundation).
Characterizing the Polycation Receptor of Paramecium
H. G. Kuruvilla, E. D. Robinette; Science and Mathematics, Cedarville University, Cedarville, OH

Paramecium are excellent model cells in which to study behavioral avoidance because of their large size and adaptability for electrophysiology. Since we had previously characterized a polycation receptor from a related ciliate, Tetrahymena, we wished to determine whether Paramecium possessed a similar receptor. Our hypothesis was that Paramecium possessed a polycation receptor with characteristics similar to the Tetrahymena receptor in terms of in vivo behavioral responses. We found that Paramecium does possess a polycation receptor, and that ligands such as lysozyme, PACAP, and VIP all elicit behavioral avoidance responses in Paramecium just as they do in Tetrahymena. However, the EC50 of the compounds were significantly different in Paramecium than they were in Tetrahymena. While in Tetrahymena the EC50 of PACAP-lysozyme-Paramecium we find that the EC50 of lysozyme-VIP-PARAMECUM. PACAP is also toxic to Paramecium at levels near those which elicit avoidance, making it an unfavorable ligand for study in this system. Future studies of the polycation receptor will involve drug studies to determine how the lysozyme pathway works in Paramecium, since lysozyme is the cheapest and most effective of the polycations that we studied in this system.

Functional Characterization of a Cloned Bacterial Virus Tail Protein
R. E. Ramirez, M. Zayas, R. Villafane; 1Biology, University of Puerto Rico-Mayaguez, Mayaguez, Puerto Rico, 2Biochemistry, Ponce School of Medicine, Ponce, Puerto Rico

To understand in detail the interaction between bacterial cell lipopolysaccharide (LPS) and protein, a molecular genetic approach using phage tail protein of Salmonella phage P22 and the c34 rsp with respect to their phage associated properties. This study reports the DNA sequence of the gene for the c34 rsp as well as reporting its initial functional characterization. The functional nature of the expressed clone tail gene suggests that it is functional and resistant to trypsin protease.

Yeast Cell Biology: Human Physiology in a Nutshell
G. Nadel, M. Mayrose, S. Bar-Nun; Biochemistry, Tel-Aviv University, Tel-Aviv, Israel

There is a remarkable conservation of cellular mechanisms responsible for quality control, transport and degradation of proteins between yeast and man. In addition, yeast has been instrumental in genetic studies of human diseases associated with quality control. Here we identify and characterize in yeast trans-acting cellular components that contribute to secretion or retention of immunoglobulins. In B-lymphocytes, secretion and degradation of secretory IgM are developmentally regulated. The μCys (the C-terminal of μ, the heavy chain of secretory IgM, and its penultimate Cys575) is the necessary cis-acting signal for μ retention in B-cells (Sita et al. 1990 Cell 60, 781-790). This motif is also sufficient to confer retention and degradation onto several reporter proteins in lymphoid and non-lymphoid mammalian cells. The evolutionary conservation of the secretory pathway from yeast to man is strikingly brought to us as we think. Two μCys motifs are thought to confer retention also onto yeast secretory proteins. To that end, μCys and its mutant μCysSer were fused to the C-terminal of invertase. Secretion of this chimeric protein from Saccharomyces cerevisiae was monitored either by its enzymatic activity or by measuring secretion from spheroplasts using immunoblotting. Interestingly, μCys, but not μCysSer, conferred retention onto invertase, although yeast neither synthesize immunoglobulins nor μCys is found in the yeast genome. We have discovered several ER resident proteins that affect the secretion of μCys-invertase. These proteins either drive secretion by specific selection and transport to the Golgi via COPII vesicles (Erv1p-Erv2p) or mediate retention through disulfide bonding with the μCys-invertase (Eg1p). We conclude that the μCys is a general cis-acting retention signal that can be used in yeast to unveil trans-acting cellular components and mostly ER resident proteins that act in concert to regulate secretion.

CREB-II, a Transmembrane Transcription Factor Subject to Alternate Pathways of ERAD and Stress Regulated Intramembrane Proteolysis
D. Bailey, P. O'Hare; Protein Trafficking and Gene Regulation, Marie Curie Research Institute, Oxted, Surrey, United Kingdom

Regulated intramembrane proteolysis (RIP) is a process whereby in response to specific cues ER-resident transcription factors, are released from the ER to the Golgi and cleaved by Golgi proteases, to release a cytosolic domain which traffics to the nucleus to effect transcription of appropriate genes. We examine the ER processing of CREB-II, a new member of the RIP class of proteins. CREB-II is localised to the ER, and glycosylated, while an N-terminal variant containing the conserved bZIP domain, accumulates in the nucleus. Brefeldin A disruption of the Golgi, induces cleavage and the production of a cytosolic product that translocates to the nucleus, indicative of processing by SIP and SIG proteases. An ER-localised form of SIP also induces CREB-II cleavage and nuclear translocation. We also find that CREB-II is subject to rapid turnover involving a cycle of ER insertion and retrotranslocation through the ER associated degradation route. Proteasome inhibition was sufficient to induce cleavage of CREB-II, to a greater extent than tunicamycin. CREB-II is subject to two pathways of retrotranslocation:ERAD and stress-induced release for SIP processing. We propose that CREB-II may monitor the ERAD/proteolysis pathway and stress or cytosolic perturbation in this pathway results in alternate transport into the secretory route for Golgi cleavage.

In Vitro Reconstitution of ATF6 Budding during ER Stress
A. Schindler, R. Scheckman; Molecular and Cell Biology, University of California, Berkeley, Berkeley, CA

ATF6 is an ER-localized transmembrane protein that traffics to the Golgi complex specifically during ER stress. In the Golgi, ATF6 is cleaved by site 1 and 2 proteases to release a soluble transcription factor that induces gene expression in the unfolded protein response (UPR). Although it is known that ATF6 trafficking is regulated by ER stress, the particular events that allow its recognition by the COPII budding machinery are not known. Because ER stress is thought to be a lumenal event, whereas budding occurs primarily through cytoplasmic proteins, ATF6 provides an example of regulation across the ER membrane. To study ATF6 trafficking, we have developed an in vitro assay that recapitulates the ER-stress induced packaging of full-length ATF6 into COPII vesicles. While crude ER membranes from mammalian cells are treated with the ER-stress inducer DTT, ATF6 is captured in COPII vesicles. Other cargo proteins were not affected by DTT treatment. ATF6 budding required nucleotides and cytosol, and was inhibited by nonhydrolysable GTP and dominant-negative forms of the GTPase Sar1. ATF6 packaging required DTT activity in the ER lumen, as a membrane-impermeable reducing agent failed to induce ATF6 budding. Specific isoforms of the COPII proteins Sec23 and Sec24 were analyzed for their specificity for ATF6. To determine the domains required for ATF6 recognition by COPII, stable cell lines were made containing ATF6 mutants and tested in the in vitro budding assay. These data indicate that ATF6 budding occurs from existing protein pools and does not require protein synthesis. Further, cleavage of disulfide bonds in the ER is sufficient to induce ATF6 budding.

Interaction of RelR1p with Nicastrin Is Required for the Initial Steps of γ-secretase Complex Assembly in Pre-golgi Compartments

γ-secretase complex, consisting of presenilin-1 or presenilin-2, nicastrin, PEN-2 and an APH-1 isoform, mediates the intramembrane proteolytic event leading to the liberation of the βγ-acting signal for γ-secretase activities. Binding to Rer1p is mediated through spaced polar residues in the nicastrin transmembrane domain that are also critical for binding to APH-1. Absence of APH-1 γ-secretase activities. Binding to Rer1p indicates that both proteins compete for nicastrin. Hence, we propose that RelR1p recycles nicastrin from the Golgi, thereby increasing the probability for nicastrin to form a complex with APH-1. This mechanism demonstrates the necessity of secondary endoplasmic reticulum quality control in proper γ-secretase complex assembly in early compartments. Our findings may open new therapeutic avenues in Alzheimer’s disease by controlling AP production through a direct interference with the levels of γ-secretase complexes at an early stage in assembly.
Secretory COPII Coat Component Sec32a Is Essential for Craniofacial Chondrocyte Maturation

L. Blue,1 C. Johnson,2 J. Clark,3 G. Vezina,1 C. L. Craft,1 1Department of Pathology, University of Virginia, Charlottesville, VA, 2Department of Medicine, University of Virginia, Charlottesville, VA, 3Department of Biology, University of Virginia, Charlottesville, VA

Craniofacial chondrocyte maturation is essential for craniofacial morphogenesis.” Since CRHCR lesion is known to cause the cranio-lenticulo-sutural dysplasia syndrome (CLSD), CRHCR provides the first vertebrate model system that links the biology of ER to Golgi trafficking with a clinically relevant dysmorphism.

Dynamics of Sar1p and Sec12p in the Endoplasmic Reticulum in Living Yeast Cells

K. Kurokawa,1 A. Nakano2,1 1Molecular Membrane Biology Laboratory, Riken Discovery Research Institute, Wako, Japan, 2Graduate School of Science, University of Tokyo, Bunkyou-ku, Japan

The budding yeast Saccharomyces cerevisiae has provided an excellent model to study cell polarity and its molecular mechanism. This unicellular organism polarizes its growth to produce a daughter cell by budding. The development of bud depends on the polarization of exocytosis and the actin cytoskeleton. Recent studies suggested that cell polarity impinges not only on the plasma membrane but also on the endoplasmic reticulum (ER) provided an excellent model. Vesicles coated with coat protein complex II (COPII) selectively transport cargo molecules and vesicle fusion proteins from the ER to the Golgi apparatus. COPII consists of Sar1p GTPase and Sec23/24p and Sec13/31p sub-complexes. How cell polarity affects the dynamics of COPII has not been elucidated. In this study, we focused on the dynamics of Sar1p and Sec12p, a specific guanine-nucleotide exchange factor of Sar1p, on the bud and the mother ERs in living yeast cells. By using a fluorescent protein, Dronpa, which can be marked reversibly for repeated measurements, we investigated the diffusion of Sar1p and Sec12p. The diffusion of Sar1p-Dronpa and Dronpa-Sec12p from the mother ER to the bud ER was inhibited, indicating that the diffusion barrier existed at the bud neck. In addition, Sar1p had a longer half life within the bud ER than within the mother ER. These results suggest that COPII dynamics is affected by the polarity of yeast cells.

Defining the Role of COP-I in Vesicular Membrane Transport through Depletion of β-COP

M. L. Stryer,1 E. Cortes-Moyaka,2 E. Szul1 1Cell Biology, University of Alabama at Birmingham, Birmingham, AL, 2Biochemistry and Molecular Biology, University of Alabama, Birmingham, AL

Within the mother ER. These results suggest that COPII dynamics is affected by the polarity of yeast cells.

Structure Function Analysis Reveals Important Regulatory Roles for a C-terminal Domain in Ralp, a Bacterial Member of the Sec7 Family of ARF Exchange Factors

L. Chesnel1, J. C. Kagan,2 C. R. Roy1 1Microbial Pathogenesis, Yale University, New Haven, CT, 2Immunochemistry, Yale University, New Haven, CT

ADP-ribosylation factor proteins (ARFs) are small GTPases that play a critical role in organelle biogenesis and membrane transport. ARFs function as molecular switches, cycling between GDP-bound inactive and GTP-bound active states. The GTPase cycle is regulated by GTPase Activating Proteins (GAPs) and GTPase Activating Proteins (GAPs). The six different mammalian ARF proteins can be divided into three different classes having distinct intracellular functions. Although ARF-GAPs often activate all ARF family members in vitro, they usually act only on a subset of ARFs in vivo. Interestingly, the bacterial pathogen Legionella pneumophila and Rickettsia prowazekii encode a protein called Ralp that functions as an ARF GEF. Ralp has an N-terminal domain highly similar to the eukaryotic Sec7 domain found in most ARF GEFs and a C-terminal domain of unknown function. Structural analysis suggests that the C-terminal domain of Ralp may mediate the activity of the catalytic Sec7 domain. Here we have used a variety of cell biological assays to investigate the function of the Ralp C-terminal domain. Our results indicate that the C-terminal domain of the Ralp protein mediates subcellular localization of the bacterial effector in the eukaryotic host cell. The L. pneumophila Ralp C-terminal domain localized primarily to the ER and early secretory vesicles, consistent with the in vivo activity of this protein being restricted to class I ARF proteins. By contrast, the highly similar C-terminal domain of the R. prowazekii Ralp protein mediated localization to actin-rich membrane ruffles and co-localized with ectopically produced ARF6. These studies indicate that the Ralp C-terminal domain mediates GEF localization. These studies provide unique insight into the mechanism by which ARF activation is controlled by demonstrating that spatial localization may dictate ARF-GEF specificity in eukaryotic cells.

SNARE Status Regulates Tether Recruitment and Function in Homotypic CopII Vesicle Fusion

M. Bentley,1 R. Mullen,2 D. Xu3 E. Sztul1 1Division of Biological Sciences, University of Montana, Missoula, MT, 2Institute of Biochemistry, Frankfurt, Germany, 3Department of Cell Biology, University of Alabama, Birmingham, AL

In mammals, COPII-coated transport vesicles deliver secretory cargo to vesicular tubular clusters (VTCs) that facilitate cargo sorting and transport to the Golgi. We documented in vitro tethering and SNARE-dependent homotypic fusion of ER-derived COPII transport vesicles to form larger cargo containers characteristic of VTCs (Xu and Hay, 2004, J. Cell Biol. 167:997). COPII vesicles thus appear to contain all necessary components for homotypic tethering and fusion, providing a pathway for de novo VTC biogenesis. Here we demonstrate that low concentrations of antibodies against the ER-Golgi SNARE syntaxin 5 inhibit COPII vesicle homotypic fusion, while higher concentrations inhibit both tethering and fusion, implying an unanticipated role for SNAREs upstream of fusion. Inhibition of SNARE complex disassembly with dominant-negative α-SNAP also inhibited tethering, implicating SNARE assembly status as a critical determinant in COPII vesicle tethering. The tethering-defective SNAREs generated in the presence of dominant-negative α-SNAP specifically lacked the rab1 effectors p115 and GM130 but not other peripheral membrane proteins. Furthermore, rab effectors, including p115, were shown to be required for homotypic COPII vesicle tethering. Thus, our results demonstrate a requirement for SNARE-dependent tether recruitment and function at future sites of membrane fusion. We anticipate that recruitment of tether molecules by an upstream SNARE signal ensures that tethering events are initiated only at focal sites containing appropriately poised fusion machinery.
A Novel Functional Domain within the p115 Tethering Factor Is Required for Golgi Ribbon Formation

E. Sztul,1 R. Grabski,1 E. Brandon,1 C. Alvarez,1 T. Sztul,1 J. Hay2
1Cell Biology, University of Alabama at Birmingham, Birmingham, AL, 2Biochemistry, University of Cordoba, Cordoba, Argentina, and Department of Biological Sciences, University of Montana, Missoula, MT

Tethering factors have emerged as key regulators of membrane traffic and organellar biogenesis. Herein, we explore the function of the p115 tethering factor operational at the ER-Golgi interface. We show that depletion of p115 disrupts the Golgi ribbon into fragments. The fragments form de novo adjacent to ER exit sites in cells subjected to BFA treatment and a subsequent wash-out. Significantly, the reformed Golgi fragments show cis- to trans-polarity. These results suggest that p115 is dispensable for traffic events generating differentiated Golgi fragments, but is required for fusion of such fragments into a Golgi ribbon. It appears that in vivo, the requirement for p115 is limited to later stages of ER-Golgi traffic. Previous studies documented that p115 coiled-coil 1 (CC1) region that binds a subset of ER-Golgi SNAREs and the Rab1 GTPase is required for Golgi biogenesis. Herein, we show that the CC1 domain is insufficient to sustain p115 function. We show that p115 mutants containing CC1 (and capable of binding SNAREs and Rab1), but lacking the CC4 coiled-coil domain act as dominant negatives and disrupt Golgi structure in cells containing endogenous p115. Furthermore, such mutants are unable to support Golgi biogenesis in cells depleted of endogenous p115. This suggests that CC4 is required for Golgi biogenesis. Significantly, CC4 has been shown to bind a subset of ER-Golgi SNAREs (Shorter et al., 2002). Our findings indicate that two non-overlapping SNAP25-interacting domains are required for Golgi biogenesis. This supports a model in which p115 facilitates SNARE complex formation by using CC1 and CC4 to simultaneously bring two SNAREs into close proximity. We postulate that membrane tethering may occur through tether-mediated SNARE-SNARE linkage.

ARF/COPI Events Regulated by the Guanine Nucleotide Exchange Factor GBF1 Maintain the Structure of the cis-Golgi and Facilitate Traffic of Developmentally Essential Proteins

E. Sztul,1 T. Sztul,1 R. Grabski,1 S. Shestopal,1 S. Lyons,3 M. Jeon,3 K. Zinn,3 S. Eimer,4 G. Marques1 1Cell Biology, University of Alabama at Birmingham, Birmingham, AL, 2Neurobiology, University of Alabama at Birmingham, Birmingham, AL, 3Division of Biology, California Institute of Technology, Pasadena, CA, 4Center for Molecular Physiology of the Brain, European Neuroscience Institute, Goettingen, Germany

The recruitment of COPI coat to membranes is required for secretory traffic and is mediated by the active form of the ADP-ribosylation factor (ARF). ARF is activated through a GDP/GTP exchange facilitated by guanine nucleotide exchange factors (GEFs). Multiple ARF-GEFs have been identified, but their exact functions within the secretory pathway remain unclear. Here, we describe the GBF1 exchange factor as a major determinant of ERGIC and cis-Golgi traffic and the key facilitator of parallel anterograde traffic of select cargo proteins. Using an RNAi-based approach, we show that GBF1 depletion causes extensive tubulation of ERGIC and cis-Golgi. The cis-Golgi derived tubules connect peripherial ERGIC sites forming a mixed compartment. The formation of the tubular ERGIC/cis-Golgi network in association with the parallel anterograde traffic of select cargo proteins. Soluble proteins such as fibronectin, laminin and cockin are efficiently secreted from GBF1-depleted cells. Thus, newly synthesized VSVG and F-selectin ligand-1 (ESL-1) are not delivered to the PM in GBF1-depleted cells. This suggests that two mechanistically distinct pathways handle protein secretion, and that GBF1 regulates ARF/COPI-dependent cargo passage through one of the pathways. The importance of the GBF1-regulated pathway in vivo was explored in D. melanogaster. Depletion of D. melanogaster homologue of GBF1 in the larval gland results in lack of cellular expansion and leads to marked disruption in salivary gland structure. This correlates with inhibition in surface delivery of cadherin (DCAD2) and flamingo, proteins known to regulate cell migration, cell sorting and epithelial polarity. Importantly, our findings indicate that ARF/COPI events facilitated by GBF1 provide an additional level of morphogenetic control by regulating the surface delivery of key developmental proteins.

Legionella pneumophila Effector Proteins Involved in Transport and Fusion of Endoplasmic Reticulum-derived Vesicles

E. M. Campodónico, C. R. Roy; Section of Microbial Pathogenesis, Yale University, New Haven, CT

Legionella pneumophila is a gram-negative pathogen that can subvert endoplasmic reticulum to Golgi transport to establish a unique vacuole that supports bacterial replication. Subversion of host vesicle transport requires a specialized secretion system called Dot/Icm that injects protein substrates directly into the host cell. Although it is predicted that Dot/Icm substrates will modulate host vesicle transport by interacting with the machinery controlling host endocytic and secretory membrane traffic, the identity and function of most Legionella effector proteins remains unknown. We have identified two homologous Legionella effectors called YlfA and YlfB using a genetic screen for bacterial genes that inhibit yeast growth. We find that a double ylfAB mutant has a decreased ability to establish a replicative compartment over 10 hours. Biochemical analysis revealed that YlfA and YlfB are capable of forming homomeric and heteromeric complexes via carboxy-terminal domain predicted to form coiled coils. Ectopic production studies in eukaryotic cells indicate that the Ylf proteins associate with membranes via amino-terminal hydrophobic residues, and that the production of Ylf results in formation of large membrane-bound compartments containing ER proteins Sec22b and calcinein and the Golgi-associated protein Rab1b. These studies establish that YlfA and YlfB are novel Legionella effectors involved in subversion of vesicular traffic in eukaryotic host cells, and suggest that the Ylf proteins may control membrane fusion events following translocation by Legionella into the host cell, possibly by mimicking host SNARE proteins.

Biochemical Characterization of a GAPDH Mutant Defective in Src-mediated Tyrosine Phosphorylation

E. J. Tisdale, C. R. Artalejo; Pharmacology, Wayne State University School of Medicine, Detroit, MI

Glyceraldehyde-3-phosphate dehydrogenase (GAPDH) is a well-characterized key enzyme in glycolysis that catalyzes the NAD-mediated oxidative phosphorylation of glyceraldehyde-3-phosphate to 1,3 diphosphoglycerate. A variety of studies have demonstrated that GAPDH has multiple intracellular activities in addition to its role in glucolysis. Indeed, we have reported that GAPDH is required for Rab2 mediated retrograde transport from vesicular tubular cisternae (VTCs) (JBC 276:2480). These diverse GAPDH activities are the result of post-translational modifications that confer a new function to the enzyme. In that regard, GAPDH is tyrosine phosphorylated by Src at residue 41 (Nature Biotech. 23:94). To establish the functional significance of this modification for GAPDH activity in Rab2-mediated events, an amino acid substitution was made at tyrosine 41(GAPDH Y41F). The inability of Src to phosphorylate purified recombinant GAPDH Y41F was confirmed in an in vitro kinase assay. We determined that GAPDH Y41F has normal glycolytic activity and efficiently binds to microtubules. The mutant was then employed in a quantitative membrane-binding assay that measures Rab2-dependent recruitment of soluble components to VTCs. As we observed with GAPDH wild type, Rab2 promoted GAPDH Y41F binding to membranes in a dose dependent manner. We learned by performing a time course that Rab2 treated membranes contain activated Src (Tyr 416) before the detection of tyrosine phosphorylated GAPDH. These results indicate that Src-dependent GAPDH phosphorylation occurs on the VTC and that GAPDH tyrosine phosphorylation is not required for VTC association. (This work was supported by NIH grants GM60881 and DK58921).

A Clamping Mechanism Involved in SNARE-dependent Exocytosis

C. G. Giraud, W. S. Eng, T. J. Melia, J. E. Rothman; Physiology & Cellular Biophysics, Columbia University, New York, NY

During neurotransmitter release at the synapse influx of calcium ions stimulates the release of neurotransmitter. However the mechanism by which synaptic vesicle fusion is coupled to calcium has been unclear, despite the identification of both the core fusion machinery (SNAREs) and the principal calcium sensor (synaptotagmin). Here we describe what may represent a basic principle of the coupling mechanism—a reversible clamping protein (Atollplexin) that can clamp SNAREpins, an assembled fusion competent intermediate on route to fusion. When calcium binds to the calcium sensor synaptotagmin, the clamp would then be released. SNARE proteins, and key regulators like synaptotagmin and complexins, can be ectopically expressed on the cell surface. Cells expressing such “flipped” synaptic SNAREs fuse constitutively, but when we co-expressed complexin fusion was blocked. Adding back calcium triggered fusion from this intermediate in the presence of synaptotagmin.
Effects of SCAMP Knockdown on Dense Core Vesicle Exocytosis Analyzed by Amperometry

H. Liao,1 J. Zhang,1 A. Castile,2 G. Szabo,1 J. D. Castle1; 1Cell Biology, University of Virginia, Charlottesville, VA, 2Molecular Physiology and Biological Physics, University of Virginia, Charlottesville, VA

SCAMPs (secretory carrier membrane proteins) comprise an integral membrane protein family with four transmembrane spans. There are four SCAMP isoforms (SCAMP1-4) ubiquitously expressed in mammalian cells and SCAMP5 primarily resides in neuronal cells. Previously, we have shown that overexpressing a SCAMP2 mutant in neuroendocrine PC12 cells leads to fusion pore formation and dilation during dense core vesicle (DCV) exocytosis. In order to examine whether other SCAMP isoforms are redundant for this process or distinct isoforms regulate DCV exocytosis differently, we knocked down SCAMP1, 2, and 5 with specific siRNA and checked the effects by amperometry. By recording individual secretory vesicles with high spatio-temporal resolution, amperometry enabled us to resolve DCV fusion into steps, which include fusion pore opening and subsequent dilation or closure. We found that all SCAMP knockdowns inhibited the rate of fusion pore opening, which was reflected by decreased number and frequency of exocytotic events. SCAMP1 and SCAMP2 knockdown but not SCAMP5 knockdown changed the dynamics of newly opened fusion pores, resulting in the initial fusion pores preferring to close rather than dilate. The average lag of response after depolarization increased in SCAMP2-deficient cells, but not in cells deficient in other SCAMPs. Finally, when both SCAMP1 and 2 were knocked down together, we observed an increase in pre- and post-fusion delay in addition to all the other effects found for individual SCAMP1 or 2 knockdown. By measuring [3H]inositol (IA) uptake, we also showed that SCAMP1 and 5 but not SCAMP2 knockdown decreased IA uptake by 23% and 50%, respectively. Therefore, the SCAMP isoforms regulate DCV exocytosis similarly and also differently, which may be due, respectively, to the conserved core structure shared by all isoforms and the specific regions of each one enabling them to interact with different protein partners.

Enrichment of Phosphatidylinositol 4-phosphate 5-kinases Ia and Ij Results in Dominant Presence of Phosphatidylinositol 4,5-bisphosphate in Secretory Granule Membranes

S. H. Yoo, Y. H. Huh, S. K. Huh, S. Y. Chu, S. Y. Park; Biochemistry, Inha University College of Medicine, Incheon, Republic of Korea

It is generally believed that phosphatidylinositol 4,5-bisphosphate (PIP2) is highly enriched at the plasma membrane and is much less abundant in intracellular organelles. Here we show that the enzymes that catalyze PIP4(2)P synthesis, PIP4(2)P 5-kinases Ia and Ij, are enriched in secretory granule membranes, and PIP2 is most concentrated in granule membranes. The PIP4(2)P 5-kinases coimmunoprecipitate the inositol 1,4,5-trisphosphate receptors (IP3Rs) that are present in secretory granule membranes, suggesting the presence of IP3R-PI(4)P5KI complexes in granule membranes. PI(4)P 5-kinase Ia and Ij localize to both the low- and high-buoyant density fractions of membranes, consistent with their presence in both raft and non-raft regions, though larger amounts are present in the high density fractions. The functional significance of these observations is highlighted by our finding that antibodies against the PI 5-kinases or PIP2 inhibit IP3-sensitive Ca2⁺ release from isolated secretory granules. These results indicate that key molecules specializing in phosphoinositide metabolism and exocytosis reside within the granule itself.

Purinergic Receptors and Calcium Signaling in the Lysosomal Granule

J. P. Girod, S. F. Hamm-Alvarez,2 M. C. Edman; 1Chemistry & Biomedical Sciences, University of Kalmar, Kalmar, Sweden, 2Pharmaceutical Sciences, University of Southern California, Los Angeles, CA

We have previously shown that the adenosine receptors A1 and A2a are expressed in rabbit lacrimal gland acinar cells and active in the regulation of acinar cell secretion. Activation of either receptor results in a 2-fold increase of acinar cell secretion. Our results also show that both A1 and A2a receptor agonists potentiate the secretory effect of carbachol (Cch), an acetylcholine analog, and that the IP3 receptor antagonist 2-APB blocked the synergistic effects as well as the carbachol-evoked secretion (Opt. Vis. Sci. 82, E055069, 2005; Invest. Ophthalmol. Vis. Sci. 47, 1943, 2006). Therefore, the aim of the present study is to further investigate the intracellular signaling events involved in the potentiation by studying the effect of adenosine A1-, A2a-, and muscarinic M3 receptor activation on intracellular levels of Ca2⁺. Primary cultures of rabbit lacrimal gland acinar cells were prepared according to our standard procedure and cultured for two days to allow for reorganization into acinar like structures (Exp. Eye Res. 83, 543-553, 2006). For Ca2⁺ measurements, cells were cultured in 35 mm glass-bottomed, live cell dishes and loaded with the fluorophore Fluo-4-green. Calcium were monitored with a cell culture equipped LSM 510 Meta microscope. The calcium imaging experiments showed that adenosine stimulation resulted in a lower but more prolonged intracellular calcium Ca2⁺ peak than that obtained by Cch. Simultaneous Cch and adenosine stimulation resulted in a higher and more prolonged Ca2⁺ peak than Cch alone. The A1 receptor agonist CPA (cyclopentyladenosine) and the A2a receptor agonist CPCA (cyclopropylcarboxamidoadenosine) both resulted in a peak of shorter duration than adenosine alone, and CPCA with the smallest response. Combinations with Cch and CPA or CPCA had similar effects as Cch + adenosine. In conclusion, our results indicate that Ca2⁺ is a more important mediator of regulated lacrimal acinar cell secretion.

Mechanisms of 1,25D-regulated ATP Release in Osteoblasts

P. Biswas, L. Zanello; Biochemistry, UCR, Riverside, CA

The hormonally active form of vitamin D3, 1,25-dihydroxyvitamin D3 (1,25D), is considered a bone anabolic hormone. 1,25D increases bone matrix production by modulating the synthesis of matrix proteins via a vitamin D receptor (VDR). In addition, 1,25D rapidly stimulates secretion via nongenomic mechanisms initiated at the plasma membrane of bone cells which appear to require a functional VDR. The present study investigates molecular pathways involved in 1,25D-regulated exocytosis in osteosarcoma ROS 17/2.8 cells, and identifies the molecular nature of the exocytosed product. We demonstrated, for the first time, a rapid (within seconds) exocytotic ATP release as a response to nanomolar concentrations of 1,25D in osteoblasts. Single exocytotic events were monitored in real time with videomicroscopy performed on live osteoblasts and stained with 3 μM quinacrine, a cell-permanent fluorophore that binds to ATP. Addition of NEM (1mM), which prevents vesicle fusion to the plasma membrane, significantly reduced 1,25D-induced release of ATP, providing further evidence that ATP release is vesicular. We investigated the Ca2⁺-dependence of the exocytotic vesicular release in osteoblasts, and found that 1,25D-induction of ATP release is coupled to rapid intracellular calcium increase. We found that 1,25D-stimulated CI⁻ channel in osteoblasts couples to rapid interfered release of glutamate in NG108-15 cells, as detected with live-cell microscopy and immunocytochemistry. Using a fluorometric assay, we found 4.8 ± 0.3% and 13.6 ± 0.4% relative increase of matrix proteins via a vitamin D receptor (VDR). In addition, 1,25D rapidly stimulates secretion via nongenomic mechanisms initiated at the plasma membrane of bone cells which appear to require a functional VDR.

Vitamin D₃-induced Exocytosis in Neuroblastoma-Glioma Cells

M. Owraghi, L. Zanello; Biochemistry, University of California, Riverside, Riverside, CA

The biologically active form of vitamin D₃, 1,25-dihydroxyvitamin D₃ (1,25D₃), promotes genomic and non-genomic responses via a vitamin D receptor (VDR) expressed in multiple target systems. In the brain, 1,25D₃ exerts neuroprotective effects, including glioma cell death, making the hormone of potential interest in the management of brain tumors. At the cell membrane level, 1,25D₃ stimulates rapid ion fluxes through different ion channel types, and activates cytoplasmic signaling cascades. Eradication of the precise molecular pathways involved in 1,25D₃-induced neuroprotective effects are of potential pharmacological value in the treatment of neurodegenerative diseases. Here we show, for the first time in neuroblastoma-glioma (NG108-15) cells, that nanomolar concentrations of 1,25D₃ activate, within minutes, outwardly rectifying chloride currents at highly depolarizing potentials. The electrical profile and pharmacology of these 1,25D₃-sensitive chloride currents resembles a CI⁻ channel expressed in neuroendocrine PC12 cells. We found that 1,25D₃-stimulated CI⁻ channel in neuroendocrine PC12 cells couples to rapid interfered release of glutamate in NG108-15 cells, as detected with live-cell microscopy and immunocytochemistry. Using a fluorometric assay, we found 8.4 ± 0.3% and 13.6 ± 0.4% relative increase of glutamate in the medium after 3 min treatment with 10 and 100 nM 1,25D₃, respectively. Significant specific binding of 1,25D₃ was measured in NG108-15 cell lysates. VDR protein expression was confirmed by Western blot. Immunocytochemistry for the VDR showed abundant cytoplasmic and plasma membrane-associated subcellular localization. In addition, we detected the
presence of voltage-gated CIC-3 and CIC-5 chloride channel proteins in dendrites and secretory vesicles. Immunostaining for CIC-1, CIC-2, and CIC-7 was significantly lower, while CIC-4 and CIC-6 were not detected. We conclude that 1,25D stimulation of exocytosis in NG108-15 cells appears to couple to chloride current potentiation via a membrane associated classic VDR, similarly to what we have shown previously in osteoblasts.

409 Characterization of Transgenic Mice Expressing HA-GLUT4-GFP in Muscle

I. Lisinski, D. Yver, H. Al-Haslani, G. D. Holman, S. W. Cushman; NIDDK, NIH, Bethesda, MD, German Institute for Human Nutrition, Potsdam-Rehbrücke, Germany, Department of Biology and Biochemistry, University of Bath, Bath, United Kingdom

Insulin stimulates glucose uptake into fat and muscle by modulating the distribution of the GLUT4 glucose transporter between the cell surface and intracellular compartments. Hypoxia/contraction in skeletal muscle stimulates glucose transport activity, and this effect is additive to glucose transport stimulated by insulin. Our hypothesis is that GLUT4 is sorted into different compartments or uses different protein interactions in response to stimulation with insulin, compared with hypoxia/contraction in skeletal muscle. Because of the difficulties in preparing muscle membrane fractions and transiently transfecting primary mammalian muscle fibers, we have prepared two lines of transgenic mice specifically expressing HA- and EGF-tagged GLUT4 in muscle. In this study, in intact skeletal muscles of these animals, we have detected and characterized HA-GLUT4-GFP distribution and compartmentalization. Western blot and confocal microscopy clearly show that these mice highly express HA-GLUT4-GFP in skeletal muscle, cardiomyocytes, and isolated FDB muscle fibers. We also observe the expected HA-GLUT4-GFP subcellular distributions in the basal, and HA-GLUT4-GFP is localized to the same degree on the t-tubules and sarcotubular of isolated FDB muscles after insulin or hypoxia/contraction stimulation. These effects are additive, which suggests two different GLUT4 trafficking mechanisms. These data directly demonstrate the versatility of using HA-GLUT4-GFP mice for studying the detailed trafficking pathways of GLUT4 in muscle cells in normal and insulin-resistant metabolic states, both in vitro and in vivo.

410 Live Cell Tracking of GLUT4 Molecule in 3T3.L1 Adipocyte Using Q-dot Nano-crystal

H. Fujita, T. Watanabe, T. Tadachi, H. Higuchi, M. Kanazaki; Tohoku University Biomedical Engineering Organization (TUBERO), Sendai, Miyagi, Japan

Insulin stimulates glucose transport into adipocytes and muscle cells by inducing the translocation of the insulin responsive glucose transporter GLUT4 from intracellular storage compartments to the plasma membrane. GLUT4 translocation is a complicated process involving budding and fission of GLUT4-containing vesicles from the storage compartments, their trafficking to and from the plasma membrane. Here, we have established a new method to visualize the movement of GLUT4 using Q-dot nano-crystal. 3T3.L1 adipocyte expressing exofacial-myc-GLUT4-eCFP was labeled with Q-dot-conjugated Myc antibody in the presence of insulin. Q-dot-labeled GLUT4 was then endocytosed back to the storage compartments by washing out of insulin. Observation was performed under real-time confocal microscope and TIRF microscope equipped with high sensitivity EMCCD camera so that movement of Q-dot-labeled GLUT4 molecules in response to the second challenging of insulin stimulation can be tracked. Real-time imaging of single GLUT4 molecule movement under confocal microscope revealed that GLUT4 molecules were transiently immobile at the basal state, and insulin stimulation increased the mobility of these molecules. Diffusion coefficient of GLUT4 molecules was 3.3 fold higher after insulin stimulation than the basal state, suggesting that insulin stimulates unearthing of GLUT4 molecules from the storage compartments. Observation by TIRF microscope revealed that insulin increased both GLUT4 approached the plasma membrane by 3.8 fold and duration of the molecules stayed at the plasma membrane by 2.1 fold. Together, these data reveal that insulin regulates at least two distinct steps of the translocation process; 1) releasing GLUT4 molecules to the transport vesicles from the storage compartments, allowing more molecules to be accessible to the plasma membrane, and 2) priming the tethering-fusion step at the plasma membrane.

411 ATPase-sensitive and that the entry of [H+] may play a role in regulating the movement of water through AQP-6 channel at the synaptic vesicle membrane. Supported by NIH grants (BPJ).

412 Myosin-V regulates Spatial Control of the Secretory Pathway and Cellular Morphogenesis in Developing Drosophila Photoreceptors

B. Li, A. K. Satoh, D. F. Ready, Biology, Purdue University, West Lafayette, IN

Rhodopsin is highly packed in a photosensitive organelle, the rhabdome, a specialization of the photoreceptor apical plasma membrane. Rab11 regulates transport of newly synthesized Rhodopsin (Rh1) from the trans-Golgi network to rhabdome (Satoh et al, 2005). Here, we investigate the role of Rab11 interacting protein, dRip11 and myosin V in the polarized Rh1 transport. We have studied loss of function mutations of both proteins and find both are required for normal vectorial membrane traffic in developing photoreceptors. Loss of either protein results in the accumulation of cytoplasmic rhodopsin, a failure of normal exocytic activity that parallels Rab11 loss. Loss of dRip11 d elocalizes Rab11 and MyoV in developing photoreceptors. Moreover, loss of myosin-V activity results in mistargeted membrane traffic that generates supernumerary, ectopic rhabdomes. These observations suggest Drosophila photoreceptors harness an evolutionarily conserved Rab11/dRip11/myosin-V dependent pathway of polarized membrane traffic for cellular morphogenesis. Supported by NEI grant #10306.

413 Glucagon-like Peptide 1 Induces Insulin Secretion via NAADP and CADPR in Pancreatic β Cells

U. Kim, B. Kim, M. Im; Biochemistry, Chonbuk National University Medical School, Jeonju, Republic of Korea

The glucagon-like peptide 1 (GLP-1) stimulates cAMP production, increases an intracellular Ca2+ level, and enhances insulin secretion in pancreatic β cell. The action of cAMP is mediated not only by cAMP-dependent protein kinase (PKA), but also by cAMP-regulated guanine nucleotide exchange factors (EPAC). To determine the mechanisms by which PKA and EPAC act on insulin secretion, we investigated PKA or EPac-mediated Ca2+ signaling in mouse pancreatic β cells. Here, we showed that PKA and EPac-selective cAMP analog (6-benzoyl-cAMP and 8-PCPT-2'-O- Me-cAMP, respectively) as well as forskolin induced rapid and long-lasting Ca2+ increases in the presence of high glucose concentration. These agonists stimulated a production of nicotinic acid adenine dinucleotide phosphate (NAADP) that initiates initial Ca2+ release from lysosome related Ca2+ pool. A cyclic ADP-ribose (cADPR) antagonistic analog (8-Br-cADPR) blocked the GLP-1 induced early phase of Ca2+ increase and the EPac-activated long-lasting late phase of Ca2+ increase. Furthermore, Ca2+ increases to those by EPac were observed by direct NAADP treatment on the β cells. Bafilomycin A1, an inhibitor of NAADP-sensitive Ca2+ store, blocked not only the initial Ca2+ increase but also long-lasting Ca2+ increase by PKA, EPac, NAADP and GLP-1, suggesting that the NAADP-initiated Ca2+ increase is essential role for triggering the late Ca2+ signaling. The long lasting Ca2+ signaling was blocked by 8-Br-cADPR or high concentration of ryanodine, suggesting that NAADP-initiated Ca2+ increase stimulates production of CADPR, which evokes the long-lasting Ca2+ increase through Ca2+ influx. Consistent with these findings, high concentration of NAADP, desensitizes NAADP channel, blocked the Ca2+ signals induced by GLP-1, PKA and EPac. These data reveal that PKA and EPac activated by GLP-1 induce sequential generation of two Ca2+ signaling second messengers, NAADP and cADPR and that Ca2+ signaling induced by these second messengers plays a pivotal role in insulin secretion in pancreatic β cell.

414 Determining the Role of Adaptor Protein 3 in the Secretory Pathway of Cytotoxic T Lymphocytes

M. Wenham, G. M. Griffiths; Sir William Dunn School of Pathology, University of Oxford, Oxford, United Kingdom

Cytotoxic T lymphocytes (CTL) execute their effector function through the tightly controlled secretion of lyosomal lytic granules toward a target cell. Upon target recognition by the T cell receptor (TcR), granules at the periphery of the CTL attach to the microtubule network and move in a plus-end direction toward the immunological synapse, where they fuse with the plasma membrane and secrete their cytotoxic contents. Adaptor Protein 3 (AP-3) is a multimeric protein complex which sorts transmembrane proteins to lysosomes and lysosome-related organelles.
with different tendencies to undergo exocytosis: azurophilic, specific and gelatinase granules and secretory vesicles. Here, we start to characterize the secretory machinery that regulates the exocytosis of these organelles. We previously showed by immunofluorescence analysis that the small GTPase Rab27a and its effector JFC1 localize in a minor subpopulation of myeloperoxidase (MPO)-containing granules (azurophilic) and that interference with the Rab27a/JFC1 secretory machinery inhibits MPO secretion in granulocytes. Here, we show that Rab27a-deficient mice have impaired secretion of MPO in vivo after intraperitoneal injection of lipo polysaccharide (LPS). Significant differences were observed at 4 and 8 hours after injection; no differences were observed for the basal level of MPO. Importantly, no significant differences were observed in the number of circulating neutrophils in the peripheral blood of control and Rab27a-/- mice suggesting that Rab27a is an essential component of the secretory machinery of azurophilic granules in granulocytes. Contrarily, mobilization of CD11b from intracellular granules (gelatinase granules and secretory vesicles) in response to the chemotactic peptide 5MIP2 was not affected in Rab27a-deficient neutrophils when evaluated by flow cytometry, despite the observation that Rab27a localizes at gelatinase granules in wild type cells. This suggested that a protein with redundant function may regulate the secretion of these granules in the absence of Rab27a. We found that Rab27a-deficient mice have a dramatic upregulation of Rab27b in their granulocytes. Moreover, although Rab27a and Rab27b co-fractionate in the organelle, only Rab27b is detected in the α and β fractions after cellular fractionation of human neutrophils. Our results suggest that Rab27b may be involved in the mobilization of low density secretory organelles but cannot overcome the defect in MPO secretion observed in Rab27a deficient mice.

415 Ribosome-Translocon Interactions Are Controlled by the Nascent Chain during Co-translational Protein Integration into the ER Membrane

C. G. Jongsma, P. J. Lin, A. E. Johnson; Texas A&M University, College Station, TX

Ribosome-translocon junction prevents ion flow through the translocon pore. Prior to opening this junction to allow nascent chain movement into the cytosol, BiP effects closure at the lumenal end of the pore. However, dynamics of recruitment of the Rab-family GTPase Sec4 is affected by loss of Cbk1 function. We also found that Cbk1 is itself controlled by phosphorylation of two conserved sites. However, the kinase's role in polarized growth, in contrast, may require only a small amount of C-terminal site phosphorylation. The yeast Ndr/LATS kinase Cbk1 promotes Rab GTPase function and is controlled by RAM network dependent phosphorylation. We will discuss, for the first time, the model about the regulatory mechanism of PLD in insulin secretion through the interaction with granuphilin-a.

416 Phosphorylation of NHERF1/EBP50 in Parietal Cells
L. Zhu, A. Abbad, T. Wu, S. Patel, S. Karvar, C. Y. Sun, J. G. Forc, M. & Cell Biology, University of California, Berkeley, CA, Department of Medicine, Emory University School of Medicine, Atlanta, GA

Sodium-proton exchanger regulatory factor 1 (NHERF1), also known as ER binding phosphoprotein 50 (EBP50), is known to link ERMs to the plasma membrane and to provide a platform for many proteins to fulfill their cellular functions. In searching for phosphoproteins in resting and stimulated parietal cells using a proteomic strategy, a phosphoprotein was assigned to NHERF1 in stimulated gastric gland sample (phosphorylated at S287), but not detected with the resting sample. 2D-Western blot analysis of NHERF1 gave multiple spots of varies pl, with more acidic spots in the stimulated sample. These results indicate that NHERF1 may have an important role in the parietal cell and that its activity may be regulated by phosphorylation. A co-immunoprecipitation experiment indicates that NHERF1 interacts with ezrin in parietal cells. Current work is designed to reveal the membrane-binding protein of NHERF1, and the effect of phosphorylation of NHERF1 on its localization and function. This may benefit the understanding on how the complex surface structure of apical membrane is remodelled and maintained after parietal cell stimulation.

417 Characterization of Interaction between phospholipase D and Granuphilin-a
H. Kwon; Life Science, POSTECH, Seoul, Republic of Korea

Mammalian phospholipase D (PLD) has been strongly implicated in the regulation of Golgi trafficking as well as endocytosis and exocytosis. Recent report suggested that PLD are also related in insulin secretion event and increase the insulin secretion from pancreatic beta-cells. However, the regulatory mechanism of PLD in this process has not been studied. In this study, we found that the PLD interacts with granuphilin-a, which is specifically localized on insulin granules and is involved in their exocytosis. We investigated the interaction between PLD and granuphilin-a in cells. The direct association between PLD and granuphilin-a was confirmed by in vitro binding analysis using the purified proteins, and their binding sites were identified as the N-terminal of PLD. Furthermore, granuphilin-a regulates the PLD activity in cells and this result suggests that interaction between granuphilin-a and PLD can be involved in exocytotic process in cells. We will discuss, for the first time, the model about the regulatory mechanism of PLD in insulin secretion through the interaction with granuphilin-a.

418 The Yeast Ndr/LATS Kinase Cbk1 Promotes Rab GTPase Function and Is Controlled by RAM Network Dependent Phosphorylation
J. Jansen, M. Barry, E. L. Weiss; Biochemistry, Molecular Biology, and Cell Biology, Northwestern University, Evanston, IL

The budding yeast RAM network is a highly conserved but poorly understood signaling pathway required for maintenance of polarized growth. It also controls Ace2, an asymmetrically segregated transcription factor that drives gene expression after cytokinesis. The network’s role in cell morphology control is independent of its transcriptional function. It thus far comprises six proteins, including the Ndr/LATS family kinase Cbk1. We found establishment of polarity (localization of septin, F-actin patches and cables, and Cdc24) occurs in cells lacking Cbk1. However, dynamics of recruitment of the Rab-family GTPase Sec4 is affected by loss of Cbk1 function. We also found that Cbk1 is itself controlled by phosphorylation of two conserved sites. One is a T-loop site of intramolecular autophosphorylation; the other is performed at a C-terminal hydrophobic motif by another kinase. The autophosphorylation site is critical for the kinase’s in vitro activity, but only partially required for in vivo function. In contrast, C-terminal site phosphorylation is essential for in vivo function but not necessary for in vitro kinase activity. Cbk1 that cannot be phosphorylated at the C-terminal site is phosphorylated at other sites in vivo, suggesting this modification promotes dephosphorylation of other sites. Using phosphospecific antibodies, we determined that the autophosphorylation site is modified throughout the cell cycle, while the C-terminal site is modified during budding and during the M/G1 transition. C-terminal site phosphorylation requires all other RAM network components. Surprisingly, this modification is greatly reduced in cells lacking Ace2. We propose that Ace2 interaction increases or protects the M/G1 phosphorylation of Cbk1’s C-terminal regulatory site. The kinase’s role in polarized growth, in contrast, may require only a small amount of C-terminally modified site phosphorylation. We further propose that Cbk1 and the RAM network promote Sec4 polarization, and that attenuation of Sec4 function ultimately abrogates polarity in cells lacking RAM network activity.

419 Ribosome-Translocon Interactions Are Controlled by the Nascent Chain during Co-translational Protein Integration into the ER Membrane
C. G. Jongsma, P. J. Lin, A. E. Johnson; Texas A&M University, College Station, TX

Most membrane proteins in eukaryotic cells are co-translationally integrated into the ER membrane at translocons. The nascent polypeptide is threaded into the aqueous translocon pore where each successive transmembrane segment (TMS) is moved laterally through the translocon into the bilayer. The hydrophobic polypeptide segments on each side of the TMS are directed, alternately, into either the aqueous cytosol or the aqueous ER lumen. For a single-spanning signal-cleaved membrane protein, nascent chain movement into the lumen occurs while an ion-tight ribosome-translocon junction prevents ion flow through the translocon pore. Prior to opening this junction to allow nascent chain movement into the cytosol, BiP effects closure at the luminal end of the pore to maintain the membrane permeability barrier. To determine whether the ribosome and BiP alternately mediate pore closure during the integration of a multi-spanning membrane protein, integration intermediates with nascent chains of different lengths were prepared with a fluorescent probe positioned in the nascent chain furthest inside the ribosomal tunnel. Nascent chain exposure to the cytosol or lumen was then detected by the collisional quenching of the probe by sidone ions on either the cytosolic or luminal side of the membrane. While the first TMS through the tunnel caused the ribosome-translocon junction to open, the second TMS elicited both the closure of this junction and the opening of the luminal end of the pore. Closure of the ribosome-translocon junction occurred only after the second TMS was 4-6 residues from the peptidytransferase center, irrespective of TMS location in the nascent chain. These changes exactly coincided with ribosome-induced TMS folding detected by FRET. Thus, nascent chain folding and binding far inside the tunnel control ribosome-translocon interactions at the ER membrane. (Supported by NIH grant GM26494 and the Welch Foundation.)
**Dissection of the Pathway for Tail-anchored Membrane Protein Insertion**

S. Stefanovic, R. S. Hegde; CBMB/NICHD, National Institutes of Health, Bethesda, MD

A large group of proteins in the cell are anchored to intracellular membranes by a single transmembrane domain at the C terminus. These tail-anchored (TA) proteins have crucial roles in the regulation of many important cellular processes such as apoptosis (members of Bcl2 family), vesicular trafficking (SNAREs), and protein translocation into various organelles. Clearly, the proper function of each of these proteins is critically dependent on their correct subcellular localization. Despite this wide functional importance, the mechanisms by which TA proteins are recognized, segregated to their target membrane, and inserted into the lipid bilayer are not known. To address this problem, we have reconstituted in vitro the membrane insertion of a model TA protein of the endoplasmic reticulum (ER) called Sec61b. Using this system, we could demonstrate by sucrose gradient analysis that Sec61b exists in a multi-protein complex in the cytosol. This cytosolic complex was competent for subsequent insertion into the TA protein insertion pathway. Crosslinking identified the interacting partners in the cytosolic complex as ~45 kD and 18 kD proteins. Using an anti-Sec61b immunoaffinity column, we purified this complex and identified the ~45 kD and ~18 kD proteins by mass spectrometry. We have raised antibodies against p54 and verified its presence in the insertion complex. Addition of the purified cytosolic insertion complex to ER membrane vesicles enabled efficient membrane insertion of Sec61b in a reaction that was shown to be dependent on both energy and at least one yet unidentified integral membrane protein of the ER. The development of this robust and readily manipulable reconstituted system has outlined the basic steps and components in the TA protein insertion pathway. Our ongoing studies aim at understanding the mechanism by which p54 and p18 facilitate TA protein insertion.

**Real-time Fluorescence Detection of Retro-translocation in a Well-defined Homogenous Mammalian System**

J. Wahlman,1 G. N. DeMartino,2 W. R. Skach,3 J. L. Brodsky,4 A. E. Johnson5; 1Texas A&M University, College Station, TX, 2University of Texas Southwestern Medical Center, Dallas, TX, 3Oregon Health & Science University, Portland, OR, 4University of Pittsburgh, Pittsburgh, PA, and 5Texas A&M University Health Science, College Station, TX

Secretory proteins that are unable to assemble into native proteins in the endoplasmic reticulum (ER) are transported back into the cytosol for degradation. To examine the roles of different components in ER-associated degradation (ERAD), well-defined and homogeneous mammalian ER microsomes were prepared biochemically by encapsulating a fluorescent labeled ERAD substrate with specific luminal components. After mixing ATP, specific cytosolic proteins, and specific fluorescence quenching agents with microsomes, substrate retro-translocation was initialized. The rate of substrate efflux from microsomes was monitored spectrophotometrically and continuously in real time by the reduction in fluorescence intensity as the fluorescent substrates passed through the ER membrane and were exposed to the quenching agents. Retro-translocation kinetics were not significantly altered by replacing all luminal proteins with only protein disulfide isomerase, or all cytosolic proteins with only the PDI-like proteins. Retro-translocation was blocked by affinity-tipped antibodies against Derlin1, but not by affinity-purified antibodies against Sec61a or by membrane-bound ribosomes. Since the substrate also photocrosslinked Derlin1, but not Sec61a or TRAM, retro-translocation of this ERAD substrate apparently involves Derlin1, but not the translocon. (Supported by NIH grant GM62494 and the Welch Foundation.)

**Visualization of the Endoplasmic Reticulum-associated Degradation of CD3delta**

H. Lorenz, J. Lippincott-Schwartz; NICHD, National Institutes of Health, Bethesda, MD

Many misfolded or unassembled proteins of the secretory pathway are efficiently retro-translocated from the endoplasmic reticulum (ER) into the cytosol and degraded by the proteasome. This process is called ER-associated degradation (ERAD). Here, we present a live-cell imaging study of ERAD of the type I glycoprotein CD3delta. The T cell receptor (TCR) subunit CD3delta has already been described to be rapidly degraded in the absence of other TCR subunits. CD3delta's complete degradation pathway from its initial localization within ER membranes to its dislocation into the cytosol and the final degradation by proteasomes was captured using novel live-cell imaging strategies. Visualization of CD3delta tagged to fluorescent protein folding reporters made it possible to precisely determine CD3delta's subcellular localization and folding state during its demise. Upon proteasomal inhibition, fully folded CD3delta accumulated primarily in the ER and not in the cytosol, indicating both its dislocation and degradation are coupled events. However, the simultaneous inhibition of protein synthesis and the proteasomal activity led to the redistribution of CD3delta from the ER into the cytosol. During this retrotranslocation event, CD3delta did not need to be completely unfolded, and the cytosolic CD3delta molecules were only partially, but not completely, unfolded. The cytosolic CD3delta also did not form aggresomes and was rapidly degraded upon re-establishment of proteasomal activity. This is, to our knowledge, the first dynamic visualization of the ERAD process in live cells.

**PDI-like Proteins Play Opposing Roles during Retro-translocation**

M. L. Forster,1 K. Sivick,2 P. Young-nam,3 P. Arvan,3 W. I. Lencer,4 B. Tsai1; 1Department of Cell and Developmental Biology, University of Michigan, Ann Arbor, MI, 2Department of Microbiology and Immunology, University of Michigan, Ann Arbor, MI, 3Division of Metabolism, Endocrinology, and Diabetes, University of Michigan, Ann Arbor, MI, 4GI Cell Biology, Children's Hospital, Harvard Medical School, Boston, MA

Misfolded proteins in the endoplasmic reticulum (ER) (RE) are retained in the organelle or retro-translocated to the cytosol for degradation. RE chaperones that guide these opposing traffic to the Golgi prior to degradation. Our study in Saccharomyces cerevisiae shows that a single context-specific N-linked glycan is a required determinant of the signal in both cases, but in a different position. We hypothesized from these data that substrates utilize a bipartite signal of the ER. The development of this robust and readily manipulable reconstituted system has outlined the basic steps and components in the TA protein insertion pathway. Our ongoing studies aim at understanding the mechanism by which p54 and p18 facilitate TA protein insertion.

**Substrate Recognition in ER Quality Control**

K. Kanehara, W. Xie, A. Sayeed, D. T. W. Ng; Temasek Life Sciences Laboratory, Singapore

Misfolded proteins in the endoplasmic reticulum (ER) are eliminated by ER-associated degradation (ERAD), which is conserved in all eukaryotes. Because of the dynamic nature of the organelle, cells must segregate actively folding and misfolding proteins, which are retained, from folded proteins, which are transported. Furthermore, misfolded proteins must be distinguished from folding proteins so they can be targeted for degradation. Despite the advances in understanding the machinery of ERAD, how cells differentiate between these different forms is unclear. To address the question, we analyzed misfolded versions of cytochrome oxidase Y (CPY*) and proteinase A (PrA*) in the yeast Saccharomyces cerevisiae. Our previous study showed that a single context-specific N-linked glycan is a required determinant of the signal in both cases, but in a different position. We hypothesized from these data that substrates utilize a bipartite signal comprised of carbohydrate and peptide elements. To test our hypothesis, systematic deletion analysis is performed on CPY* with the aim of disrupting the peptide determinant. Deletion spanning most of the protein had no significant effects on degradation suggesting the possibility of redundant determinants. We did, however, find a small protein domain, when combined with a specific carbohydrate, which is sufficient for ERAD. We hypothesize that the lectin Yos9p, a critical factor in sorting misfolded proteins, recognizes a signal comprised of the specific carbohydrate and the unfolded domain. In the folded protein, the determinant is buried into the structure of the protein allowing it evade surveillance by Yos9p.
Uncoupling of a Regulatory Function of VCP in ER Stress From Its Role in ER-associated Degradation: Evidence from RNAi of the VCP-Ufd1-Npl4 Complex
C. Wojcik, M. Rowicka, A. Kudlicki, D. Nowis, G. Adams, M. Kujawa, G. N. DeMantino; 1Anatomy and Cell Biology, Indiana University School of Medicine—Evansville, Evansville, IN; 2Biochemistry, UT Southwestern Medical Center, Dallas, TX; 3Physiology, UT Southwestern Medical Center, Dallas, TX; 4Histology and Embryology, Medical University of Warsaw, Warsaw, Poland
VCP (p97, cdc48) is a hexameric AAA ATPase involved in multiple cellular functions. VCP in a complex with the Ufd1-Npl4 dimer participates in the degradation of proteins by the ubiquitin-proteasome system (UPS), including proteins which are dislocated from the endoplasmic reticulum (ER) in a process known as ERAD (ER-associated degradation). The objective of this work was to scrutinize the role of VCP-Ufd1-Npl4 in the structure and function of mammalian ER using as the main method RNA interference (RNAi) of the components of this complex in cell lines expressing model substrates of the UPS. A new stringent method of microarray analysis demonstrated that only 4 transcripts were non-specifically affected by RNAi of VCP, while ~30 transcripts were affected in response to reduced VCP levels in a sequence-independent manner. Those transcripts encoded proteins involved in ER stress, apoptosis, and amino acid starvation. RNAi of VCP promoted the unfolded protein response, without eliciting a cytotoxic stress response. RNAi of VCP promoted accumulation of polyubiquitinated proteins in multiple compartments, and inhibited the degradation of R-GFP and Ub-G76V-GFP, two cytoplasmic reporter proteins degraded by the UPS. In surprising contrast, RNAi of VCP had no detectable effect on the ERAD substrates, α-syntrophin and iC3D. Moreover, RNAi of Ufd1 and Npl4 accelerated degradation of some ERAD substrates. These results indicate that VCP is required for maintenance of normal ER structure and function, mediates the degradation of some proteins via the UPS, but is dispensable for the UPS-dependent degradation of certain ERAD substrates. The VCP-Ufd1-Npl4 complex may perform a regulatory role in ERAD rather than directly participate in substrate degradation.

Rescue of Trafficking and Folding Defects Associated with an Aberrant Yeast ABC Transporter
E. Miller, J. Barry, M. Dorrington, R. Louie, S. Pagant, L. Kung; Biological Sciences, Columbia University, New York, NY
Eukaryotic cells dedicate significant resources to the deployment of proteins to the membrane compartments that comprise the secretory pathway. Cells impose a strict quality control checkpoint to ensure that only fully folded and properly assembled proteins are allowed to leave the endoplasmic reticulum (ER), a growing number of human diseases are caused by defects in proteins that render them incapable of passing this ER quality control. We study the close relationship between protein folding and packaging into ER-derived transport vesicles using a model membrane protein, Yor1p, which functions as a plasma membrane drug pump in Saccharomyces cerevisiae. Deletion of a conserved Phe residue (analogous to the predominant mutation associated with human cystic fibrosis) causes Yor1p to misfold, precluding its capture into ER-derived transport vesicles. We have undertaken a genome-wide screen to identify cellular components involved in the quality control of forward protein transport through the secretory pathway. Some of these quality control mutants show an improved ability to package the misfolded Yor1p deltaF into COP1 vesicles. In vitro folding assays suggest that these mutants fall into two classes: those in which the mutant Yor1p deltaF adopts a native conformation, and those in which the aberrant protein is packaged despite remaining in an unfolded state. Rescue of the folding defect associated with Yor1p deltaF in one of these mutants is linked to the ability to mount the unfolded protein response (UPR), deletion of the UPR-specific transcription factor, Hac1p, in this strain background abrogates the rescue of Yor1p deltaF folding and ER export. Our results suggest that activation of the UPR can improve the ability of cells to handle misfolded proteins and suggest novel therapeutic targets for cystic fibrosis drug development.

The Hinge Stem of XBP1 mRNA Is a Novel Structure Required for Unconventional Splicing in the Unfolded Protein Response
K. Yanagitani, Y. Imagawa, A. Hosoda, T. Iwawaki, K. Kohno; 1Bioscience, Nara Institute of Science and Technology, Nara, Japan, 2Iwawaki Initiative Research Unit, RIKEN, Saitama, Japan
Accumulation of unfolded and misfolded proteins in the endoplasmic reticulum (ER) activates an intracellular signaling pathway termed the unfolded protein response (UPR). In mammalian cells, the UPR is signaled in part through activation of ER localized type I membrane-spanning protein IRE1α harboring a kinase/endoribonuclease activity. Activated IRE1α cleaves XBP1 mRNA at two sites to initiate an unconventional splicing reaction, which is a very unique reaction because it doesn’t depend on spliceosome and occurs in cytoplasm. The 5’ and 3’ fragments are subsequently joined by an RNA ligase activity, thereby removing a 26-base intron. This reaction creates a translational frameshift to produce a functional XBP1α transcription factor. This unconventional splicing is very unique and its molecular mechanism has been largely unknown. To study this splicing mechanism, we focused on the secondary structure of XBP1 mRNA. XBP1 mRNA has a characteristic stem-loop structure at two exon-intron junctions, which is cleaved by activated IRE1α. By comparing the secondary structure of XBP1 mRNA in various species, we found the novel conserved structure to bind up two stem-loops, termed a hinge-stem. When the hinge stem was disrupted by base substitutions, mRNA attenuation in vivo. On the contrary, when the hinge stem structure was reconstructed by additional base substitutions, splicing efficiency was recovered. Thus the structure, but not the sequence was critical for the splicing of XBP1α. Our results suggest that activation of the UPR can improve the ability of cells to handle misfolded proteins and suggest novel therapeutic targets for cystic fibrosis drug development.

Analysis of XBP1 mRNA Splicing Reaction in Unfolded Protein Response In Vitro
Y. Imagawa, M. Inoue, K. Kohno; Graduate School of Biological Sciences, Nara Institute of Science and Technology (NAIST), Ikoma, Nara, Japan
When the cells are exposed to various stresses such as glucose deficiency, viral infection, and calcium disturbance in the ER, unfolded proteins accumulate in the endoplasmic reticulum (ER). This is called ER stress that causes fatal damage for living cells. Therefore, cells activate a pathway called unfolded protein response (UPR) to prevent the accumulation of misfolded proteins in the ER. In mammalian cells, one of the UPR is signaled through dimerization of ER-located type I transmembrane protein IRE1α to activate its protein kinase and endoribonuclease activities. Activated IRE1α cleaves XBP1 mRNA at two sites to initiate an unconventional splicing reaction, which is a very unique reaction because it doesn’t depend on spliceosome and occurs in cytoplasm. The 5’ and 3’ fragments are subsequently joined by an RNA ligase activity, thereby removing a 26-base intron. This splicing reaction creates a translational frameshift to produce a functional XBP1α transcription factor. However, the RNA ligase and physiological processes required for unconventional splicing of XBP1 mRNA have not been well characterized. To study precisely these processes, we tried to reconstruct XBP1 mRNA splicing reaction in vitro, and finally we found that HeLa cell extract contains an RNA ligase activity to join two exon-fragments of XBP1 mRNA cleaved by IRE1α recombinant protein in vitro. Using this system, we have searched essential factors for XBP1 mRNA splicing. As a result, GTP is essential for the ligation of XBP1 mRNA splicing, but ATP is not. In yeast, it is reported that activated eIF4e cleaves both 5’ and 3’-exon-intron junctions of HAC1 mRNA, then the cleaved HAC1 mRNA fragments are joined by a RNA ligase Rlp1p, and the ligation reaction requires both GTP and ATP. These evidences suggest that the character of RNA ligase in XBP1 mRNA splicing reaction is at least different from that of HAC1 mRNA.
Serine 23 and 36 phosphorylation of Caveolin-2 Is Reciprocally Regulated by Caveolin-1 induced Sequestration of Caveolin-2 to Plasma Membrane Caveolae

G. Sowa,1 L. Xu,2 W. C. Sessa3; 1Medical Pharmacology and Physiology, University of Missouri, Columbia, MO, 2Pharmacology, Yale University, New Haven, CT

Previously, we have shown that caveolin-2 (Cav-2) is phosphorylated under basal conditions at N-terminal serine residues 23 and 36 and that this phosphorylation of Cav-2 plays a positive role in caveolae assembly in a prostate cancer cell line LNCaP cells. In the present study, we show in reconstituted systems LNCaP and fisher rat thyroid (FRT) cells as well as in endogenously expressing caveolin endothelial cells that serine phosphorylation of Cav-2 is a regulated process. More specifically, using adenosinergic expression and phospho-specific antibodies to Cav-2, we show that co-expression of Cav-1 increases phosphorylation of Cav-2 at serine residue 23, and decreases phosphorylation of serine 36. Insolubility in Triton X-100 and sucrose flotation gradients separating detergent resistant membranes (DRMs) from the remaining proteins have determined that serine 23 phosphorylation of Cav-2 preferably occurs in DRMs consisting of lipid rafts and caveolae. On the other hand, serine 36 phosphorylation takes place in non-DRMs. Furthermore, immunofluorescence labeling studies determined that serine 23-phosphorylated Cav-2 mostly localizes to plasma membrane in adenosinergic expressing human Cav-2 and -1 FRT cells and in endothelial cells, while serine 36 phosphorylated Cav-2 primarily resides in intracellular compartments. In addition, our data show that oligomerization with Cav-1 protects both phospho-serines from dephosphorylation by calf intestinal phosphatase (CIP), suggesting that Cav-2 engaged in high molecular heterologerm with Cav-1 in caveolae may be relatively resistant to dephosphorylation by cellular phosphatases. In summary, serine phosphorylation of Cav-2 is a regulated process largely dependent on Cav-1-driven translocation of Cav-2 from detergent soluble intracellular compartments to detergent insoluble plasma membrane associated lipid rafts and caveolae.

AHNAK Is a Potential Component of Insulin Signaling Located Within Lipid Raft Microdomains in 3T3-L1 Adipocytes

D. Caces, J. E. Pessin; Pharmacological Sciences, Stony Brook University, Stony Brook, NY

The selective partitioning of signaling molecules within lipid raft microdomains represents one mechanism by which cell signaling specificity and fidelity is maintained. Insulin-regulated exocytosis of the facilitative glucose transporter GLUT4 in adipocytes is one system that benefits from this paradigm. To identify key lipid raft molecules that may be involved in the insulin-signaling cascade, we did a proteomic screen of lipid raft fractions obtained from fully differentiated 3T3-L1 adipocytes. Cells grown on collagen-coated plates were passively treated with 1% Triton X-100 for 25 minutes at room temperature. The detergent-insoluble fraction was collected, separated by one-dimensional SDS-PAGE and visualized by silver staining. Protein bands corresponding to bands on an immunoblot that was ran in parallel using an anti-phosphorylated-Akt antibody were harvested and sent for LC/MS/MS. The screen identified 21 novel proteins with the Akt-phosphorylation motif RXRXXSST and 1 known Akt substrate, AHNAK. AHNAK, or desmyosin, is a 700 kDa protein reported to be involved in the regulation of cell membrane architecture in MDCK cells. In HeLa cells, phosphorylation by Akt is thought to regulate the protein’s subcellular localization. Whole cell immunofluorescence in adipocytes revealed that AHNAK is primarily associated with the plasma membrane. Similar studies done on plasma membrane lawns showed significant co-localization of the protein with the lipid raft marker caveolin, with both proteins forming elegant rosette structures. Treatment with MijCD disrupted both proteins’ distinct organization and resulted in a more cytoplasmic localization for AHNAK. However, treatment with Lantrunculin B to disrupt actin, which has been reported to interact with AHNAK, did not affect AHNAK localization to the caveolin rosette structures. In conclusion, we report that AHNAK in adipocytes is a lipid raft associated Akt substrate that may potentially play a role in insulin-mediated GLUT4 translocation and/or transcriptional activation.
Calcimycin-induced Upregulation of Caveolins and Formation of Caveolae in the Rat Lens Epithelium

W. Peng, 1 S. Biswas, 1 W. Lo, 1 2 3 Anatomie & Neurobiologie, Morehouse School of Medicine, Atlanta, GA, 4 Ophthalmo, Emory University, Atlanta, GA

Caveolae contain a variety of components, which are co-expressed and assembled into heterooligomeric complexes. Our previous study showed that caveolae were prominent only in the lens epithelia of rabbit and guinea pig. This study was undertaken to determine whether formation of caveolae could be induced by calcimycin-induced apoptosis in the rat lens epithelium in organ culture. The lens epithelial apoptosis was induced by the treatment of calcium ionophore calcimycin (0.5-3.0 μM) in M-199 for 1 h and followed by 3-72 hours of culture in M-199 alone. A cleared caspase-3 antibody was used to detect the early apoptosis. RT-PCR and immunofluorescence were used to determine upregulation of caveolin mRNA and protein, and the formation of caveolae was examined by TEM. RT-PCR analysis showed that expression of both Cav-1 and Cav-2 mRNAs was significantly increased at 3 h, and reached the peak (∼8-fold increase) at 6 h after calcimycin (1μM) treatment. However, the level of Cav-1 mRNA was approximately twice as high as that of Cav-2 at 3 h of culture. Both caveolin mRNAs were gradually decreased at 9 h, and returned to the controlled low level after 12-48 h of culture. Immunofluorescence studies on epithelial whole mounts revealed that both Cav-1 and Cav-2 labeling were significantly increased after 48-72 h of culture time. TEM confirmed the colleague findings that caveolae, usually in clusters, were regularly found along the lateral epithelial cell membranes in rat lenses treated with 1μM calcimycin for 1 h followed by 48 h of culture in M-199 alone. These results suggest that caveolae in the lens epithelium are dynamic structures whose appearance can be induced by stimulation of external factors such as an increase in cytoplasmic calcium by calcimycin which leads to apoptosis. Supported by NIH grant EY05314.

Dopamine D1-like Receptor Regulates Small GTPase Rab in Lipid Rafts in Human Kidney Cells

P. Yu, J. R. T. Altea, W. Han, H. Li, P. A. Jose; Pediatrics, Georgetown Medical Center, Washington, DC

Human cells contain more than 60 Rab proteins which participate in translocation vesicle formation, motility, docking and fusion within endocytic and secretory pathways. Among them, Rab4, Rab5, and Rab11 are important in regulating internalization, intracellular trafficking, and recycling of G protein-coupled receptors (GPCRs). We and others have reported that several GPCRs, including the D1 dopamine receptor (D1R), are regulated in lipid rafts. Here we report that D1R regulates Rab4, Rab5, and Rab11 in lipid rafts in HEK-293 cells heterologously expressing human D1R (HEK-D1R) and in human proximal tubule (hPT) cells endogenously expressing D1R. All three Rab tested co-fractionated with the lipid raft marker proteins, flotillin-1 and flotillin-2 in HEK-hD1R cells, and caveolin-1 in hPT cells. Fenoldopam (1M/10 min), a D1R agonist increased Rab4 protein in low density fractions (LDF) (fractions 3-5) but decreased Rab5 expressed in LDF (fraction 4). Rab11 was not affected. Treatment with methyl-b-cyclodextrin (JCD), a cholesterol-depleting reagent, decreased Rab4 and Rab11 but not Rab5, indicating that Rab4 and Rab11, but not Rab5, associated with lipid rafts (LR). JCD also decreased monomeric and dimeric D1R in LR. Confocal images showed that fenoldopam induced D1R co-localization with Rab4, Rab5, and Rab11 in a time-dependent manner. Fenoldopam also increased the amount of Rab11 associated with D1R in time-dependent manner which peaked at 1h (fenoldopam: 22.9±2.9% vs control: 9.8±1.9% area, ANOVA, P<0.05, n=4). Triple immunofluorescence staining showed D1R, Rab4, and Rab11 co-localization at 30-60min. Taken together, our data suggest that D1R differentially regulates Rabbs that are involved in D1R trafficking.

P-Akt and Caveolin-1 Differentially Regulate the Raft-dependent Endocytosis of Autocrine Motility Factor in Invasive Breast Tumor Cells

L. Kojic, 1 B. Jodhi, 1 P. Lajose, 1 M. Almilohammadi, 1 F. Ghadi, 1 F. U. Le, 1 M. Amraei, 1 M. Cox, 1 D. A. Turbin, 1 S. A. Wiseman, 1 L. R. Nabi, 1 Cellular and Physiological Sciences, University of British Columbia, Vancouver, BC, Canada, 2Pathology, University of British Columbia, Vancouver, BC, Canada, 3Pathology, University of British Columbia, Vancouver, BC, Canada, 4Surgery, University of British Columbia, Vancouver, BC, Canada

The heterogeneity of tumors necessitates the development of targeted therapies tailored to molecularly-defined populations of tumors. Receptor-mediated internalization of extracellular motility factor (AMF) via caveolin-1 regulated, raft-dependent endocytosis to the smooth endoplasmic reticulum represents a potential mechanism to target tumor cells. Importantly, AMF expression and AMF uptake are generally reduced in normal pulmonary and thymus cells and dysplastic MCF10A mammary epithelial cells relative to tumorigenic and metastatic breast cancer cells. However, AMF uptake is also limited in aggressive, caveolin-1-expressing MDA-231 cells identifying caveolin-1 as a critical regulator of the raft-dependent internalization of AMF in breast carcinoma cells. The heterogeneity of the AMF endocytic response in breast carcinoma cells was further characterized by tissue microarray analysis of invasive primary breast carcinomas. Caveolin-1 expression was identified as an independent, poor prognosticator for breast cancer. AMF expression neither impacted on survival nor correlated with caveolin-1 and Her2 expression but did correlate significantly with phospho-Akt. Consistently, phospho-Akt expression was increased in AMF internalizing MCF7 and MDA-435 breast carcinoma cells and PI3K inhibition reduced raft-dependent AMF uptake. AMFR, PI3K activation and the raft-dependent endocytosis of AMF may therefore define a cohort of invasive breast carcinomas suitable for AMFR targeted therapy. Supported by the Canadian Institutes of Health Research.

Caveolae Formation Regulates the Internalization of E-cadherin at Cell-Cell Contacts during the Onset of Tumor Cell Migration

L. Orfienko, 1 M. A. McNiven 1 Center for Basic Research in Digestive Diseases, Mayo Clinic College of Medicine, Rochester, MN, 2Department of Biochemistry and Molecular Biology and Center for Basic Research in Digestive Diseases, Mayo Clinic College of Medicine, Rochester, MN

BACKGROUND: Pancreatic tumor cells rapidly disseminate and invade making these cancers particularly aggressive. Recently, we demonstrated that EGF stimulation results in the e-Cadherin-mediated phosphorylation of caveolin 1 (Cav-1/Y14) and induces the formation of large numbers of caveolae at cell borders (JBC, 2006). We found that EGF-stimulated caveolae formation occurs concomitantly with the loss of cell-cell contacts during pancreatic tumor cell dissemination; therefore, the GOAL of this study was to determine whether regulation of Cav1 affects pancreatic ductular cell-cell integrity. First, we observed a significant relationship between the protein levels of Cav1 and E-cadherin (E-Cad) in different tumor cell lines. Interestingly, cells with low Cav1 levels had very high E-Cad levels and displayed strong cell-cell adhesion, whereas cells with high Cav1 levels expressed modest amounts of E-Cad and exhibited poor adhesion. We next tested how disruption of Cav1 function, through the expression of a mutant Cav1 Y14F protein or depletion of Cav1 through siRNA knockdown, might affect cell-cell contacts. Under these conditions we observed a marked increase in E-Cad at cell-cell contacts, which were also resistant to EGF treatment. Western blot analysis of these cells showed that proteolysis of E-Cad was reduced by over 90%, consistent with a reduction in adhesions junction internalization. However, cells expressing wild-type Cav1, when treated with EGF, disassembled cell-cell contacts and subsequently formed large, internal endosome/caveosome-like structures filled with E-Cad. Finally, immunoprecipitation of Cav1 from these cells indicated a marked increase in Cav1-E-Cad complexes, suggesting a physical interaction between these proteins. CONCLUSION: These observations suggest that Cav1 levels and regulated assembly of caveolae play an important role in maintaining the integrity of pancreatic tumor cell adhesions by affecting E-Cad internalization and degradation following EGF stimulation. This study provides new molecular insights into tumor cell dissemination and the role of Cav1/caveolae in this process.

Uptake of Angiostatin by Endothelial Cells through Caveolae-dependent Endocytosis

H. Wu, 1 C. Cho, 2 C. Huang, 2 H. Chang, 1 G. Shi 1 Department of Biochemistry and Molecular Biology, National Cheng Kung University, Tainan, Taiwan, 2Institute of Basic Medical Sciences, National Cheng Kung University, Tainan, Taiwan

Angiostatin is a 44-kDa kringle domain fragment of plasminogen. It can inhibit the proliferation and tube formation of endothelial cells. Interaction of angiostatin with several different molecules in the endothelial cells has been proposed. In this study, we demonstrated that angiostatin can be uptaken by human umbilical vein endothelial cells (HUVECs). Confuent primary culture of HUVECs was incubated with rhodamine-labeled kringle 1-5 (K1-5), one of the most potent angiostatins, and fluorescein isothiocyanate (FITC)-conjugated cholera-toxina subunit B (CTxB). The confocal microscopy images of the cell cultures showed that angiostatin and CTxB were colocalized in the vesicles in the perinuclear region. The HUVECs after being incubated with rhodamine-labeled K1-5 was immunostained with anti-caveolin-1 and anti-clathrin antibodies. The results demonstrated that K1-5 was located in the caveolin-associated vesicles but not in the clathrin-associated vesicles. The endocytosis of K1-5 was inhibited when the cells were pretreated with methyl-b-cyclodextrin that inhibits lipid raft formation. Our results implicated that K-15 binds to the cell surface receptors and is concentrated to the lipid raft domains on the cell surface; then is internalized by caveolin-dependent endocytosis.
**B-DNA Conformation ≠ Salt Bonds in A-DNA: The Watson/Crick DNA Twist Model Is Illogical**

S. R. Erlander; Erlander's Natural Products, Alhadena, CA

The B-DNA helix exists as A-DNA [Erlander, Stig R.; Erlander's Natural Products, Altadena, CA] and can be visualized as a flat ribbon wound around an empty pipe, with phosphate salt bonds holding the two strands together, and with either the syn or anti base pair structure. Incorporation of the salt bond into Manning's polyelectrolyte equations [2], equalizes experimental and theoretical values for DNA. Melting temperatures, for both cationic and anionic sequences, follow the isomolarity of the added salt, e.g., NaCl > KCl > CsCl and Cs > K > Na for both Ta and Ts and insolubility values. Using alcohols, Geiduschek and Hershkovits (1961) reversibly denatured DNA to a double stranded coil. Using the carcinogen AAA [3], CD spectra show [4] that native (syn) DNA is reversibly denatured by methanol, 8 M urea, or pH 3.1 to a double stranded coil, and converted back to either the native syn or the anti structure. These conversions must be by the proposed A-DNA structure, since it is impossible to convert this coil into the Watson/Crick twisted helix, because twisting the coil produces a helix with phosphate salt bonds on the inside and no hydrogen bonds can be formed. Also the Watson/Crick model cannot be formed from the syn base structure. Variations of DH/Tc, (proportional to the distance between charges) show zero DNA charge at 0.0011, 0.040 and 4.44 M MgCl2, which correspond, respectively, to the triple helix point (Murray and Morgan), “zero diameter” (Shaw and Wang), and reversal of charge (Manning). It is therefore concluded that the condensation occurs against the anti syn base structure. [1] Erlander, SR (1970) Starch/ Starke, 22: 352-362. [2] GS Manning, (1972) Biopolymers 11, 937.

**444 A Novel Transcription Domain within CREBH, a Membrane Anchored BZIP Factor Subject to Regulated Intramembrane Proteolysis**

C. Barreira, J. Stirling, P. O'Hare; Protein Trafficking and Gene Regulation, Marucie Curie Research Institute, Oxford, Surrey, United Kingdom

CREBH is a newly identified member of the class of transcription factors which are anchored in membranes and subject to inter-compartmental trafficking and Regulated Intramembrane Proteolysis (RIP). Similar to the other members of this family (ATF-6, CREBF4, OAISIS, LUMAN), CREBH is normally retained within the endoplasmic reticulum and subject to stress induced transport and subsequent cleavage by Golgi resident proteases SIP and S2P to liberate an N-terminal transcriptionally active product. Recent data indicate a convergence between the unfolded protein response and inflammatory signals, and that CREBH selectively regulates aspects of the acute-phase response through ER stress. We identify a new domain (the DWA/n domain) of about 30 residues immediately flanking the BZIP DNA binding domain, specifically conserved in CREBH, CREB4, Luman and OAISIS, but lacking in ATF-6 and other BZIP transcription factors. We constructed deletion mutants of the DWA/n domain within the transcriptionally active N-terminal cleavage products of CREB4 and CREBH and analysed the ability to activate transcription of a promoter containing consensus ATF-6 binding sites. C-termis (or CREBH) lacking the DWA/n domain, while expressed in the nucleus, were virtually inactive compared to the active cleavage product. We are currently examining the role of this novel domain in DNA binding and co-factor specific interactions on potential physiological target genes including the acute phase gene C-Reactive protein.

**445 The Disc Large Tumour Suppressor Protein Connects Cell Polarity to Transcriptional Control**

P. Massimi, L. Banks; ICGEB, Trieste, Italy

The Disc Large (Dlg) tumour suppressor protein is targeted for degradation by the mucosal high risk HPV E6 proteins and shows greatly reduced levels of expression in cervical lesions as they progress towards malignancy. Dlg is mainly localised at the cell-cell junction but previously we, plus others, have also shown the presence of the protein in the nucleus. Moreover, it is this fraction of Dlg which appears to be particularly targeted by E6 for degradation. Although there is a large literature on the function of Dlg at the cell periphery, very little is known about the function of nuclear forms of the protein. Obviously one potential function would be regulation of transcription of certain target genes, and to investigate this we have analysed interaction between Dlg and the HAT domain of p300. Interestingly, the association between p300 and Dlg results in efficient acetylation of Dlg within its carboxi-terminal region, and cell cycle analyses indicate that this occurs preferentially in G1/S phase. In conclusion, these studies highlight the existence of a novel function of nuclear forms of Dlg that is related to the regulation of transcription through association with p300.

**WNt3-Fzd1 Chimera as a Model to Study the Canonical Wnt Signaling**

R. A. Bhat, B. Stauffer, A. Dellia Pietra, P. V. N. Bodine; Wyeth Research, Collegeville, PA

Wnts are secreted glyco/ioproteins that interact with a membrane receptor complex composed of the Frizzled (Fzd) receptor and a Lipoprotein-related protein (LRP). So far 19 Wnt genes and 10 frizzled receptors have been identified, however the specificity of their interaction has not been fully defined. In the present study, we have developed a chimera of Wnt3-Fzd1 and have validated that the chimeric protein activates canonical Wnt signaling. Moreover, the chimera was used to understand the role of Wnt signaling in osteoblast differentiation. The Wnt3-Fzd1 chimera activated TCF-Luciferase reporter, and the fold induction was much higher than that obtained from Wnt3 cDNA alone. The deletion of the cytoplasmic tail and several point mutations highlight the existence of a novel function of nuclear forms of Dlg that is related to the regulation of transcription through association with p300.

**SF3A60 as a Constitutive Androstane Receptor (CAR) Interacting Protein**

J. Kwon, H. Jeong, W. Seol; Inst. of Brain Science & Technology, Daegon, Republic of Korea

CAR (Constitutive Androstane Receptor) is a member of nuclear receptor superfamily which plays an important role for degradation of xenobiotics in liver. Using yeast two-hybrid screening, we have identified SF3A60 (SF3A3), 60KD subunit of splicing factor 3a, as one of CAR-interacting proteins. Recently, it has been shown that steroid hormone receptors such as PR (Progesterone Receptor) and ER (Estrogen Receptor) and a transcriptional coactivator, CoAA, exhibit different effect on alternative splicing decision and stimulate the production of spliced variants produced from genes driven by hormone dependent promoter. Therefore, we investigated physiological meaning of interaction of CAR with SF3A60. At first, we confirmed this interaction of murine CAR and SF3A60 by co-immunoprecipitation and GST-pull down assay. Overexpression of SF3A60 in HepG2 cells did not activate CAR’s transcription activity. However, overexpression of murine CAR showed mild change on production of splicing variants of a gene driven by a promoter containing CAR binding sequence. These results suggest that CAR can affect differential splicing by interaction with SF3A60.
Nonsteroidal Anti-inflammatory Drugs Inhibit Lymphangiogenic Marker Prox-1-mediated Transcriptional Activity
M. Pan,1 W. Hung,2 Kaosong Medical University, Institute of Medicine, Kaosong, Taiwan, 1National Sun Yat-Sen University, Institute of Biomedical Sciences, Kaosong, Taiwan
A positive association between cyclooxygenase-2 (COX-2) expression and lymphangiogenesis has been reported in several cancers. Here, we studied the correlation between COX-2 and the specific lymphangiogenic factor Prox-1 in vein endothelial cells. In addition, we also try to determine whether COX-2 specific inhibitor NS398 affects cancer cell-mediated tube formation of EAHy926 endothelial cells on Matrigel gel. We showed that conditioned medium of COX-2-overexpressing lung cancer cells induced Prox-1 expression in EAHy926 cells in a PGE2-independent manner. It has been reported that COX-2-mediated the induction of VEGF-C in certain cancers. We confirmed that VEGF-C induced Prox-1 expression and ecdysoexpression of VEGF-C in endothelial cells indeed elevated prox-1 expression. NS398 not only significantly inhibited basal Prox-1 expression, but also reversed the promotion of conditioned medium of COX-2-overexpressing lung cancer cells or VEGF-C on Prox-1 expression. Furthermore, we found that NS398 suppressed the expression of Prox-1 via regulation of transcriptional activity and RNA stability. More importantly, NS398 also abolished Prox-1-mediated stimulation of VEGF-3 expression. These results suggest that COX-2 stimulated Prox-1 expression, and NS398 attenuates lymphangiogenesis via down-regulation of Prox-1/VEGF-3 signaling.

HER-2/neu Transcriptionally Activates Jab1 Expression via the AKT / β-catenin Signaling Pathway
M. Hsu,1 W. Hung,2 Kaosong Medical University, Institute of Medicine, Kaosong, Taiwan, 1National Sun Yat-Sen University, Institute of Biomedical Sciences, Kaosong, Taiwan
Jab1/CSN5, the fifth subunit of COP9 signalosome, facilitates the mislocation of p27 from nucleus to cytoplasm and promotes its degradation. It has been reported that Her-2/neu causes the decrease of p27 protein level by inducing Jab1-mediated cytoplasmic exportation and ubiquitin-dependent degradation. In this study, we investigated the effect of Her-2/neu on Jab1 expression. Our data demonstrated that Her-2/neu up-regulated Jab1 expression via transcriptional level. We isolated the 5'-flanking region of human Jab1/CSN5 gene to elucidate the mechanism how Her-2/neu transcriptionally activates Jab1 expression. Luciferase reporter assay, site-directed mutagenesis analysis and DNA affinity precipitation assay (DAPA) revealed that Her-2/neu acted via a TCF-4 binding site to induce Jab1 promoter activity. We next explored the signaling pathway that mediated the effect of Her-2/neu on Jab1 expression by chemical inhibitors. Our results showed that inhibition of AKT activity by wortmannin blocked Her-2/neu-mediated Jab1 promoter activity. Co-expression dominant-negative AKT or constitutively GSK-3β also decreased Jab1 promoter activity. Conversely, co-expression β-catenin or myristoylation signal-attached AKT (myr-AKT) increased Jab1 promoter activity in NIH3T3 cells. Jab1 knockdown by small interfering RNA ( siRNA ) restored p27 protein level and induced G1 phase arrest. These results support that Her-2/neu transcriptionally regulates Jab1 expression via AKT/β-catenin signaling pathway and Jab1 may be a therapeutic target in breast cancer with Her-2/neu overexpression.

Regulation of GAPDH in Prorocentrum micans According to Nutritional Condition
J. B. Shim,1 Y. D. You,1 H. J. Jeong,2 G. H. Kim1; 1Department of Biology, Kongju National University, Kongju, Republic of Korea, 2School of Earth & Environmental Science, Seoul National University, Seoul, Republic of Korea
We investigated changes of inner-cellular metabolism processes using 2-D electrophoresis. These changes are surely needed when mixotrophic organisms change their trophic method from photosynthesis to heterotrophy. We analyzed and compared proteomes extracted from Prorocentrum micans ( Dinoflagellate ) in autotrophic and heterotrophic condition respectively. About 800 proteins were detected in two conditions, 55 proteins among these proteins showed significantly different expression aspect between two conditions. Some proteins differed in expression amount and others newly expressed. 16 proteins, firstly expressed in autotrophic condition, had basic pl value. In other hand 12 proteins expressed in heterotrophic condition had acidic one. There are wide difference of revelation quantity and total amount of proteins were enough to Ethan MALDI-TOF Mass spectrometry analysis. So, we selected eight spots and Amino acid sequencing. Consequently one of Spots(#6404)was indentified GAPDH(glyceraldehyde-3-phosphate dehydrogenase) which is participate in photosynthesis and glycolysis. There are wide differences of revelation quantity and total amount of proteins were enough to Ethan MALDI-TOF Mass spectrometry analysis. These results suggest that GAPDH is the enzyme participate in photosynthesis and Calvin cycle. When think over GAPDH is one of representative house keeping gene, this protein's discriminatory manifestation on the lines of nutritional condition is not so much dinoflagellates progress photosynthesis and heterotrophy come together as to select specific nutrition intake method.

Erk2-mediated Phosphorylation of P300 Involves in the Regulation of EGF-induced Keratin 16 Gene Expression in Keratinocytes
Y. Chen,1 Y. Wang,2 W. Chang3; 1Department of Pharmacology, National Cheng Kung University, Tainan, Taiwan, 3Department of Molecular and Cellular Oncology, MD Anderson Cancer Center, Houston, TX
Overexpression of keratin 16 has been observed in those skin diseases characterized by hyperproliferation such as psoriasis. In studies of gene regulation of keratin 16, we reported previously that the coactivator p300 interacted with Sp1 and API proteins, and participated in EGF-induced keratin 16 gene expression in HaCaT cells. In addition, EFG treatment was found to up-regulate p300 recruitment to the keratin 16 promoter through ERK signaling pathway. According to the documents previously reported, activated ERK2 phosphorylated GST-p300 (aa 1572-2370) in vitro and the transcriptional activity of p300 was enhanced. However, it is still unclear that which kinases are responsible for p300 phosphorylation in vivo and where the exact phosphorylation sites occur upon stimulation. Therefore, in this study, we want to explore that the effect of p300 phosphorylation on EGF-induced keratin 16 gene expression in keratinocytes. According to our results, the purified p300 protein was phosphorylated by activated ERK2. Furthermore, phosphorylation of p300 was increased upon EGF treatment in a time-dependent manner in HaCaT cells and this phosphorylation was regulated by ERK signaling pathway. We also found that ERK2-induced phosphorylation of p300 increased its HAT activity in vitro. Moreover, six potential ERK phosphorylation sites on p300, including Thr317, Thr938, Thr960, Ser2279, Ser2315, and Ser2366, were identified. Reporter assays revealed that, comparing with the effect of p300WT overexpression, no apparent effect on EGF-induced keratin 16 promoter activity was observed in overexpression of p300-T3A with the three mutated threonine residues (Thr317, Thr938, and Thr960) all replaced by alanine. However, a significant decrease in EGF-stimulated response was found in p300-S3A with the three mutated serine residues (Ser2279, Ser2315, and Ser2366) all replaced by alanine. Taken together, these results suggest that ERK2-phosphorylated p300 on Ser2279, Ser2315, and Ser2366 might play a role in EGF-induced keratin 16 gene expression by its increased intrinsic HAT activity.

Role of PLC1 and MOT1 in Preinitiation Complex Assembly
A. M. Demczuk, A. Vancura; Biological Sciences, St. John's University, Queens, NY
Phospholipase C (Plc1p encoded by PLC1 gene in S cerevisiae) and inositol polyphosphates have been shown to function in transcriptional activation by regulating the activity of chromatin remodeling complexes, such as the SWI/SNF complex. One of the rate-limiting steps in transcriptional activation is the binding of TATA-binding protein (TBP) to promoter DNA, leading to the formation of the preinitiation complex (PIC). Mot1p is an essential Swi2/Sfn2-related protein that catalyzes dissociation of TBP from DNA. In this study we examined whether Ptc1p regulates PIC formation by affecting Mot1p function and recruitment or dissociation of TBP. Mutations in PLC1 and MOT1 display strong genetic interactions. However, chromatin immunoprecipitation experiments showed that Plc1p does not affect recruitment of Mot1p to Mot1p-regulated promoters. Expression of Mot1p-repressed genes in mot1Δ double mutants is strongly increased in mot1ΔΔ cells. In addition, the formation of the preinitiation complex (PIC). Mot1p is an essential Swi2/Sfn2-related protein that catalyzes dissociation of TBP from DNA. In this study we examined whether Plc1p regulates PIC formation by affecting Mot1p function and recruitment or dissociation of TBP. Mutations in PLC1 and MOT1 display strong genetic interactions. However, chromatin immunoprecipitation experiments showed that Plc1p does not affect recruitment of Mot1p to Mot1p-regulated promoters. Expression of Mot1p-repressed genes in mot1ΔΔ cells.

Role of Schistosomal Lipids in Activating the Innate Immune Responses through Toll-like Receptor (TLR)-2 Signaling Pathways
K. G. Magalhães,1 P. E. Almeida,1 G. C. Atella,2 M. P. Machado,3 P. T. Bozza1; 1Imunofarmacodinamica, Instituto Oswaldo Cruz - FIOCRUZ, Rio de Janeiro, Brazil, 2Instituto de Bioquímica Médica, Universidade Federal do Rio de Janeiro, Rio de Janeiro, Brazil, 3Biotecnologia, Instituto Oswaldo Cruz - FIOCRUZ, Rio de Janeiro, Brazil
The activation of cells of the host innate immune response by signature molecules of schistosomiasis may determine the course of the pathologic process and immunity to infection, emphasizing the importance of studying the response to such parasite molecules. It is becoming clear that ligands and their receptors may play an important role in regulating immune responses. Here, we...
have focused on the role of schistosome lipids in activating the innate immune response through TLR activation. To investigate the role of TLR2 in the innate immune response to *Schistosoma mansoni* and verify the immunomodulatory properties of their lipids, we isolated and purified lipids from *S. mansoni* eggs and adult worms, to stimulate macrophages from both wild type and TLR2 deficient mice in vitro. Our results show that stimulation by *S. mansoni* lipids in vitro of mouse peritoneal macrophage induced a translocation of the transcription factor NF-κB to the nucleus as assessed by confocal microscopy. Schistosome lipids, mainly lyso-phosphatidylcholine fraction, also induced a time-dependent increase of TNF-α and IL-6 expression, increased formation of lipid bodies and significantly enhanced the production of eicosanoids in wild type but not in TLR2 deficient mice. The co-localization of 5-lipoxygenase (5-LO) within lipid bodies showed that such organelles might function as specialized cytoplasmic domain for eicosanoid-forming enzyme localization in macrophages. Taken together, our results indicate that a spectrum of immunomodulatory activities can be attributed to *S. mansoni*, indicating a role for these lipids in enhancing the expression of cytokines and lipid mediators, inducing lipid body formation and stimulating innate immunity through TLR2 dependent pathway.

453 Genes Express during Elicited Spider Fibroin Production
G. Candelas, G. Arroyo, I. Cintón, L. Capó, A. Plazaola, A. González, C. Ayala, J. Canabal, University of Puerto Rico—Río Piedras Campus, San Juan, Puerto Rico
We are exploiting the large amounts of spider, Nephila clavipes, a model system in which to study the elicited production of a specific spider protein. This is made possible due to the fact that we are able to virtually abolish the process and subsequently elicit it to high levels of production. The transient responses elicited, have been monitored through time sequence by providing the adequate labeled precursors. In so doing, we have observed a large wave of the full size protein product, which peaks at ninety minutes after stimulation. This wave is preceded by a sixty minutes interval by the production of the fibroin’s template. A third peak of minor intensity is observed following the production of the template, which adaptively shifts the gland’s RNA population, enriching it with the mRNAs cognate to the fibroin’s preponderant amino acids, glycine, alanine and proline. The earliest of the stimulus elicited activities, which peaks at fifteen minutes after stimulation, enriches the glands with a variety of small RNAs, among which, we have thus far, identified a tissue-specific alaline tRNA, two isoforms of SS RNAs and all the members of the U subset of small nuclear RNAs. We have initiated our search with the genes which code for alanine tRNA. A cluster of four alanine tRNA genes was isolated, the individual genes were subcloned and sequenced. The genes displayed microheterogeneity within their coding as well as their flanking sequences. The genes were transcribed in an heterologous extract derived from Bombyx mori, displaying differentiation of expression. Of interest is the gene with the highest transcriptional activity, which requires a far upstream sequence element. The presence of this sequence places this alanine tRNA gene in a category of Pol III genes such as, U6snRNA TskRNP and tRNA see, which possess distal positive regulatory elements.

454 Regulation of Pluripotency Gene Repression upon Differentiation
A. J. Cooney, P. Gu; Molecular and Cellular Biology, Baylor College of Medicine, Houston, TX
ES cell self-renewal is maintained by a core of key transcription factors that include Oct4, Sox2 and Nanog that through feed forward and feed back mechanisms maintain pluripotence gene expression. However, specific mechanisms are required to disrupt this novel pattern of gene expression upon differentiation to down regulate the pluripotent phenotype and inhibit the pluripotent phenotype. Upon differentiation of ES cells Oct4 gene expression is repressed and subsequently silenced. Nuclear receptors are critical for the regulation of pluripotent gene expression during embryonic stem cell differentiation and embryonic development. The orphan nuclear receptor GCNF has been shown to play a central role in the repression of Oct4 by binding to a response element in its promoter. Efforts to characterize mediators of GCNF’s repressive function on the Oct4 promoter identified Methy1 DNA binding protein, MBD3, as a GCNF interaction factor. The ligand binding GCNF interacts with methyl DNA binding domain of MBD3. In addition, GCNF also interacts with the closely related factor MBD2. In P19 and ES cells, upon differentiation, endogenous GCNF binds to the Oct4 proximal promoter and recruits MBD2 and MBD3, in a retinoic acid dependent manner. In differentiated GCNF−/− ES cells recruitment of MBD2 and MBD3 is lost and subsequently repression of Oct4 expression fails to occur. RNAi mediated knock-down of MBD3 expression results in reduced Oct4 expression in differentiated P19 cells. Thus, we have shown that GCNF recruits MBD2 and 3 to the Oct4 promoter to mediate repression of Oct4 expression during differentiation of P19 ES cells. The direct interaction between GCNF with MBD2 and MBD3 provides specificity of recruitment for a relatively non-specific DNA binding factors. Thus, MBD2 and MBD3 are novel nuclear receptor co-repressors that are required to repress pluripotent gene expression upon ES cell differentiation.

455 Dominance of SOX9 Function over RUNX2 during Skeletogenesis
G. Zhou,1,2 Q. Zheng,2 F. Engin,3 E. Munivez,2 Y. Chen,2 E. Sebald,4 D. Krakow,4 B. Lee2,3; 1Orthopaedics, Case Western Reserve University, Cleveland, OH, 2Department of Molecular and Human Genetics, Baylor College of Medicine, Houston, TX, 3Howard Hughes Medical Institute, Houston, TX, 4Medical Genetics Institute, Cedars-Sinai Medical Center, Los Angeles, CA, 5Obstetrics and Gynecology, David Geffen School of Medicine at UCLA, Los Angeles, CA
Mesenchymal stem cell-derived osteo-chondroprogenitors express two master transcription factors SOX9 and RUNX2 during condensation of the skeletal anlagen. They are essential for chondrogenesis and osteogenesis, respectively, and their haploinsufficiency cause human skeletal dysplasias. We show that SOX9 directly interacts with RUNX2 and repress its activity via their evolutionarily conserved HMG and runt domains. Ectopic expression of full-length SOX9 or its RUNX2-interacting domain in mouse osteoblast results in an osteodysplasia characterized by severe osteopenia and down regulation of osteoblast differentiation markers. Thus, SOX9 can inhibit RUNX2 function in vivo even in established osteoblastic lineage. Finally, we demonstrate that this dominant inhibitory function of SOX9 is physiologically relevant in human campomelic dysplasia (CMD1). In CMD1, haploinsufficiency of SOX9 resulted in upregulation of the RUNX2 transcriptional target COL1A1 as well as all the three members of RUNX gene family. In summary, SOX9 is dominant over RUNX2 function in mesenchymal precursors that are destined for a chondrogenic lineage during endochondral ossification.

456 Interleukin-2 Treatment of HuT 78 Cells Induces the Activities of DNA Topoisomerase I and DNA Topoisomerase II
P. D. Foglesong; Biology, University of the Incarnate Word, San Antonio, TX
HuT 78 is a human T cell lymphoma line that expresses a high affinity receptor for interleukin-2 (IL-2). Upon binding of IL-2 to its receptor signal transduction pathways cause the activation of protein kinases and an increase in transcription and DNA replication. This study investigated the effects of IL-2 treatment upon the activities of DNA topoisomerase I and DNA topoisomerase II, enzymes that are involved in transcription and DNA replication. HuT 78 cells were treated with 1,000 U/ml of IL-2, and nuclear extracts were prepared at various times after treatment. The nuclear extracts were assayed quantitatively for the catalytic activity of DNA topoisomerase I (Topo I) by relaxation of supercoiled plasmid pH2624 DNA and for the catalytic activity of DNA topoisomerase II (Topo II) by unknotting of bacteriophage P4 DNA. The concentrations of protein in the nuclear extracts were determined by a modified Bradford assay, and the specific activities of Topo I and Topo II were measured. The specific activities of both Topo I and Topo II increased 10-fold to 20-fold after treatment of HuT 78 cells with IL-2. The specific activity of Topo I increased with peaks observed at 0.5, 2 and 12 hours following treatment, and the specific activity of Topo II increased with peaks observed at 2 and 4 hours following treatment. The times of increased specific activities of these enzymes coincide with periods of increased transcription (0.5 - 4 hours) and increased DNA replication (12 hours) in HuT 78 cells following treatment with IL-2. These results suggest that Topo I and Topo II function in transcription and DNA replication in activated human T lymphocytes and that the increased activities of these enzymes are significant consequences of the activation of T cells by IL-2.

457 cis-regulatory Mechanisms of Anterior Visceral Endoderm-specific Genes
C. Kimura-Yoshida,1 H. Nakano,1 J. Rossant,2,8 S. Aizawa,1,8 I. Matsui,1,2,8; 1Department of Molecular Embryology, Osaka Medical Center for Maternal and Child Health, Osaka, Japan, 2Program in Developmental Biology, Hospital for Sick Children, Toronto, ON, Canada, 3Vertebrate Body Plan Group, RIKEN, Center for Developmental Biology, Kobe, Japan
Anterior visceral endoderm (AVE) plays essential roles with respect to anterior pole development in the early mouse embryo. However, the molecular mechanisms underlying the formation of AVE remain largely unknown. To assess the genetic cascade involved in AVE formation, the cis-regulatory elements directing expression of four vertebrate, mouse, human, chicken and pufferfish, Otx2 genes in the AVE were analyzed comparatively via generation of transgenic mice. Precise cis-analysis employing deletion and point mutant constructs revealed that one highly conserved element, TTTTCCGC, directs Otx2 expression in the PE1 element. Consistent with this, Otx2 expression is identical to Otx2 expression in the visceral endoderm during AVE migration and the distal visceral endoderm fails to migrate anteriorly in
These findings provide profound insights into conserved roles of γ into the pAAV plasmid with a H1 promoter. Subsequently the PKC γ Whitehead siRNA design program. Next, the siRNAs were subjected to a NCBI BLAST search that checks the specificity of each siRNA for the targeted gene and identifies similar sequences.

mGluR6 mice in which reporter gene expression was directed under the control of the distribution of retinal bipolar cell types in the mouse central retina using bipolar cell type-specific immunohistological markers. To facilitate our quantitative analysis we generated transgenic Retinal bipolar cells mediate the vertical transfer of visual signals from photoreceptors to ganglion cells. At least 10 morphologically distinct bipolar cell types have been characterized. These

mechanisms underlying bipolar cell type diversity.

The Role of Elip-like Gene in Cold Condition Survival of Green Alga, Spirogyra varians (Zygnematales) J. W. Han, M. Yoon, K. P. Lee, G. H. Kim; 1Department of Chemistry, Kongju National University, Kongju, Republic of Korea, 2Department of Biology, Kongju National University, Kongju, Republic of Korea.

Plant cells respond to cold stress by the expression of gene encoding specific stress proteins with possible protective functions. Simultaneous comparison of differentially expressed protein profiles of a freshwater alga, Spirogyra varians, grown under two different temperature conditions (4°C and 20°C) indicated the generation of cold-stress responsive proteins. We isolated a 20 KDa protein (pI 4.5) which was most strongly up-regulated in 4°C (about 500-fold higher than in 20°C). As the protein has never been reported before, we named it as SVCR1 (Spirogyra varians cold regulated) protein. The cDNA encoding SVCR1 was cloned using degenerated primers designed from the internal amino acid sequence of the protein and a λZAP cDNA library of Spirogyra varians. The deduced amino acid had a high sequence similarity with early light-inducible proteins (ELIPs) of higher plants which are known as nuclear-encoded chloroplast proteins induced by light stress. The northern blot results showed that the accumulation of SVCR1 transcript could be induced by cold treatment (4°C) even under the dark condition. To understand the relationship between SVCR1 and cold stress, we used the RNA interference method, in which knockdown strains with reduced SVCR1 levels were isolated. We compared life cycle between knockdown strain and wild type strain under low temperature. Based on these results, the possible role of SVCR1 in cold stress defence is discussed.

Design of siRNAs That Target the Pain Gene PCkγ M. Lozada, S. Garraway, C. Inturrisi; 1Industrial Biotechnology Program, University of Puerto Rico - Mayaguez Campus, Humacao, Puerto Rico, 2Department of Pharmacology, Weill Medical College of Cornell University, New York, NY.

RNA interference is a powerful genetic approach for efficiently silencing target genes. One advantage of this technique is the high specificity it offers over pharmacological antagonism in it cleaves the mRNA of a precise protein. The purpose of this study is to use RNA interference to target PCkγ, a protein kinase that has been identified in neurons of the brain and spinal cord and implicated in the production of persistent pain. Firstly, we designed five 21 base pair small interfering RNAs (siRNA) that target the gene that encodes the mouse PKC γ it cleaves the mRNA of a precise protein. The purpose of this study is to use RNA interference to target PCkγ, a protein kinase that has been identified in neurons of the brain and spinal cord and implicated in the production of persistent pain. Highly Conserved Non-coding Sequences Mediate Species-specific Regulation of the ATH5 Gene during the Course of Mouse and Chick Retina Ontogenesis D. Skowronska-Krawczyk,2 F. Chiodini,1 C. Alliod,2 M. Ebeling,2 D. Castro,2 L. Matter-Sadzinski,1 F. Guillemot,1 M. Ballivet,2 J. Matter2,2; 1University of Lausanne, Eye Hospital Jule Gonin, Lausanne, Switzerland, 2Department of Biochemistry, University of Geneva, Geneva, Switzerland, 3Pharmaceuticals Division, Hoffmann-La Roche Ltd., Basel, Switzerland, 4National Institute for Medical Research, London, United Kingdom.

The atonal homologue 5 (ATH5) is predominantly expressed in the developing vertebrate retina. In zebrabfish and in the mouse, inactivation of the ATH5 gene results in a retina lacking most retinal ganglion cell (RGC) types. In the chick retina, the acute upregulation of ATH5 coincides with the period of development when the majority of RGCs are specified and this upregulation is required to occur on transcription of genes defining the RGC phenotype. Promoter occupancy and functional analysis indicate that the neurogenin 2 (Ngn2) and ATH5 proteins are directly required for transcription of the chicken ATH5 gene. In contrast, the late onset of Ngn2 expression in the mouse retina and the standing expression of ATH5 in Matθ5/5-/- mice have suggested that bHLH proteins might not be required for the regulation of ATH5. To address this issue we have conducted a comparative analysis of the role of Ngn2 in the regulation of ATH5 during development of the mouse and chick retinas. In contrast with previous studies, we found that the onset of Ngn2 and ATH5 expression coincides in early mouse retina and that ATH5 expression is downregulated in Ngn2-/- mice. Despite the fact that ATH5 promoter elements are highly conserved, their in vivo occupancy by Ngn2 is very different in the mouse and chick retinas. We show how the proximal and distal regions act together to bring expression of ATH5 at a level which is about 50 folds higher in the chick than in the mouse retinas. In sum, our study reveals that evolutionary conserved regulatory elements are instrumental to mediate species-specific regulation of the ATH5 gene. We propose that such difference between species may have permitted the development of RGC populations that differ in size and properties. Changes in the Distribution of Spermidine Synthase during Spermiogenesis in Marsilea vestita 85, F. Deeb, S. M. Wolnai; Cell Biology and Molecular Genetics, University of Maryland, College Park, MD. The microspore of the water fern, Marsilea vestita, contains a single cell that undergoes a series of nine mitotic divisions to produce 32 spermatids and 7 sterile cells. Cytoplasmic movements precede the first division in the transcriptionally-quiescent gametophyte; certain proteins and mRNAs aggregate into zones that later become spermatogenous initials. Asymmetric divisions produce jacket cells, and then, symmetric divisions produce spermatids. As the spermatids differentiate into motile gametes, the jacket cells undergo a form of programmed cell death (PCD). Our published work shows that translation is controlled both spatially and temporally. We developed RNAi strategies to target mRNA degradation and thereby arrest development. We have focused on spermatogeny, spore nuclear remodeling, to determine whether jacket cells play a role in the development of spermatogenous cells. dsRNA probes were made from cDNAs encoding spermidine synthase (SPDS) and spermidine transporter (SPDT) that were isolated from our gametophyte cDNA library. Spores treated with these dsRNAs showed fewer but larger spermatogenous cells than control gametophytes. Normal gametophytes labeled with anti-SPDS and anti-spermidine antibodies show that spermidine first appears in the jacket cells and then in the spermatogenous cells. Spores treated with SPDT dsRNA showed reductions in spermidine in spermatogenous cells, suggesting that spermidine is transported from the jacket cells into the spermatogenous cells before it starts to be made in the spermatogenous cells. Treated cells were labeled with anti-sense centrin RNA and anti-centrin antibody to assess patterns of transcript distribution and patterns of new translation, respectively. Like untreated spores, centrin mRNA was present throughout the microspore, and centrin protein was localized in the spermatogenous cells. Our results show that the jacket cells support the development of the spermatogenous cells by providing molecules that are important for the gamete differentiation process. (Supported by NSF grant MCB-0234423 to SMW).
Regulation of Human Rac2 during Human Chronic Myelogenous Leukemia Cell Line (K562) Differentiation

R. Mukushirman, 1 D. G. Shalakin, 1 Department of Biochemistry and Molecular Biology, Indiana University School of Medicine, Indianapolis, IN; Departments of Pediatrics and Biochemistry and Molecular Biology, Indiana University School of Medicine, Indianapolis, IN; Rac2 belongs to the family of Rho GTPases. Rac2 is expressed only in hematopoietic cell lineages and is up regulated upon terminal myeloid cell differentiation. Rac2 plays an important role in many of the hematopoietic cellular functions such as neutrophil chemotaxis, superoxide production, cytoskeletal reorganization, and stem cell adhesion. The current study aims at investigating the molecular mechanisms regulating human Rac2 gene expression during cell differentiation using an in vitro model system. Stimulation of K562 cells with PMA resulted in an increased human Rac2 mRNA expression as analyzed by real-time PCR analysis. PMA activation of K562 cells at different time periods showed time dependent induction of Rac2 mRNA expression. This indicated that the Rac2 gene expression accompanies cell differentiation. To further delineate the regulatory elements required for the Rac2 induction upon cell activation, the human Rac2 promoter region was analyzed for the presence of cis elements. Transient expression analysis using the luciferase reporter gene revealed the induction of human Rac2 gene expression to be mediated by increased transcriptional activity of Rac2 promoter region. Series of 5’ deletion derivatives of the Rac2 promoter region used in the transient transfection assays identified a 1 kb region between -4558 bp and -3500 bp to contain the regulatory element required for the transcription of Rac2 gene expression. Future studies will aim at identifying the minimal Rac2 promoter region present within this 1 kb region that is sufficient to direct PMA induced Rac2 transcription. Chromatin Immunoprecipitation assays will be done to identify the transcription factors that bind to the DNA element(s). Identification of the DNA elements and the transcription factors that bind to these regulatory elements will help in the understanding of molecular mechanisms regulating Rac2 gene expression during cell differentiation.

Intestinal Flora Alters DNA Methylation in Intestinal Mucosal Cells

Y. Iwamoto, K. Hirabayashi, N. Hattori, S. Tanaka, S. Yagi, K. Doi, K. Shiota; The University of Tokyo, Tokyo, Japan

Genome-wide analysis of gene area revealed that there are many loci that have tissue-dependent and differentially methylated regions (T-DMRs). Importantly, DNA methylation profile of the T-DMRs is unique in each tissue or cell type including embryonic stem cells, somatic cells and germ cells. Therefore, DNA methylation profiles of T-DMRs are useful to evaluate and characterize the cells. Intestinal epithelium is one of the rapidly renewed cells in mammals and has multiple functions as transporter of nutrients and helping to prevent infection. Interaction with the bacterial flora is another feature of the intestinal epithelium. Many documents have been accumulated that bacterial flora influences the physiology and differentiation of epithelial cells. The objectives of this study are to characterize the epithelium by T-DMRs analysis and to know if bacterial flora may affect epigenetic status. The mucosa was collected by scratching the surface layer of intestine using razor from germ free (GF) and specific pathogen-free (SPF) mice. First, we confirmed that the intestinal mucosa has a unique DNA methylation profile of T-DMRs compared to other genome DNA from kidney, liver, brain, spleen, and testis, by methylation sensitive real-time PCR focusing on 93 Not I sites. Interestingly, there are two loci that are differentially methylated in the mucosa between SPF compared to GF: Agpat3, encoding 1-acetylcyto-ol-3-phosphate-O-acetyltransferase 3, and Kcnk5, encoding a member of potassium channel subfamily K, member 5. Agpat3 showed hypermethylation in SPF compared to GF, suggesting that intestinal flora may regulate the DNA methylation in genome. Differentiation of cells from the stem condition generally associates with both DNA methylation and demethylation. Therefore, the intestinal epithelium may be under the pressure of DNA methylation by bacterial flora at the conventional condition. Thus, the bacterial flora has an impact on formation of DNA methylation profile in intestinal mucosal cells.

Dppa3 is Expressed by DNA Methylation

H. Muramoto, N. Hattori, S. Tanaka, S. Yagi, K. Shiota; The University of Tokyo, Tokyo, Japan

Dppa3 gene (also known as stella or PGC7) encodes a maternal factor, essential for murine preimplantation embryogenesis. It is expressed in oocytes, preimplantation embryos, primordial germ cells (PGCs) and embryonic stem (ES) cells but not in placenta or other somatic tissues. Dppa3 is located within a conserved cluster of genes, such as Gdf3 and Nanog, which is associated with pluripotency and tumors in the mouse and human. The similar expression pattern of these genes implies a possible transcriptional co-regulation. To address if DNA methylation is involved in the regulation of Dppa3, we first analyzed a DNA methylation status of the Dppa3 upstream region by methylation sensitive restriction mapping in ES cells and compared this with trophoblast stem (TS) cells and liver, both of which were confirmed to show no Dppa3 expression. In a good correlation with its expression activity, the 5’-flanking region up to 2 kb upstream of Dppa3 transcription start site showed a lower methylation status in ES cells than in TS cells and liver. Bisulfite sequence analysis further revealed a hypomethylation status of 15 CpG dinucleotides within 1 kb of Dppa3 proximal upstream region in ES cells while TS cells showed hypermethylation status of these CpGs. NIH/3T3 cells, in which Dppa3 was not expressed, were also revealed to have hypermethylated Dppa3 upstream region. These 15 CpGs were also hypomethylated in PGCs while were hypermethylated in the liver isolated from mouse fetuses at embryonic day 12.5. Thus, the Dppa3 upstream region appeared to be a tissue-dependent differentially methylated region (T-DMR). Ectopic Dppa3 expression was induced in TS cells by treatment with an inhibitor of DNA methylation, 5-aza-2’-deoxycytidine and in Drom1-deficient mouse placenta. In conclusion, the results suggest a potential role of DNA methylation in silencing of Dppa3 gene.

A Molecular Insight of Hes5-dependent Inhibition Mechanism: Old Partners and New Players

A. Liu; Neuroscience and Cell Biology, UMDNJ-Robert Wood Johnson Medical School, Piscataway, NJ

This study identifies novel mechanisms of Hes5 function in developmental myelination. We report here up-regulation of myelin gene expression in Hes5-/- mice compared to wild-type siblings and down-regulation in overexpressing progenitors. This effect was only partially explained by the ability to regulate the levels of Mash1 and bind to N boxes in myelin promoters, since deletion of the DNA-binding domain of Hes5 does not suppress its inhibitory role on myelin gene expression. Novel mechanisms of Hes5 function in the oligodendrocyte lineage include the regulation of feedback loops with the cell-specific transcriptional activator Sox10. In progenitors with low levels of Sox10, Hes5 further decreases the bioavailability of this protein by transcriptional inhibition and direct sequestration of this activator. Increasing levels of Sox10 in progenitors, in turn, bind to Hes5 and titrate out its inhibitory effect by sequestration and displacement of the repressive complexes from myelin promoters. Thus, Hes5-dependent modulation of myelin gene expression involves old players (i.e. Mash1) and novel mechanisms of transcriptional regulation involving cell-specific regulatory loops with transcriptional activators (i.e. Sox10).

XRN4/EIN5, an Exoribonuclease, Is Required for Regulation of Defense and Developmental Pathways through Regulation of Small RNA-target mRNA Levels

B. D. Gregory, J. R. Ecker; Plant Biology, Salk Institute for Biological Studies, La Jolla, CA

Ethylene is a gaseous plant growth regulator that controls a multitude of developmental and stress responses. Recently, the levels of Arabidopsis EIN3 protein, a key transcription factor mediating ethylene-regulated gene expression, have been demonstrated to increase in response to the presence of ethylene gas. Furthermore, in the absence ethylene, EIN3 is quickly degraded through a ubiquitin/protasme pathway mediated by two F box proteins, EBF1 and EBF2. We have found that ETHYLENE-SENSITIVE5 is in fact the 5’-3’ exoribonuclease XRN4. Additionally, we demonstrated that the role of EIN3 in ethylene perception is to antagonize the negative feedback regulation on EIN3 by promoting EBF1 and EBF2 mRNA decay, which consequently allows the accumulation of EIN3 protein to trigger the ethylene response (1). Furthermore, tilting microarray analysis of the entire Arabidopsis genome has demonstrated that in addition to EBF1 and EBF2 mRNAs this ribonuclease regulates the levels of many other putative targets of small RNAs including known targets of microRNAs and small interfering RNAs. Through regulation of these specific targets, EIN5/XRN4 plays an important role in pathways involved in defense responses and plant development. 1. Gabriela Olmedo*, Hongwei Gao*, Brian D. Gregory*, Saeid D. Noushradze†, Laura Aguilar-Henonin, Hongjian Li, Fengying An, Flinio Guzman, and Joseph R. Ecker. (2006). ETHYLENE-SENSITIVE5 encodes a 5’-3’ exoribonuclease required for regulation of the EIN3-targeting F-box proteins EBF1/2. Proc. Natl. Acad. Sci. U.S.A. Nuclear Import of Viral Genomes

S. Cohen, B. Sun, W. Wu, N. Pantel; Department of Zoology, University of British Columbia, Vancouver, BC, Canada
To spread infection, many viruses enter the nucleus of their host cells where they use the cellular replication and transcription machinery. Today many steps of viral replication and cell entry are well understood at the molecular level. However, very little is known about how viruses deliver their genomes into the nucleus. We are analyzing the mechanism by which a variety of animal viruses enter the nucleus. It is apparent from our studies that viruses have developed different strategies for successfully entering the nucleus. These strategies, in most cases, involve the nuclear pore complex (NPC), which can also have a role in virus disassembly. The viruses that we are studying include influenza virus, hepatitis B virus (HBV) and minute virus of mice (MVM). Influenza virus disassembles during cell entry and the RNPs (made of RNA, polymerases, and the protein NP) enter the nucleus through the NPC. NP contains three putative nuclear localization signals (NLSs). Studying nuclear import of purified influenza RNPs by fluorescence microscopy we have found that the non-conventional NLS, located at the N-terminus of NP, is responsible for influenza RNP nuclear uptake. HBV loses its envelope during cell entry and releases its nuclear capsid into the cytoplasm. With diameters of 32 and 36 nm, HBV capsids are close to the size limit for transport through the NPC. However, using an electron microscopy (EM) import assay in Xenopus oocytes we have demonstrated that HBV capsids are able to cross the NPC without disassembly. While HBV capsids cross the NPC intact and release their genome at the NPC nuclear face, MVM capsids can enter the nucleus through a process that is independent of the NPC. Using both Xenopus oocytes injection and cell infection, we have found that MVM induces nuclear membrane disruptions that allow virus access to the nucleus.

469 Nucleoporin 153 Mediated Arrest of Hepatitis B Virus Capsids in the Nuclear Basket
A. Schmitz,1 A. Schwarz,2 N. Pante,3 B. Rabe,3 M. Kann4; 1 Institute of Medical Virology, Giessen, Germany, 2 Department of Zoology, University of British Columbia, Vancouver, BC, Canada, 3 Umr-cnrs 5097, Present address: Université Victor Segalen Bordeaux, Bordeaux, France
Facilitated nuclear transport occurs via nuclear pore complexes (NPCs), large protein assemblies embedded in the nuclear envelope. Molecules between 9 nm and 39 nm in diameter are imported using cellular transport receptors that mediate the passage through the NPC into the nuclear basket. Within this filamentous structure at the nuclear face of the NPC the receptors dissociate from the cargo by means of the small GTPase Ran in its GTP bound form. While the receptors recycle to the cytoplasm, the cargo diffuses deeper into the karyoplasm. Exceptions in which the cargos stay attached to the NPC are NT2F, the nucleoporin 153 (Nup153) and the protein Tpr that is attached to Nup153. Here, we show that the cap of the hepatitis B virus (HBV) shows a similar aborted nuclear import reaction. The HBV cap is imported into the nuclear basket via the transport receptors importin (karyopherin) αβ and fail to diffuse deeper into the karyoplasm. Using digitonin-permeabilized cells, pull-down assays and microinjections into Xenopus laevis oocytes we found that HBV capsids have a stable interaction with Nup153. HBV contains a DNA genome, but replicate by means of an RNA pregenome (PG). During virus production, the PG is encapsidated into an immature capsid (Impm5-C) that is converted into capsids containing mature DNA genome (Mat-C) by the viral polymerase, also encapsidated in the Impm-C. We observed that the Mat-C disintegrated into the nuclear basket, depicting a well-coordinated strategy to deliver mature viral DNA into the nucleus. As we exemplified for the nuclear import of artificial NLS- and M9-containing capsids the HBV capsids may moreover serve as a tool for investigation of Nup153 function.

470 Regulation of ATF2 Subcellular Localization
H. Liu, D. C. Hu; Purdue University Pharmacy School, West Lafayette, IN
Activating transcription factor 2 (ATF2) is a basic region leucine zipper (bZIP) transcription factor and belongs to activator protein 1 (AP-1) family. ATF2 functions as either homodimers or heterodimers with other AP-1 family proteins Fos, Jun, and CRE binding protein (CREB), to regulate a variety of cellular responses. Although it was believed that all mammalian AP-1 proteins are localized in the nuclear zone, they were activated by mitogen or phosphorylated and distributed in the nucleus. The presence of activating protein kinases (MAPKs), it was not known whether subcellular localization of AP-1 proteins is regulated by regulation. By employing the coexpression of cellular bZIP proteins (bZIPf), we have recently demonstrated that ATF2 homodimer localizes in the cytoplasm. Further analysis has led to the finding that ATF2 possesses two bipartite nuclear localization signals (NLS) in its basic region DNA binding domain and a CRM-1 dependent nuclear export signal (NES) in its leucine zipper region, and continuously shuttles between the cytoplasm and nucleus in nonmorphic form. Dimerylation with Jun family member proteins masks the NES, resulting in ATF2 nuclear localization. In addition to this Jun-dependent regulatory mechanism of ATF2 nuclear localization, we have also observed that deletion of the N-terminal 341 residues results in nuclear export (Fig.1b), suggesting that the N-terminal region ofcytoplasmic nuclear export signals. This model explicitly recognizes that the number, identity, and distribution of molecules within the pore affects cargo translocation through the pore. Our results demonstrate that maximum nucleocytoplasmic transport velocities can be modulated at least ~10-fold by the importin β concentration. We postulate that cargo trafficking rates in general depend on pore occupancy. This model explicitly recognizes that the number, identity, and distribution of molecules within the pore affects cargo translocation through the pore. Factors that could be affected by changes in pore occupancy include: i) the accessible volume for the transiting cargo; ii) the concentration and distribution of RanGTP in the NPC; and iii) the general nuclear pore occupancy. This model explicitly recognizes that the number, identity, and distribution of molecules within the pore affects cargo translocation through the pore. Factors that could be affected by changes in pore occupancy include: i) the accessible volume for the transiting cargo; ii) the concentration and distribution of RanGTP in the NPC; and iii) the structure and physical properties of the permeability barrier.

471 Nuclear Import Time and Transport Efficiency Depend on Nuclear Pore Occupancy
W. Yang, S. Musser; Molecular and Cellular Medicine, The Texas A&M HSC, College Station, TX
While many components and reaction steps necessary for the bidirectional transport of macromolecules across the nuclear envelope (NE) have been recognized, the mechanism and control of cargo migration through nuclear pore complexes (NPCs) remains poorly understood. In earlier work, we demonstrated that single cargo molecules could be visualized interacting with nuclear pore complexes (NPCs) in permeabilized cells by single molecule narrow-field epifluorescence microscopy (Yang, et al. 2004 101:12887-12892; and Yang & Musser, Methods, in press). Here, this approach was used to track cargo movement, and during and after interaction with NPCs in permeabilized and live cells. At low importin β concentrations, about half of the signal-dependent cargos that interacted with an NPC were translocated across the NE, indicating a nuclear import efficiency of ~50%. The NPC transport times for cargos that actually transported through the NPC and those that underwent abortive transport were both ~8.3 ms under these conditions. At high importin β concentrations, the import efficiency increased to ~80% and the transit speed increased ~7-fold. The transit speed and import efficiency of 10 kDa dextrans, a signal-independent cargo, was also increased by high importin β concentrations. These results demonstrate that on average nuclear transport velocities can be modulated at least ~10-fold by the importin β concentration. We postulate that cargo trafficking rates in general depend on pore occupancy. This model explicitly recognizes that the number, identity, and distribution of molecules within the pore affects cargo translocation through the pore. Factors that could be affected by changes in pore occupancy include: i) the accessible volume for the transiting cargo; ii) the concentration and distribution of RanGTP in the NPC; and iii) the structure and physical properties of the permeability barrier.

472 The Repeat Domain of the Nucleoporin p62 Interacts with Other FXFG-containing Nucleoporins in Interphase
P. Banks, M. Kodila, X. Quan, D. Tran, U. Stochaj; Physiology, McGill University, Montreal, PQ, Canada
Nuclear pore complexes provide the only intracellular pathway between nucleus and cytoplasm. The nucleoporin p62, a component of higher eukaryotic NPCs, is located at the central gated channel and involved in trafficking of various cargos. p62 is organized into an N-terminal segment that contains FXFG repeats and binds the soluble transport factor NTF2. The C-terminal portion associates with other nucleoporins and the nuclear cargo importin-β. We have identified several potential sites of interaction specifically with the p62 N-terminal domain. Using the p62 N-terminal segment as bait, we affinity-purified nucleoporins Nup358, Nup214 and Nup153 from crude cell extracts. In ligand binding assays, the N-terminal p62 segment associated with Nup358 and p62, suggesting their direct binding to the p62 N-terminal portion. Furthermore, p62 was isolated in complex with Nup358, Nup214 and Nup153 from growing HeLa cells, indicating that the interaction Nup358/p62, Nup214/p62 and p62/Nup153 also occur in vivo. Comparison of interphase and mitotic cells revealed that the formation of Nup358/p62 and p62/Nup153 complexes was restricted to interphase cells. By contrast, the association Nup214/p62 was detected in interphase as well as during mitosis. Our results support a model of complex interactions between FXFG containing nucleoporins, and propose that during interphase some of these interactions may contribute to the movement of cargo across the NPC.

473 Nup214 Is Required for Efficient CRM1-dependent Nuclear Protein Export
S. Hutter, R. H. Kehlenbach; Biochemistry, University of Göttingen, Göttingen, Germany
While little is known about the role of individual nucleoporins in different nucleocytoplasmic transport pathways, the cytoplasmic nucleoporin Nup358/RanBP2 has previously been suggested to function as a platform for disassembly of CRM1-containing export complexes. We now specifically depleted cells of the cytoplasmic nucleoporins Nup214/CAN and Nup358 by RNA interference. Depletion of Nup214 resulted in co-depletion of its binding partner Nup88. Nuclear pore complexes assembled in the absence of Nup214/Nup88 or Nup358 were fully functional in nuclear protein import, whereas nuclear mRNA export was slightly impaired. Depletion of Nup358 had only a minor effect on nuclear protein export. In contrast, depletion of Nup358 resulted in the failure of nuclear protein export. Our inability to rescue the CRM1-mediated nuclear protein export in Nup214 depleted cells suggests that Nup214 is required for efficient nuclear export.
Regulated and signal-mediated export of molecules across the nuclear membrane is required for several cellular processes and essential for cell viability. Nuclear translocation of macromolecules is mediated by a specific export signal that is recognized by a transport receptor, referred to as an exportin. The mechanism by which many proteins, such as the von Hippel-Lindau (VHL) tumor suppressor and ubiquitination factor, exit from the nucleus is still however unknown. To study the nuclear export of VHL we established an in vivo nuclear export assay based on fluorescence loss in photobleaching (FLIP). This led to the identification of a simple and discreet motif “DxGx2Dx2L” that governs efficient nuclear export of VHL as well as a wide spectrum of unrelated proteins such as the mRNA nuclear export and translation factor Poly(A)-Binding Protein (PABP1), the cell cycle regulator Cyclin C, the Progesterone hormone Receptor and the pro-apoptotic BAX. We define the motif as EDNA (Elongation Factor Dependent Nuclear Export Adaptor) since it mediates nuclear egression of proteins by interacting in the nuclear compartment with a component of the translation apparatus, the Elongation Factor 1A (EF1A), which engages in highly dynamic nuclear-cytoplasmic trafficking. The specific interaction of EF1A with EDNA can be destabilized by the inhibition of polymerase II transcription leading to a substantial reduction in the nuclear export activity. Variants of EDNA with substitutions of the aspartic acid to glutamic acid or leucine to isoleucine retain activity and are present in countless proteins of different phyla. We suggest that EDNA directs basal nuclear export of molecules by exploiting the cellular dynamic properties of a conserved and highly abundant translation factor and links the protein synthesis and subcellular trafficking machineries.
A Mechanism for the Nuclear Export of the Transcription Factor Tbx5
A. Kulisz, T. Camarata, B. Bimber, H. Simon; Pediatrics, Northwestern University Feinberg School of Medicine, Chicago, IL

In vertebrates, the transcription factor Tbx5 is important in controlling the differentiation of the mesoderm. Mechanisms that regulate the initiation of follicular growth (follicle activation) and the ensuing growth and differentiation of preantral follicles are of considerable interest. In an effort to clone follicular development-related genes, we identified a novel gene (OoGra1) by differential display reverse-transcription PCR (DDRT-PCR) and a rapid amplification of cDNA ends (RACE) reactions. RACE reactions were performed with the SMART RACE CDNA amplification kit (Clontech) with total RNA extracted from mouse ovaries. Using Northern blot, we detected mRNA specific to OoGra1, 1.7Kb in length, in multiple tissues with predominance in mouse ovary, testis and lung. Next, we focused on OoGra1 in mouse ovaries. With Northern analyses, we found that OoGra1 was expressed in vivo at high level on day 10, with a subsequent decrease on days 15, 20 or adult testes. However, OoGra1 was undetected in ovaries of day 5. Moreover, we studied production of OoGra1 protein including a 574-residue polypeptide by using an antisem recognizing a peptide sequence unique to this gene in Western blotting and in immunolocalization. The antiserum recognized a single prominent band of approximately 66kDa in immunoblots. Subsequently, the antiserum was used by basal echinoderms.

In this study, the expression patterns of several germ line gene homologs were examined in entering the larval left coelomic pouch, the site of primordial germ cell accumulation. Due to their slow cell cycle and larval location, the small micromeres are candidate primordial germ cells.

SoxE used by basal echinoderms. In this study, the expression patterns of several germ line gene homologs were examined in entering the larval left coelomic pouch, the site of primordial germ cell accumulation. Due to their slow cell cycle and larval location, the small micromeres are candidate primordial germ cells.

The Forkhead Transcription Factor FoxY: A Potential Transcriptional Regulator of Germ-Line and Oocyte-specific Genes
J. L. Song, G. M. Wessel; Molecular, Cellular Biology, and Biochemistry, Brown University, Providence, RI

The Forkhead Transcription Factor FoxY, whose RNA transcripts localized to the vasa-positive, small micromeres, are the putative primordial germ cells in the sea urchin. Using real time, qPCR and whole mount RNA in situ hybridizations, we observed the expression of FoxY to be of low abundance in eggs and then peaks in mesenchyme blastulae, specifically in the small micromeres. In these same cells, mRNA of FoxY co-localizes with mRNA of several germ-cell genes including vasa, nanos, sef, and seaf. Immunolocalization analysis of FoxY indicated that in the ovary it selectively accumulates in the germinal vesicle of oocytes. In embryos, while mRNA localization of FoxY is exquisitely specific to the small micromeres, its protein localization is in nuclei of all embryonic cells. FoxY protein in the embryo may be maternal in origin, and zygotic transcription of FoxY in the small micromeres may enhance its continuous translation. mRNA co-localization of FoxY and germ-line genes in the small micromeres and putative binding sites of FoxY within the promoter regions of these genes suggests that FoxY may be a transcriptional regulator of these germ-line determinants. We are investigating the interacting partners of FoxY by immunoprecipitation and its DNA targets by chromatin immunoprecipitation. These results will contribute to our understanding of transcriptional regulation of germ-line and oocyte-specific genes.

Molecular Cloning and Characterization of a Newly Identified OoGra1
Z. Yang, J. Wu; Biologic Engineering, Shanghai Jiao Tong University, Shanghai, China

Ovarian follicle development is a complex process. Mechanisms that regulate the initiation of follicular growth (follicle activation) and the ensuing growth and differentiation of preantral follicles are of considerable interest. In an effort to clone follicular development-related genes, we identified a novel gene (OoGra1) by differential display reverse-transcription PCR (DDRT-PCR) and a rapid amplification of cDNA ends (RACE) reactions. RACE reactions were performed with the SMART RACE CDNA amplification kit (Clontech) with total RNA extracted from mouse ovaries. Using Northern blot, we detected mRNA specific to OoGra1, 1.7Kb in length, in multiple tissues with predominance in mouse ovary, testis and lung. Next, we focused on OoGra1 in mouse ovaries. With Northern analyses, we found that OoGra1 was expressed in vivo at high level on day 10, with a subsequent decrease on days 15, 20 or adult testes. However, OoGra1 was undetected in ovaries of day 5. Moreover, we studied production of OoGra1 protein including a 574-residue polypeptide by using an antisem recognizing a peptide sequence unique to this gene in Western blotting and in immunolocalization. The antiserum recognized a single prominent band of approximately 66kDa in immunoblots. Subsequently, the antiserum was used in immunolocalization and in immunoblotting. The antiserum was recognized in a single prominent band of approximately 66kDa in immunoblots. Subsequently, the antiserum was used in immunolocalization and in immunoblotting. The antiserum was recognized in a single prominent band of approximately 66kDa in immunoblots. Subsequently, the antiserum was used in immunolocalization and in immunoblotting.
Molecular Cloning and Expression of a Novel Gene, Oocyte-G1 in Oocyte and Granulose Cells of Mouse Ovary
Y. Zhang, J. Wu, Biological Technology, Shanghai Jiao Tong University, Shanghai, China

The oocyte is recognized as a source of regulatory molecules that influence follicular development through an array of actions on granulose cells. During efforts to clone oocyte development-related genes, we isolated a cDNA fragment by differential display reverse-transcription PCR (DDRT-PCR). To obtain cDNA 5′-and 3′-end sequences, mouse ovarian cDNA library (Stratagene) was screened. The library was constructed with poly(A) + mRNA from mouse ovaries of day 15. Using both oligo(dT)-and random hexamer priming with superscript reverse transcriptase (Invitrogen), EcoRI-adapter cDNAs were ligated to AZAP Express vector arms and packaged with Gigapack III packaging extracts (Stratagene). In the end, an open reading frame of 2886bp for the novel gene (Oocyte-G1) encoding a 960-residue protein was cloned. Northern blot analysis revealed presence of the 2.9Kb Oocyte-G1 mRNA in ovary, lung, kidney and testis. In Northern analysis of RNA from ovaries in vivo, Oocyte-G1 was expressed at moderate level on day10. Thereafter, on day 15, there was an increase in expression, followed by a decline in ovaries of day 20 and adults. However, Oocyte-G1 was undetected in ovaries of day 5. Furthermore, we studied production of Oocyte-G1 protein by using an antiseraum recognizing a peptide sequence unique to this gene in Western blotting and in immunolocalization. Signal was detected in oocyte and most granulose cells. The antiseraum recognized a single prominent band of approximately 110Kda in immunoblots. Taken together, our results suggest that Oocyte-G1 play an important role in oocyte development.

MicroRNA Profiling of Ovaries during the First Wave of Folliculogenesis in Mice
O. Suzuki, M. Koura, K. Takano, Y. Noguchi, K. Uchido-Yamada, J. Matuda; Lab. Exp. Animal Models, National Institute of Biomedical Innovation, Ibaraki, Japan

Oocytes accumulate a large quantity of mRNA in order to gain in oocyte development competence, but not all of this mRNA is translated into proteins before fertilization. MicroRNAs (miRNAs) are small non-coding RNAs that have critical roles in gene suppression, similar to siRNA mechanisms, in a wide variety of organs, which suggests that miRNAs are involved in gene regulation during oocyte growth. We reported that mouse oocytes gradually acquire developmental competence during the first wave of folliculogenesis (ASCB 2003). As the first step in analyzing the involvement of miRNAs in this process, we compared miRNA profiles at the whole-ovary level between ovaries of 17- and 24-day-old females; oocytes from the latter have greater developmental competence than those from the former do. miRNAs were extracted from the ovaries of thirty 17-day-old and ten 24-day-old Slc.B6D2F1 females, labeled with fluorescent dyes, and compared using a miRNA microarray (Filgen Array miRNA384 containing triplicate spots of Ambion’s mirVana miRNA probe set; Filgen). Of the 384 miRNAs tested, 11 (miR-223, miR-1224, miR-105, miR-143, miR-106b, miR-34b, miR-319d, miR-194, miR-140, miR-154, and let-7g) were upregulated (>1.5-fold increase) and 8 (let-7b, let-7i, let-7d, miR-20b, miR-129-3p, miR-207, miR-365, and miR-183) were downregulated (>1.5-fold decrease) in the ovaries of 24-day-old females compared with those from 17-day-old females. The marked difference in the miRNA profiles of ovaries of females of different ages suggests that miRNA is involved in the progression of oocyte growth during the first wave of folliculogenesis in mice.

Phosphorylation of the Oocyte-Embryo Specific Protein PAD16 following Oocyte Maturation
A. J. Snow, S. Vijayaraghavan, D. Kline; Biological Sciences, Kent State University, Kent, OH

PAD16, a peptidylarginine deiminase, is an abundant protein in mouse oocytes, eggs, and early embryos. Members of the peptidylarginine deiminase (PAD) family are known to catalyze the calcium-dependent conversion of a peptide-bound arginine to the non-standard citrulline residue, known as citrullination. PAD1s are known to be involved in the posttranslational modification of histones by citrullination. They are also associated with intermediate filaments and may be involved in cytoskeletal reorganization. The function, specificity, and enzymatic activity of PAD16 in oocytes, eggs, and embryos remain largely undefined. We found a cell cycle-dependent change in PAD16 phosphorylation during oocyte maturation, which may provide insight into PAD16 activity and its interactions with other cellular proteins. We identified an abundant 75 kDa protein that appears to be phosphorylated at a phosphoserine 14-3-3 binding motif in mature, metaphase II eggs and early embryos but not in immature, germinal vesicle stage oocytes. Gel electrophoresis and mass spectrometric analysis of the 75kDa protein band revealed that it was likely to be PAD16. One- and two-dimensional electrophoresis and immunoblotting with an anti-PAD16 antibody confirmed this. A phosphopeptide gel stain of oocyte and egg extracts revealed a number of phosphorylated proteins including a 75 kDa protein. Indirect immunofluorescence with anti-PAD16 demonstrated the PAD16 is present in oocytes and eggs, predominately in the cortex. Immunofluorescence staining with the anti-phosphoserine 14-3-3 antibody was not detected in oocytes. Far-western analysis using a GST-tagged 14-3-3 protein indicates that PAD16 may interact with 14-3-3. The striking developmental change in the phosphorylation state of PAD16 following oocyte maturation suggest that phosphorylation and/or 14-3-3 binding may serve as a means of intracellular PAD16 regulation.

Hypermotorization-activated Cyclic Nucleotide-gated (HCN) Channel Expression in the Rat Ovary
J. Yeh, L. Gaines, B. Kim, J. Peresie, A. Arroyo; Gynecology-Obstetrics, University at Buffalo, Buffalo, NY
Ion channels have been identified in the mammalian ovary, and they have been suggested that these channels may have a role in steroidogenesis and luteolysis. Hypermotorization-activated cyclic nucleotide-gated (HCN) channels are proteins that regulate electrical activity in the heart and brain. HCN channel actions are modulated by AMP. Whether HCN channels are present in the ovary and have a role in ovarian function are unknown. The purpose of this study was to analyze HCN2 channel expression and localization in the rat ovary. We used RT-PCR, western blot, and immunohistochemistry to study adult rat ovaries. Messenger RNA expression was found for HCN2 in ovarian tissue using RT-PCR. Western blot analysis showed protein expression of HCN2 in ovarian tissue lysates. Immunohistochemistry showed intense immunostaining for HCN2 in the granulosa cells, theca cells and oocytes of ovarian follicles and in corpora lutea. In summary, we found gene expression, protein expression, and follicular and luteal localization of HCN2 in the rat ovary. Based on these data, we hypothesize that HCN2 may be involved in ovarian follicular and/or luteal function.

Oocyte Signals Derived from Polyunsaturated Fatty Acids Control Sperm Recruitment
H. M. Kabagaya, 1 J. Watts, 2 C. Corrigan, 1 J. W. Edmonds, 1 E. Sztul, 1 J. Browse, 2 M. A. Miller 1; 1Cell Biology, University of Alabama at Birmingham, Birmingham, AL, 2Biological Chemistry, Washington State University, Pullman, WA

A fundamental question in animal development is how do motile cells find their correct target destinations. During mating in the nematode Caenorhabditis elegans, males inject sperm through the hermaphrodite vulva into the uterus. Amoeboid sperm crawl around fertilized eggs to the spermatheca, a convoluted tube where fertilization occurs. We show that polyunsaturated fatty acids (PUFAs), the precursors of oecosin signaling molecules, are necessary and sufficient in oocytes to control directional sperm motility within the uterus. PUFAs are transported from the intestine, the site of fat metabolism, to oocytes in yolk, a lipoprotein complex. Loss of the RME-2 low-density lipoprotein receptor, which mediates yolk endocytosis and fatty acid transport into oocytes, causes severe defects in sperm targeting. We used an RNA screen to identify genes required in oocytes for directional sperm motility. Ten genes encode lipid regulators implicated in the synthesis and transport of sperm-targeting signals. Our results support the hypothesis that PUFAs function in oocytes as precursors of signals that control sperm recruitment to the spermatheca. During mammalian immune responses, the eicosanoids prostaglandin D2 and Leukotriene B4 are rapidly generated at sites of inflammation and are required for eosinophil and T cell recruitment, likely by acting as chemoattractants. Thus, a common property of PUFAs in mammals and C. elegans is that these fats mediate local recruitment of motile cells to their target tissues.

Mechanochemical Signal Transduction: Potential Mechanism for Induction of Sperm Acrosome Exocytosis
B. Baibakov1, L. Gauthier1, T. L. Rankin2, P. Talbot2, J. Dean2; LCBH, NIDDK/NHLBI, Bethesda, MD, 1Department of Cell Biology and Neuroscience, University of California, Riverside, CA

The induction of sperm acrosome exocytosis in mouse fertilization has long engaged investigitative interest, but remains incompletely understood. At fertilization, spermatozoid bind to the zona pellucida (ZP), and undergo the acrosome reaction during initial gamete interactions. Following fertilization, ZP is proteolytically cleaved and sperm no longer bind to embryos. We assessed Acet-EGFP sperm binding to normal and huZP2 rescue eggs in which huZP2 replaces mouse ZP2, but remains uncleaved. Surprisingly, mouse sperm remain acrosome-intact for 2-3 hours after binding normal and up to 24 hours when bound to huZP2 rescue embryos, regardless of whether sperm are added before or after fertilization. The persistence of an intact acrosome indicates that sperm binding to the zona pellucida is not sufficient to induce acrosome exocytosis. A filter penetration assay suggests an alternative mechanism in which penetration into the zona matrix initiates a mechanochemical signal transduction, necessary to activate the acrosome reaction rather than signaling pathways involving zona-ligand binding to a sperm receptor.
The Spermatid Acroplaxome, Which Overlaps a mRNA Transcriptionally Silent Nuclear Domain, Contains Fer Tyrosine Kinase and Phosphorylated Cortactin

A. L. Kierszenbaum, E. Rivkin, L. L. Tres; Cell Biology & Anatomical Sciences, CUNY Medical School, New York, NY

The acroplaxome, a cytoskeletal plate with a desmosome-like marginal ring, anchors the acrosome to the spermatid nuclear envelope-nuclear lamina complex. F-actin and keratin 5 are two major cytoskeletal components of the acroplaxome. Three functions have been ascribed to the acroplaxome: (1) tethering of Golgi-derived proacrosomal vesicles transported by microtubule- and F-actin based molecular motors; (2) modulation of exogenous contractile forces generated by Sertoli cell ectoplasmic F-actin during spermiad head shaping; and (3) a positional stabilizer of the perinuclear microtubular manchette. Acroplaxome-related nuclear shape abnormalities occur in acrosomless rodent and human infertile sperm displaying globozoospermia. Studies were carried out to determine the dynamics of F-actin, and RNA transcription activity in the juxta-acroplaxome nuclear area. Testis Fer tyrosine kinase and phosphorylated cortactin were immunodetected in the acroplaxome during spermiad head elongation (steps 8 to 12 of spermiogenesis). Cortactin phosphorylation, known to be mediated by the Fer/Fyn tyrosine kinase pathway, has a role in F-actin depolymerization. Unphosphorylated cortactin was seen in the acroplaxome and manchette of elongating spermiads. Heterogeneous nuclear RNA (hnRNA) is not present in the juxta-acroplaxome nuclear region but is visualized in the rest of the nucleus of round spermiads. We postulate that cortactin tyrosine phosphorylation may modulate the cytoskeletal dynamics of F-actin in the acroplaxome in response to extracellular stimuli, including acrosome and chromatin in cell volume, two events associated with spermiogenesis. Anchorage of the acroplaxome to the subjacent spermatid nuclear envelope-nuclear lamina complex correlates with transcriptionally hnRNA silencing, presumably representing the initiation of regional chromatin remodeling during spermiad head shaping.

Orphan Neurotransmitter Transporter Required for Drosophila Spermiogenesis

N. Chatterjee, J. Rollins, C. W. Bazinet; Biological Sciences, St. John's University, Queens, NY

Neurotransmitter transporters play an essential role in synaptic transmission. Variation in transporter structure, distribution, and substrate play a large role in differentiating the specialized functions of the nervous system. A Drosophila gene, neurotransmitter transporter-like (ntl; CG7075) encodes a predicted protein that is a member of the well-known class of neurotransmitter sodium symporters with 12 transmembrane domains. Mutants have been isolated in this gene by mobilization of a nearby P transposable element. Males homozygous for disruptions in the ntl gene are sterile, but no other phenotypic effects of the mutations are apparent. Sexual dimorphism of sodium symporter family in spermiogenesis. Electron microscopy confirms this phenotype. Continuing studies are aimed at further understanding the unexpected role of an otherwise highly-conserved member of the neurotransmitter

Detection of DNA Damage Induced by MTT Using Alkaline Comet Assay in Porcine Spermatozoa

D. Han, S. Cho, Y. Kim, Y. Lee, J. Kim, S. Kim, J. Jang, S. Park, D. Choi, H. Ko, Y. Hwang, D. Kim; Biological Sciences, Gachon University of Medicine & Science, Incheon, Republic of Korea

Intracytoplasmic sperm injection (ICSI) is considered as an effective method for treatment with male factor infertility to conceive. Viable sperm has more fertilization rate than nonviable sperm in ICSI. The selection of viable sperm is important and it can be used for ICSI, if sperm DNA is not damaged. MTT (3-(4,5-dimethyl thiazol-2-yl)-2,5-diphenyl tetrazolium bromide) reduction assay is commonly used for evaluating sperm viability because it is simple and inexpensive. Yellow tetrazolium salt of MTT is converted to purple formazan by dehydrogenase in sperm mid-piece mitochondria. The decrease in percentage of MTT spermatozoa was detected after 2h added MTT because the formazan could be toxic. Comet assay can observe DNA damage in sperm. Fresh semen samples were diluted to 1 x 10^5 sperm/ml in PBS. MTT(5mg/ml of PBS) was added and incubated in 2h at 37 °C. Control group was not treated with same amount of PBS. Positive control group is treated with hydrogen peroxide. Every group was embedded in agarose gel on slide, lysed, and electrophoresed in alkaline phosphate. Slides were stained with Hoechst 3342 to detect sperm DNA damage by using fluorescence microscopy at absorption maximum 350nm and emission maximum 461nm. All procedures are progressed in blockage of the UV light to avoid extra sperm damage. The formazan produced by MTT reduction assay is not severely affected to sperm DNA. In conclusion, sperm MTT viability assay could be used as a reliable and appropriate method to select viable sperm for ICSI. This work was supported by the Research Project on the Production of Bio-organs ( No. 200508020701 ) Ministry of Agriculture and Forestry, Republic of Korea.

The C. elegans Germinal Center Kinase GCK-1 Is a P-Body Component That Inhibits Precocious Map Kinase Dependent Meiotic Maturation

K. R. Schouest, T. Furuta, N. Hisamoto, K. Matsumoto, J. M. Schumacher; Molecular Genetics, University of Texas MD Anderson Cancer Center, Houston, TX, 1Department of Molecular Biology, Nanyang University for Advanced Research, Nagona, Japan

P-bodies are enigmatic cytoplasmic RNA-protein (RNP) particles that have been implicated in RNA degradation, translational control, and RNA-mediated interference. In metazoans, evolutionarily conserved components of germ line P-bodies have recently been shown to be required for germ cell survival and the production of functional oocytes. In many species, oocyte development and maturation is also controlled by a highly conserved MAP kinase signaling cascade. Deciphering how these two critical regulatory pathways intersect is key to understanding evolutionarily conserved components of germ line P-bodies.

Expression and Localization of Plasma Membrane Ca2+-ATPase Isoform 4 in Bovine Testis and Epididymis

K. R. Schouest, 1 T. Furuta, 1 N. Hisamoto, 2 K. Matsumoto, 2 J. M. Schumacher 1; 1Molecular Genetics, University of Texas MD Anderson Cancer Center, Houston, TX, 2Department of Molecular Biology, Nanyang University for Advanced Research, Nagona, Japan

Capacitation, motility and acrosomal reaction are essential functions of the spermatozoon in the process of fertilization. Several steps of these functions are triggered by calcium dependent pathways, requiring pumping systems to remove excess intracellular calcium. It is known that the plasma membrane Ca2+-ATPase (PMCA) performs the major task of Ca2+-clearance in mouse spermatozoa. Four different isoforms (PMCA 1-4) have been identified and multiple splice variants of these isoforms have been described. Especially PMCA 4 has been reported to be important for male fertility. We therefore examined the protein- and gene expression of PMCA 4 in bovine testis and epididymis. In situ-hybridization was performed to analyse the distribution pattern of the gene expression. PMCA 4 expression was restricted to spermatogonia and epithelial cells of the epididymis (head, body, tail). Performing immunohistochemistry we detected the protein in the plasma membrane of spermatocytes and spermatids in bull testis as well as in the basal layer of the epididymal epithelium. Using RT-PCR we could show a splice variant switch of PMCA 4 from the epididymal head/body to the epididymal tail. Generating an antibody against the PMCA 4 splice variant, we detected this splice variant exclusively in the apical plasma membrane of epithelial cells of the epididymal tail. Presently, we are analysing the distribution pattern of the PMCA 4 in bull epididymal spermatozoa. We have recently shown that bovine sperm PMCA is stimulated by PDC-109, a secretory protein from bovine seminal vesicles. Further studies have to elucidate, whether or not PMCA 4 is the isoform which is stimulated by PDC-109.

Ca2+-ATPases Are Required for Motility and the Acrosome Reaction of Sea Urchin Spermatozoa

H. J. Gunaratne, V. D. Vacquier; Marine Biotechnology and Biomedicine, Scripps Institution of Oceanography, La Jolla, CA
Three Ca\(^{2+}\)-ATPases regulate intracellular Ca\(^{2+}\) concentrations in animal cells: plasma membrane Ca\(^{2+}\)-ATPase (PMCA), sarco-endoplasmic reticulum Ca\(^{2+}\)-ATPase (SERCA) and secretory pathway Ca\(^{2+}\)-ATPase (SPCA). There are few studies of Ca\(^{2+}\)-ATPases in spermatozoa, which is surprising considering the importance of these enzymes in all cells. Here we describe the expression, protein and gene features, localization, and importance of Ca\(^{2+}\)-ATPases in sea urchin spermatozoa. Sea urchin (Strongylocentrotus purpuratus) spermatozoa express PMCA and SPCA, but not SERCA. Sp-PMCA is 1,154 amino acids and has 30% identity and 50% similarity to all four human PMCA. Sp-SPCA shares the fastest of typical PMCA, including domains for calmodulin binding, ATP binding, Sp-SPCA phosphorylation, and 10 putative transmembrane segments with two large cytoplasmic loops. Sp-SPCA is 912 amino acids and has 66% identity and 80% similarity to human SPCA1. As is common for a typical SPCA, Sp-SPCA has ATP binding and ATPase phosphorylation sites, 10 transmembrane helices and conserved Ca\(^{2+}\) binding residues. Southern blots and genome analysis show that both are single copy genes. Further genome annotation reveals that Sp-PMCA and Sp-SPCA have 17 and 23 exons. Immunofluorescence and immunoblotting show that PMCA localizes to the sperm head, whereas SPCA localizes to the mitochondrion. Treatment of live sea urchin sperm with the PMCA inhibitor, 5-(4-carboxyphenyl)-N-endoethylcarboxamido-1-2/(4-nitrophenyl)benzamide (pH 7.2) inhibits both PMCA and SPCA blocks the sperm acrosome reaction. Ca\(^{2+}\) measurement using the above inhibitors show that 75% of Ca\(^{2+}\) is expelled by PMCA and SPCA and 25% by Na\(^{+}\) dependent Ca\(^{2+}\) exchangers. These findings indicate that PMCA and SPCA regulate Ca\(^{2+}\) signals required for successful fertilization in sea urchins.

496 Adenosine- and Catecholamine-signaled Activation of Sperm Motility Does Not Involve Standard Receptors

S. M. Schuh, B. Hille, D. F. Babcock; Physiology and Biophysics, University of Washington, Seattle, WA Various extracellular signals may alter the motility of mammalian sperm as they progress through the female reproductive tract. Our past work used stop-motion imaging and waveform analysis to show that sperm motility is increased by adenine nucleotides and catecholamines, two classes of small molecules found in mammalian reproductive fluids. We also showed that acceleration of the flagellar beat by 2-chloro-2'-deoxyadenosine (Cl-dAdo) or isoproterenol (ISO) requires extracellular Ca\(^{2+}\), the atypical sperm adenylyl cyclase, cAMP, and protein kinase A. We now find several known agonists of the adenosine and β-adrenergic receptors of somatic cells also speed the flagellar beat of mouse sperm, suggesting that sperm may possess similar receptors. However, the potent adenosine receptor antagonist DPCPX did not block the action of Cl-dAdo on sperm. Also unexpectedly, the β-adrenergic antagonists propranolol, metoprolol, atenolol, and butoxamine acted as accelerating agonists in sperm. Furthermore, the flagellar beat was increased by both the β- and α-isomers of the catecholamines ISO, noradrenaline, and epinephrine, whereas α-isomers have much greater potency for typical adrenergic receptors. These results are inconsistent with involvement of standard G protein-coupled receptors that mediate adenosine and adrenergic actions in somatic cells. In support of the alternative hypothesis that these agonists may act at an intracellular site, we find that the accelerating actions of Cl-dAdo and 2'-deoxyadenosine are slowed more than 5-fold by the potent nucleoside transport inhibitors, diprydamole and nitrobenzylxanthine. Hence the action of adenosine nucleosides on sperm motility may require their transport into the cell. Further study of the underlying signaling pathways may reveal how sperm respond to extracellular signals received enroute to the egg.

497 Role of PDZ Domain-containing Proteins in Sperm-Oviduct Interaction

H. Peng,1 C. Yeh,2 C. Chiuchang,2 H. Ho1; 1Life Science, Tzu Chi University, Hualien, Taiwan, 2Anatomy, Tzu Chi University, Hualien, Taiwan, 3Institute of Integrative Physiology and Clinical Sciences, Tzu Chi University, Hualien, Taiwan Recent studies showed that PDZ (PSD-95/Discs-large/ZO-1) domains are ubiquitous protein interaction modules that play an important role in cellular signaling, adhesion, transport, etc. We found that in mated female mice, a putative PDZ domain-containing protein (accession reference: AK012129.1) was highly expressed in the oviduct using a cDNA microarray assay. We further examined the protein profiles among oviducts collected at different time points after coitus and in control. In western blot using mouse anti-PDZ antibody as primary antibody, two PDZ domain-containing proteins were clearly detected. Both 25 kDa and 50 kDa proteins showed increased expression level as ovulation approached and number of hyperactivated sperm increased. Besides, using overacclimated mouse model, we found that expression level of PDZ domain-containing proteins and number of sperm found in the oviduct decreased in ovariecotomized oviduct; interestingly, ovariecotomized proteins might play a role in sperm expression as well as serving as the receptors or modulators. Some of the PDZ domain-containing proteins have been recognized to regulate transmembrane proteins. It is possible that sperm protein recognition molecules were regulated by PDZ domain-containing proteins and led to release of sperm from the oviductal epithelium around the time of ovulation.

498 Annexins Are Candidates for the Oviductal Sperm Receptors That Hold Bull Sperm in a Storage Reservoir

G. G. Ignotz, M. Y. Cho, S. S. Suarez; Biomedical Sciences, Cornell University, Ithaca, NY Sperm of eutherian mammals are held in a storage reservoir in the posterior segment of the oviduct by binding to the mucosal epithelium. In the bovine, we determined that seminal vesicle secretory proteins in the BSP family, namely PDC-109 (BSP A1/A2), BSP-A3, and BSP-30-kDa, coat the sperm head and enable sperm to bind to the epithelium. Our subsequent objective was to identify the receptors for sperm on the oviductal epithelium. Antibodies to each of the BSPs were covalently linked to agarose beads. Each BSP was purified and bound to the beads coated with the corresponding antibody. Proteins extracted from apical membranes of bovine oviducal epithelium were passed over columns of each BSP protein bound to its corresponding antibody. Unbound proteins were washed from the beads and bound proteins were eluted using EGTA, because sperm binding to oviductal epithelium is dependent on calcium. The eluates were resolved on SDS PAGE gels. Protein bands of 34 and 38 kDa were the sole prominent bands detected by silver staining in the eluates from each of the three columns. Protein constituents of the bands were identified by tandem mass spectrometry of tryptic digests to be annexins (ANXA) 1,2,4, and 5. Subsequently, commercial antibodies to ANXA1, 2, and 4 were used to confirm their identity. In the eluates from an antibody to ANXA1, M. Y. Cho, S. S. Suarez; Biomedical Sciences, Cornell University, Ithaca, NY and 50 kDa proteins showed increased expression level as ovulation approached and number of hyperactivated sperm increased. Beside, using overacclimated mouse model, we found that expression level of PDZ domain-containing proteins and number of sperm found in the oviduct decreased in ovariecotomized oviduct; interestingly, ovariecotomized proteins might play a role in sperm expression as well as serving as the receptors or modulators. Some of the PDZ domain-containing proteins have been recognized to regulate transmembrane proteins. It is possible that sperm protein recognition molecules were regulated by PDZ domain-containing proteins and led to release of sperm from the oviductal epithelium around the time of ovulation.

499 Altered Wnt Signaling in the Megf7 Deficient Mouse Results in the Expansion of the Apical Ectodermal Ridge and Polydactyly

E. B. Johnson,1 R. E. Hammer,1 J. Herz1; 1Molecular Genetics, UT Southwestern Medical Center, Dallas, TX, 2Biochemistry, UT Southwestern Medical Center, Dallas, TX Multiple EGF-like domains-7 (Megf7/Lrp4) is a member of the low-density lipoprotein receptor gene family, a class of ancient and highly conserved cell surface receptors with broad functions in cargo transport and cellular signaling. To gain insight into the as yet unknown biological role of Megf7, we have disrupted the gene in mice. The Megf7 deficient mouse has polydactyly, which is characterized by the multiplication and fusion of digits in both the forelimbs and hind limbs. During limb development, Megf7 is expressed in the ventral ectoderm as well as the Apical Ectodermal Ridge (AER). The AER is expanded along the ventral and dorsal aspect of the limb in the Megf7 deficient embryo. In contrast, the AER in wild type embryos is restricted to a thin band of pseudostratified epithelium at the distal edge of the developing limb. The expansion of the AER in the Megf7 deficient limbs results in the disruption of the expression pattern of many genes that are required for limb development such as Bmps, Shh, Fgts, Wnts and Lmx1b. The Megf7 deficient phenotype is very similar to that of the double mutant mutant mice (Adamska et al. 2003) suggesting that Megf7 is involved in the Wnt signaling pathway. The hypothesis of Megf7 as a Wnt modulator is supported by the fact that Megf7 inhibits the Wnt1 induced stabilization of β-catenin in a dose dependent manner in the TOPflash reporter system, a reporter system that measures the activity of the canonical Wnt signaling pathway. In conclusion, the inhibition of the Wnt pathway by Megf7 is required for patterning during limb development. This work significantly contributes to our understanding of the regulation of limb development, provides a new mechanism for the modulation of Wnt signaling, and adds to our understanding of the many important functions of LDL receptor gene family.

500 A Putative Transcriptional Factor, Seson Establishes Left-Right Asymmetry in Zebrafish Embryo via Nodal Signaling Pathway

Y. Park,1 C. Lee,2 M. Rhee1; 1Biology, Chungnam National University, Daejeon, Republic of Korea, 2Biological Sciences, Inha University, Incheon, Republic of Korea We are reporting here that a novel C2H2 zinc finger protein, Seson is a critical element for left-right asymmetry establishment in the vertebrate embryo. It is a critical element of Left-Right asymmetry establishing mechanism in the zebrafish embryo. Seson is localized in the cytoplasm, but translocated to the nucleus in response to TGFB and TNF, suggesting that it might be involved in the intracellular signaling pathway. Second, Seson transcripts are highly expressed in the whole blastomes at early embryonic stages, but restricted in the head region and the anterior midline after 24 hpf, and in the anterior midline including otic vesicle, particularly observed as a symmetrical oblique line in the midbrain at 48 hpf. Third, functional analysis using overexpression and knock-down experiment found that Seson is critical to the establishment of left-right asymmetry in brain and cardiac development during zebrafish embryogenesis. Analysis of expression
pattern of various molecular marker genes involved in left-right asymmetry found that fluctuation of sexon expression gives rise to significant changes in the expression patterns of the genes. In particular, sexon is essential for formation of dorsal forerunner cell as well as expression of lerdr in the Kappler’s vesicle (KV). Finally, knock-down of sexon significantly reduces expression of sqt at the marginal cells. Considering that Sqt is a ligand of Nodal, a critical morphogen for KV, it appears that Sexon functions as a modulator of sqt-mediated Nodal signaling pathway to establish left-right asymmetry in the zebrafish embryo.

MIP-1α Increased Osteoclastogenesis and Survival of Osteoclast
H. Shin, J. Lee, V. Pham, M. Park, B. Kwon, H. Choi; Department of Biological Sciences and the Immunomodulation Research Center, University of Ulsan, Ulsan, Republic of Korea

After receptor activator of nuclear factor-kappaB ligand (RANKL) binding, increased osteoclast formation was observed by bone marrow macrophages (BMM) from BALB/c strain, comparing with that from C57BL/6 mice. Expression of MIP-1α mRNA and protein level was much higher in BMM stimulated by RANKL from BALB/c mice than those of C57BL/6 mice, suggesting a possible role of MIP-1α in enhanced osteoclast formation. Transcripts of CCR1 and CCR5, MIP-1α receptors, were detectable in un-stimulated BMM cells of both at similar level. Blockade of MIP-1α inhibited osteoclast formation when the BMM from BALB/c were incubated with RANKL, suggesting that MIP-1α plays a role as a positive regulator of osteoclastogenesis. MIP-1α enhanced osteoclast formation not only at early stage, but also at late stage, preventing loss of in vitro osteoclast formation through induction of apoptosis. The prolongation of survival of mature osteoclast by MIP-1α was via NF-kappaB activation. The survival activity of RANKL was dependent on its ability to induce MIP-1α.

IL-20 Promotes Angiogenic Processes in PAE Endothelial Cells
K. Tritsaris, 1 M. Myren, 1 M. V. Hulshmans, 1 S. Ditte1, A. J. Hansen, 2 S. Dissing; 1 Department of Medical Physiology, University of Copenhagen, Copenhagen, Denmark, 2Cancer & Immunobiology, NOVO Nordisk A/S, Måløv, Denmark

Previous findings have suggested that IL-20 is implicated in psoriasis. The fact that angiogenesis and hypervascularization are characteristic features of the psoriatic plaque which is observed in IL-20 transgenic mice, prompted us to investigate whether IL-20 has a potential role in the angiogenic process. We employed pig aorta endothelial (PAE) cells and found mRNA for both IL-20Rα and β as well as IL-22R mRNA. Cell signalling studies revealed that the JAK/STAT pathway becomes activated (STAT5 and Jak2 phosphorylation) after IL-20 stimulation (5 min) and furthermore that IL-20 activates the MAP kinase pathway (Erk1/2 phosphorylation) and the PI3K/Akt pathway. In addition, IL-20 activation causes a rapid and transient increase in the intracellular, free Ca²⁺ concentration ([Ca²⁺]i). This rise in [Ca²⁺]i was due to Ca²⁺ mobilization from intracellular stores and was completely inhibited by 5 µM SU73122 - an inhibitor of the Ca²⁺-induced Ca²⁺ release (CICR) channels. Furthermore that IL-20 activates the MAP kinase pathway (Erk1/2 phosphorylation) and the PI3K/Akt pathway. In conclusion, endothelial cells possess IL-20 receptors and IL-20 activates cell signaling that support angiogenic processes and causes endothelial cell apoptosis.

Increased Phosphorylation and Transactivation Properties of IPF1/PDX1 by HIPK2-dependent Mechanisms
M. Boucher, M. Edlund; UCMC (Umeå Center for Molecular Medicine), University of Umeå, Umeå, Sweden

The transcription factor IPF1/PDX1 plays a crucial role in both pancreas development and maintenance of beta-cell function. Indeed, homozygous disruption of the ipf1/pdx1 gene results in pancreas agenesis in both mice and human. Moreover, targeted disruption of ipf1/pdx1 gene in beta-cells leads to diabetes, whereas reduced expression levels affect insulin secretion and glucose homeostasis. In differentiated beta-cells, IPF1/PDX1 has been shown to bind and regulate the transcription of several genes involved in glucose sensing and insulin synthesis (plin2, glucokinase, insulin) underlying his key role in glucose homeostasis. Nevertheless, despite this clearly established role in pancreas development and beta-cell function, the mechanisms involved in IPF1/PDX1 protein expression and function remain to be clarified. METHODS AND RESULTS. 1- Transparent transfection of the newly identified cofactor homeodomain-interacting protein kinase-2 (HIPK2 WT) increased, in a dose-dependent manner, the phosphorylation and the protein expression level of IPF1/PDX1, whereas the kinase-dead HIPK2 (K221R) had no effect. 2- Luciferase assays (using either the IPF1/PDX1 minimal binding site or the insulin promoter) demonstrated that HIPK2 WT, and not the kinase-dead HIPK2 K221R, dose-dependently increased IPF1/PDX1 transactivation properties. 3- Immunofluorescence studies showed a co-localization of HIPK2 and IPF1/PDX1 in the nucleus of co-transfected cells. 4- More importantly, in situ experiments revealed that hipk2 mRNA is detected in IPF1/PDX1-expressing cells during mouse pancreas development i.e. hipk2 is detected in pancreatic progenitor cells early during pancreas development and, as the epithelial pancreatic cells differentiate, hipk2 expression become restricted to beta-cells. CONCLUSION. These results identify HIPK2 as a new IPF1/PDX1 regulator and suggest that the kinase activity of this newly identified cofactor could modulate IPF1/PDX1 function during pancreas development and, later on, in differentiated beta-cells.

JSAPI Regulates Proliferation of Granule Precursor Cells in the Developing Mouse Cerebellum
T. Sato, 1 T. Tomishima, H. Hira, M. Asano, K. Yoshio; 1Division of Molecular Cell Signaling, Cancer Research Institute, Kanazawa University, Kanazawa, Japan, 2Department of Cellular Neurophysiology, Graduate School of Medical Science, Kanazawa University, Kanazawa, Japan, 3Division of Transgenic Animal Science, Advanced Science Research Center, Kanazawa University, Kanazawa, Japan

MAP kinase (MAPK) intracellular signaling system employs scaffold proteins, in part, to organize the MAPK signaling components into functional modules, thereby enabling the efficient activation of specific MAPK pathways. The c-Jun N-terminal kinase (JNK)/stress-activated protein kinase (JNK) becomes involved in glucose sensing and insulin synthesis (plin2, glucokinase, insulin) underlying his key role in glucose homeostasis. Nevertheless, despite this clearly established role in pancreas development and beta-cell function, the mechanisms involved in IPF1/PDX1 protein expression and function remain to be clarified. METHODS AND RESULTS. 1- Transparent transfection of the newly identified cofactor homeodomain-interacting protein kinase-2 (HIPK2 WT) increased, in a dose-dependent manner, the phosphorylation and the protein expression level of IPF1/PDX1, whereas the kinase-dead HIPK2 (K221R) had no effect. 2- Luciferase assays (using either the IPF1/PDX1 minimal binding site or the insulin promoter) demonstrated that HIPK2 WT, and not the kinase-dead HIPK2 K221R, dose-dependently increased IPF1/PDX1 transactivation properties. 3- Immunofluorescence studies showed a co-localization of HIPK2 and IPF1/PDX1 in the nucleus of co-transfected cells. 4- More importantly, in situ experiments revealed that hipk2 mRNA is detected in IPF1/PDX1-expressing cells during mouse pancreas development i.e. hipk2 is detected in pancreatic progenitor cells early during pancreas development and, as the epithelial pancreatic cells differentiate, hipk2 expression become restricted to beta-cells. CONCLUSION. These results identify HIPK2 as a new IPF1/PDX1 regulator and suggest that the kinase activity of this newly identified cofactor could modulate IPF1/PDX1 function during pancreas development and, later on, in differentiated beta-cells.

Roles of Src Family Kinases in the Development of Neural Crest Cell Lineages
A. Takatsuka, 1 M. Koike, 2 Y. Uchiyama, K. Nishida, S. Nada, C. Oneyama, M. Okada; 1Oncogene Research, RMD, Osaka University, Osaka, Japan, 2Cell Biology and Neurosciences, Graduate School of Medicine, Osaka University, Osaka, Japan, 3Ophthalmology and Visual Science, Graduate School of Medicine, Tohoku University, Miyagi, Japan

Src family kinases (SKs) are non-receptor tyrosine kinases that play pivotal roles in regulating cellular functions, including cell adhesion and migration. The activity of SKs is negatively regulated by Carboxy-terminal Src Kinase (Csk). The analysis of Csk knockout mice has shown that SKs play critical roles under the control of Csk in normal animal development. However, the precise in vivo functions of SKs/Csk complex remain to be clarified. To address this issue, we generated mutant mice in which Csk was conditionally inactivated in the neural crest lineage by Cre-loxP system using a Protein Zero (P0) promoter. The mutant mice exhibited facial dysplasia so-called “short nose” and prominent defects in the anterior ocular segment. In the cerebellum, the mutant mouse showed severe opacity, extensive vasculization and anterior synchie. Electron microscopic analysis revealed the deletion of conral endothelium as well as its basement membrane in the central part of mutant cerebellum and the abnormal arrangement of collagen fibrils in the stroma. The mutant mice showed a constitutive activation of SKs accompanied by elevated tyrosine phosphorylations of several cellular proteins, although there was substantial degradation of activated SKs. These mutant cells also exhibited hypomotility and morphological changes compared with control cell lines. RT-PCR and zymography analyses revealed that molecules involved in collagen fibril construction, including procollagen1a1, Adamts2 and MMP2, were up-regulated in the mutant cells. These results suggest that the SKs/Csk system plays crucial roles in pancreas development through regulating the organization of extracellular matrices.

**Fibroblast Cells from Young and Aged Long-lived Ames Dwarf Mice Exhibit Resistance to ROS Generated by Mitochondrial Dysfunction**

C. Hsieh, J. Papapantoniou; Biochemistry & Molecular Biology, University of Texas Medical Branch, Galveston, TX

The Free radical theory of aging proposes that oxidative stress (ROS) generated by mitochondrial dysfunction plays a major role in determination of rates of aging and longevity. This is supported by observations that resistance to ROS is a characteristic of experimental models of longevity, e.g., *C. elegans*, *Drosophila* and rodents. Previously we demonstrated that activation of the p38 MAPK stress response pathway by mitochondrial generated ROS is linked to the dissociation of an inhibitory threonine (Trx)-ASK1 complex. Thus, the ratio of (Trx)-ASK1 : free ASK1 regulates the level of p38 MAPK activity. Furthermore, the (Trx)-ASK1 pool level is significantly higher in both young and aged long-lived Snell dwarf mice which explains their decreased levels of endogenous ASK1 and downstream p38 MAPK activities. We propose that these are characteristics indicative of resistance to oxidative stress and decreased levels of endogenous ROS production. In this study we investigated whether dermal fibroblasts from long-lived Ames dwarf mice exhibit resistance to ROS generated by mitochondrial dysfunction. Our data indicate that the dwarf fibroblasts exhibit: (1) resistance to rotenone (Rot)-mediated induction of p38 MAPK activity. In fact, higher doses of this electron transport chain inhibitor of Complex I were required to activate the dwarf fibroblast p38 MAPK activity to the level that occurs in the wild-type cells. (2) upon each transfer the dwarf fibroblasts exhibit an initial lag period of growth followed by a slower growth rate. Our results suggest that Ames dwarf fibroblasts are resistant to the ROS generated by dysfunction of electron transport chain Complex I.

**Role and Control of Patched Traffic in Hedgehog Signaling during Fly Development**

A. Brigui, A. Pleus; Genetics of Development and Evolution, Institut Jacques-Monod, Paris, France

Hedgehog (HH) signaling plays key roles during development of many animals and its mis-regulation is associated with numerous cancers. The precise events governing the reception and transduction of the HH signal remain elusive, but links between HH signaling and vesicular traffic have recently emerged. HH action on its target cells involves: the 12 transmembranes receptor Patched (PTC) and the transduce related protein Smoothened (SMO). SMO is associated with an intracellular signaling complex which modulates the activity of the transcription factors GLI1/Cubitus interruptus. In absence of HH, PTC down-regulates the pathway by inhibiting SMO. SMO is endocytosed and targeted to the lysosome. After reception of HH, PTC inhibition is relieved, PTC bounded to HH is endocytosed and degraded in the lysosome. SMO is then stabilized at the plasma membrane which is sufficient to activate the pathway. We use the fly *Drosophila melanogaster* to study the role and the control of PTC traffic in HH signalling. We are characterizing PTC traffic (with and without HH) by colocalisation with vesicular markers. Moreover, we have isolated new physical interactions between PTC and different proteins that could regulate its traffic, including an HECT ubiquitin ligase of the Rsp5/NEDD4 family which is known to regulate the stability, the activity and the localization of their target proteins. All the PTCs, SMO and Patched interact with multiple proteins involved in vesicular transport and the ubiquitin/proteasome machinery (Rsp5, NEDD4, Skp1, Smurf1...). We propose that these interactions could control the activity of the PTC traffic and could be a strategy to regulate the activity of the HH pathway.

**The Role of Drosophila Auxillin in Notch Ligand Endocytosis**

H. C. Chang, T. Bai, J. Bayaraktar, E. Hagedorn, V. Kandachar; Biological Sciences, Purdue University, West Lafayette, IN

The Notch cascade, a highly conserved signaling module, plays a central role in diverse aspects of metazoan development. Mutations disrupting components of this pathway can cause severe tissue malformations and cancers in mammals. As the receptors and ligands are both widely expressed, the activity of this signaling cascade needs to be tightly regulated. Recent data from many groups have suggested that ligand endocytosis is critical for the activation of the Notch cascade, although the mechanism of how the internalization of Notch ligands leads to receptor activation remains poorly understood. We have isolated several mutations in the Drosophila homolog of auxillin, a J-domain-containing protein known to cooperate with Hsc70 in the disassembly of clathrin coats from clathrin-coated vesicles in vitro. Consistent with this biochemical role, animals with reduced auxillin function exhibit genetic interactions with Hsc70 and clathrin.

Interestingly, the auxillin mutations interact specifically with Notch and disrupt several Notch-mediated processes. Experimental analysis suggests that the J-domain, N-terminal kinase domain, and the C-terminal clathrin binding domain are all required for Notch signaling. Genetic evidence places auxillin function in the signal-sending cells, upstream of Notch receptor activation, suggesting that the relevant cargo for this auxillin-mediated endocytosis is the Notch ligand, Delta. Indeed, the localization of Delta protein is disrupted in auxillin mutant tissues. Thus, our data suggest that auxillin is required for Notch signaling and that ligand endocytosis in the signal-sending cells needs to proceed past coat disassembly to activate Notch.

509

**A Functional Role of ADAM 10 on Chondro-inhibitory Action of TGFβ3 in Chick Leg Bud Mesenchymal Cells**

E. Jin, K. Park, Y. Yoo, Y. Choi, S. Kang; Biological Sciences, Kyungpook National University, Daegu, Republic of Korea

Among the numerous factors involved in the regulation of chondrogenesis, transforming growth factor β (TGF-β) family has been implicated in controlling cartilage development. However, the regulatory mechanism of TGF-β3 during chondrogenesis of primary mesenchymal cells remains to be characterized in detail. Using differential display polymerase chain reaction screening, we identified a novel metalloproteinase (ADAM 10) which resulted in downregulation of ADAM 10 and a concomitant activation of Notch signaling. Electrotransporation of ADAM 10 morpholino antisense oligonucleotides suppressed precartilage condensation via downregulation of proliferation and subsequent chondrogenic differentiation as observed when chondrogenic-competent cells were exposed to TGF-β3. Downregulation of ADAM 10 inhibited ectodermal shedding of delta, a ligand of Notch receptor and led to upregulation of Notch signaling. Electroporation of Notch specific siRNA overcome the chondro-inhibitory effect of TGF-β3 by upregulation of cell proliferation and subsequent precartilage condensation. Collectively, our data suggest that downregulation of ADAM 10 is responsible for chondro-inhibitory action of TGFB3 through activation of Notch signaling.

**The Function of BRE Gene in Embryonic Interdigital Tissues**

W. Wong; Department of Anatomy, The Chinese University of Hong Kong, Hong Kong

In multicellular organisms, programmed cell death (PCD) is one of the most important developmental processes in determining the morphology of organs and tissues. For instance, PCD helps in sculpting the final shape of the limb - with death of the interdigital tissues in hand- and foot-plates. Consequently, the limb has been universally adopted as a model for studying PCD - because of the ease of manipulation and the defined spatial and temporal expression pattern of PCD in the interdigital tissues. Limb model was used to study the function of a gene called Brain and Reproductive organ-Expressed (Bre) which is a stress-modulating gene. Bre expression was previously found to be inhibited when fibroblasts were treated with UV and DNA-damaging agents. Similar results could also be produced by treating brain gliona cell U251 and promyelocytic cell HK-60 with retinoic acid. Retinoic acid is known to play a major role in tissue malformations and cancers in mammals. As the receptors and ligands are both widely expressed, the activity of this signaling cascade needs to be tightly regulated. Recent data from many groups have suggested that ligand endocytosis is critical for the activation of the Notch cascade, although the mechanism of how the internalization of Notch ligands leads to receptor activation remains poorly understood. We have isolated several mutations in the *Drosophila* homolog of auxillin, a J-domain-containing protein known to cooperate with Hsc70 in the disassembly of clathrin coats from clathrin-coated vesicles in vitro. Consistent with this biochemical role, animals with reduced auxillin function exhibit genetic interactions with Hsc70 and clathrin.

Interestingly, the auxillin mutations interact specifically with Notch and disrupt several Notch-mediated processes. Experimental analysis suggests that the J-domain, N-terminal kinase domain, and the C-terminal clathrin binding domain are all required for Notch signaling. Genetic evidence places auxillin function in the signal-sending cells, upstream of Notch receptor activation, suggesting that the relevant cargo for this auxillin-mediated endocytosis is the Notch ligand, Delta. Indeed, the localization of Delta protein is disrupted in auxillin mutant tissues. Thus, our data suggest that auxillin is required for Notch signaling and that ligand endocytosis in the signal-sending cells needs to proceed past coat disassembly to activate Notch.

**Dots Versus Stripes: MAPK/ERK Signaling Pathway in Periodic Feather Pattern Formation**

C. Lin, T. Jiang, R. Baker, P. Maini, R. Widelitz, C. Chuong; Pathology, University of Southern California, Los Angeles, CA, Centre for Mathematical Biology, Mathematical Institute, Oxford, United Kingdom

A fundamental problem in developmental biology is to understand the molecular basis of pattern formation. To address this issue, we examined the role of growth factors in a cultured embryonic chicken skin model. FGF activates feather bud formation, but the cellular and molecular mechanisms of this “activation” remain unknown. We show here that FGF4 induces MAPK/ERK phosphorylation during bud morphogenesis. The MAPK/ERK pathway was suppressed in skin explant cultures using three methods: RCAS mediated expression of a soluble dominant negative FGFRI, chemical ERK inhibitor U0126 and siRNA against Raf. Dose- and stage-dependent studies show a critical range of FGF doses, reflecting inhibited feather bud regression (e.g., increased with higher inhibitor dosage and earlier times of administration). Unregulated stripes show moderate levels of Shh, Notch and delta expression which, unlike the controls, are unpatterned. Epithelial-mesenchymal recombination showed that the ERK inhibitor acts primarily on the mesenchyme. Real time effects were recorded by time-lapse video-microscopy. Skin explants were grown in an environmental chamber (Wafergen SmartSlide) enabling us to continually observe cell movements and track cells using fluorescent markers. Cultures remained healthy for 5 days. The movie shows the distinctive formative process of stripes versus dots. Analyses of Dot labelled cells showed an increase in mesenchymal cell motility following ERK inhibition. In the controls, plaque epithelia emerge by cell rearrangement and coordinated cell shape elongation. In explants treated with ERK inhibitors, epithelial cells remain hexagonally shaped and randomly arranged. Earlier we proposed that a reaction-diffusion mechanism is involved in periodic feather bud pattern formation and that FGF is required for the stochastic induction of initial peaks. Here we further show that the FGF pathway acting through MAPK/ERK is required in chemotactic cell migration to stabilize and pattern the periodically arranged feather primordia. A mathematical model is developed.

512 A Genome-wide Survey and Characterization of SFKs and PLCs in the Sea Urchin I. K. Townley, M. Raisch, S. R. Saxon, K. R. Foltz; MCDB, UCSB, Santa Barbara, CA

In echinoderms (sea urchin and sea star), a current model of egg activation at fertilization involves the stimulation of at least one Src family kinase (SFK) and subsequent activation of phospholipase C gamma (PLCγ). PLCγ generates inositol trisphosphate (IP3) causing release of Ca2+ from the egg endoplasmic reticulum (ER). Inhibition of SFK or PLCγ activity blocks Ca2+ release. In the purple sea urchin Strongylocentrotus purpuratus, multiple SFKs of the Src (SFK1, Frk, SFK5, SFK7), Abl, Tec and Csk families as well as PLCs (orthologs of 2 forms of β and single gene copies of δ, γ, and ε) have been identified through genome mining. CDNs encoding the SFKs have been cloned partially or in full, but the SFK orthology assignments are not obvious. While SpSFK1 is necessary for Ca2+ release at egg activation (Giusti et al. 2003. Dev Biol, 256, 367-378), the roles of the other SFKs are unknown and currently are being investigated using kinase activity profiling and dominant interference. Immunolocalization using specific antibodies revealed that SpSFK1 and SpPLCγ are localized to the cortex of the egg after fertilization enriched especially around the point of sperm-egg interaction. Often, a patchy cortical localization is observed after fertilization, but the biological relevance of this is unknown at present. Supported by an NSF award to KRF.

513 Histone Deacetylase Regulates Type II Collagen Expression in Articular Chondrocytes Y. Huh, Y. Sung-Sook, J. Chun; Life Science, GIST, Gwangju, Republic of Korea

Histone deacetylase (HDAC) regulates various cellular processes including differentiation by modulating transcription of a number of target genes. Differentiated phenotypes of articular chondrocytes are unstable in culture and rapidly lost during a serial monolayer culture. This process is designed as “dedifferentiation” which is characterized by the cessation of type II collagen expression, a hallmark of differentiated chondrocyte phenotypes. This study investigated a role of HDAC in type II collagen expression in primary culture chondrocytes. We found that HDAC activity in differentiated articular chondrocytes was dramatically decreased during dedifferentiation of chondrocytes caused by a serial monolayer culture. Inhibition of HDAC activity with trichostatin A (TSA) or PDX101 promoted hyperacetylation of histone 4 in articular chondrocytes without affecting cell viability. HDAC inhibition was also sufficient to cause chondrocyte dedifferentiation by blocking type II collagen expression in both transcriptional and translational levels. HDAC inhibition also blocked redifferentiation of dedifferentiated chondrocytes, which was induced by a three dimensional pellet culture of dedifferentiated chondrocytes. Because up-regulation of Wnt-5a and down-regulation of Wnt-11 is known to regulate chondrocyte dedifferentiation (i.e., type II collagen expression), we examined whether HDAC regulates type II collagen expression by modulating these Wnts expression. HDAC inhibition in chondrocytes caused the expression of Wnt-5a to increase and Wnt-11 expression to decrease. Taken together, our results suggest that HDAC activity regulates type II collagen expression by suppressing the transcription of Wnt-5a.

514 Why Are Proteins Associated with Drosophila Telomeres Rapidly Evolving? N. Elde, H. Malik; Basic Sciences, Fred Hutchinson Cancer Research Center, Seattle, WA

The telomeres of Drosophila are remarkable evolutionary variants, which do not employ telomerase to replenish chromosomal ends. Instead, specific retrotransposons function as telomeres. Despite this fundamental difference, telomeres of all species share many common features. Numerous factors interact with telomeres to protect these vital genomic regions. This includes telomere-capping proteins, some of which are DNA repair factors. The involvement of such proteins in the regulation of telomeres highlights the relationship between telomeres and chromosomal stability. Defects in telomeres result in abnormalities associated with aging and nearly all forms of cancer. A novel and fast evolving Drosophila gene, named caravaggio, has an essential role in telomere capping. Disruptions of caravaggio are known to cause extensive telomere fusions. This was unexpected because genetic features are commonly under strong evolutionary constraints to maintain vital functions. To explain this paradox, we considered the observation that many rapidly evolving genes co-evolve in relationships promoting adaptive changes. Examples include genes engaged in host-pathogen interactions. Drosophila telomeres appear similar because cells co-opted otherwise autonomous retrotropansons to maintain chromosomal ends. Therefore, a hypothesis accounting for the rapid evolution of caravaggio is that it has been subject to opposing selective forces that promote co-evolution with telomeric retrotransposons, yet also maintain an essential function. Supporting this view, we detected evolutionary signatures consistent with positive selection in a defined region of caravaggio in independent comparisons between Drosophila species. Experiments testing the consequences of rapid evolution in Drosophila will provide clues toward understanding the role of such fast evolving, yet essential, genes in telomere function.

515 Age Impairs Flight and Increases Muscle Stiffness in Drosophila M. S. Miller,1 E. G. Brown,2 P. Lekkas,2 J. M. Bradlock,1 G. P. Farman,1 T. C. Irving,1 D. W. Maughan,1 J. O. Vigoreaux 2,1; 1Molecular Physiology and Biophysics, University of Vermont, Burlington, VT, 2Biology, University of Vermont, Burlington, VT, 3BCPS, Illinois Institute of Technology, Chicago, IL

Age increases mobility due to reductions in muscle performance (functional senescence) and muscle mass (sarcopenia) in species. A key aging theory proposes that reactive oxygen species, resulting from mitochondrial metabolism, impairs cell function by injuring oxidative damage on macromolecules. We investigated the effects of aging on Drosophila indirect flight muscle (IFM), a strictly aerobic muscle and one of the most metabolically active tissues known. A wild-type strain (Oregon R) with a ~51 day mean lifespan (~80 day maximum lifespan) became flight impaired between 42-46 days. Old flies (~49 days) were flight competent, but had reduced performance compared to young flies (2-3 days) (flight index 3.3 ± 0.2 vs. 5.6 ± 0.1, range = 0-6; wing beat frequency 183 ± 8 vs. 215 ± 4 Hz). Flies older than 56 days were unable to beat their wings and skin fibers failed to be calcium activated. Old flies (vs. young) had normal number and packing of myofilaments, but had longer sarcomeres (3.66 ± 0.05 vs. 3.20 ± 0.03 μm) and enlarged mitochondria with large cristae-free regions. Small amplitude sinusoidal length perturbation analysis showed IFM isolated from old flies developed greater isometric force (82%) , oscillation work (132%), and power output (121%) compared to young, yet indices of crossbridge kinetics appeared normal. The up to 143% increase in elastic and viscous moduli amplitude under active, passive, and rigor conditions suggest that old fibers become stiffer longitudinally, thereby enhancing force transmission and oscillatory work generation. Small-angle x-ray diffraction indicates that crossbridges in aged fibers move towards the thin filament (presumably increasing actin-myosin interactions), thereby increasing transverse stiffness. The increase in stiffness with age is most likely due to oxidative damage and/or changes in myofilibrillar protein expression. We speculate that the greater stiffness associated with aging increases internal resistance to stretching, driving the decreased flight performance.

516 Effects of Different Rates of Stretching on Muscle Fiber Differentiation and Characteristics of Cultivated Myoblasts K. Kurokawa,1 K. Okubo,2 K. Sakiyama,1 T. Takeda,1 S. Abe1, Y. Ide1, K. Ishigami,1,2; Sports Dentistry, Tokyo Dental College, Chiba, Japan, 3Anatomy, Tokyo Dental College, Chiba, Japan

In vivo studies of humans and rats have shown that different exercise and training methods bring about changes in muscle fiber characteristics of skeletal muscle. Furthermore, in vitro studies have clarified that application of various mechanical stimuli to myoblasts not only facilitates cell proliferation and differentiation, but also brings about changes at the isometric level. However, past studies on mechanical stimulation have used constant intensity of stimulation, and no studies appear to have varied the intensity of stimulation. A basic study was therefore conducted to ascertain the effects of different exercise and training methods on muscle fibers. By stretching myoblasts at different rates, differentiation and characteristics were investigated.
Using the Flexercell® strain unit, myoblasts were stretched at 3 rates, and expression of myosin heavy chain (MyHC) mRNA was compared and analyzed on 1 day, 3 days, and 5 days. Expression of MyHC-perinatal, one indicator of differentiation, was high with fast stretching at first and then decreasing thereafter. As influence of a muscle fiber characteristics, expression of MyHC-2b (fast contraction) was high with fast stretching, expression of MyHC-2a (slow contraction) was high with slow stretching. MyHC-2d is considered an isoform that can change to either MyHC-2a or -2b, and expression was high with long stretching. In other words, fast mechanical stretching of myoblasts appears to facilitate differentiation for early stage and myoblasts acquire muscle fiber characteristics suitable to each rate of stretching.

517 Increase of Reactive Astrocytes in Development of the Cerebral Cortex in POMGnT1 Mutant Mouse
Y. Yang, X. Xiong, Y. Qi, H. Hu. Neuroscience and Physiology, SUNY Upstate Medical University, Syracuse, NY
Muscle-eye-brain disease (MEB) is a congenital muscular dystrophy associated with central nervous system (CNS) lesions, represented by cobblestone lissencephaly and eye anomalies. The gene responsible for MEB is O-linked-mannose β1,2,3-acetylglucosaminyltransferase I (POMGnT1). The molecular and cellular mechanisms of brain malformation in this enzyme deficiency are poorly understood. The mouse model of MEB recapitulates many aspects of the human phenotype. Previous studies have shown that the brain surface basement membrane and the glial limitans disappear during development of the cerebral cortex. In this study, we investigated the effect of enzyme deficiency on the development of astrocytes. Astrocytes were analyzed by immunofluorescence staining for glial fibrillary acidic protein (GFAP) and S-100 and by electron microscopy. In the adult mutant animals, GFAP-positive astrocytes were observed throughout the cerebral cortical wall while only the glial limitans, marginal zone, and ependymal layer showed GFAP-positive cells in the wildtype animals. During development, GFAP-positive astrocytes were detected at the hemisphere midline of corpus callosum beginning at E17.5 and P0 in both the wildtype and the mutant. Beginning at E12, astrocytes began to appear at the brain surface in mutant as well as in wildtype and formed the continuous glia limitans in wildtype. Compared with the wildtype, the mutant brain exhibited hypertrophic astrocytes and an increase in the number of astrocytes throughout the cerebral cortex, especially at the subpia of the cortex. Contrary to GFAP staining, S-100 immunostaining showed different staining pattern that S-100-positive cells were scattered throughout the white matter and cortex in both the wildtype and the mutant. More S-100 positive cells in cerebral cortex especially at the subjacent of cortex were seen in mutant. In mutant, there are more a reactive gliaosis in POMGnT1 deficiency.

518 Developmentally Regulated Expression of a 28-kDa Peptide in the Rat Brain
L. A. Haddad, A. M. Vinha-Morgante; Genética e Biologia Evolutiva, University of Sao Paulo, Sao Paulo, Brazil
Alternative splicing is a major mechanism leading to protein functional diversity, believed to occur in up to 80% of brain transcripts. Fragile Mental Retardation 1 (FMR1) gene transcripts undergo alternative splicing of four exons creating 20 possible non-redundant fragile gential geration protein (FMRP) isoforms. To understand the functional relevance of FMR1 alternatively spliced exon 12, we raised polyclonal antibodies that recognize the encoded exon. The antibodies detected 50 to 70-kDa FMRP isoforms, which localized in dendritic spines of cultured rat cortical neurons. A 28-kDa peptide was additionally identified on Western blots of rat brain cortex, cerebellum, and hippocampus. This 28-kDa peptide is developmentally regulated after birth, with the highest expression levels in the adult brain. FMR1 alternative splicing may produce 47.3 to 71.1-kDa FMRP isoforms as previously documented by RT-PCR and Western blotting data. Therefore, it is unlikely that the 28-kDa peptide is a product of FMR1 alternative splicing. It may be generated from FMRP developmentally regulated proteolysis or, alternatively, be unrelated to FMRP. Under either hypothesis, the 28-kDa-peptide expression regulation may be of functional relevance during rat brain development and aging. Purification and sequencing experiments are underway to characterize this peptide.

519 Immunocytochemical Distribution of Mammosomatotrophs in Porcine Anterior Pituitary
J. Lee, M. H. Stromer, L. L. Anderson; Department of Animal Science, Iowa State University, Ames, IA, Department of Biochemistry, Biophysics and Molecular Biology, Iowa State University, Ames, IA, Department of Biomedical Sciences, Iowa State University, Ames, IA, Department of Poultry Science, Mississippi State University, Starkville, MS
The existence of a novel anterior pituitary cell type, the mammosomatotroph (MST), secreting both growth hormone (GH) and prolactin (PRL) was proposed to function as transitional cells or progenitor cells between GH cells (somatotrophs) and PRL cells (mammatrophs). Double fluorescence immunocytochemistry was used to identify distribution patterns of MS cells in anterior pituitary glands from newborn and prepubertal stages of pigs. Immunopositive MS cells were morphologically similar to the mammatrophs including polygonal or irregular shape and diameter from 10 to 15 μm in diameter. The confocal detection of a MS demonstrated uneven distribution of GH and PRL. Anterior lobes were sampled at 3 positions in each of 5 radial regions in each of 3 levels perpendicular to the gland axis. There were changes in spatial distribution with different levels of the gland and this specific pattern is similar among different age groups (day 1, day 45, and day 90). Although MS are rare in number, significant differences were observed among the total MS cells across three age groups (P < 0.0001). MS cells were most numerous in region 3 where originates from embryonic Rathke’s pouch (6.0±1.4; mean ± standard error of the mean per 30,495 μm²) compared to rest of regions (0.7±0.1). There were significant decreases at position a (P < 0.001) and significant increases (P < 0.0001) at position c in region 3 from proximal to distal level. The total number of MS cells at the proximal level at position a increased from day 1 to day 45 (2.5×) and from day 45 to day 90 (2.4×). The results suggest that there may be regional specificity of cellular transformation to facilitate GH and PRL secretion during the rapid growing period in the young pig. Supported by research grant USDA/CSREES NRI 2003-35206-12817 (L.L.A., S.J., and C.G.S).

520 Immunocytochemical Distribution of Mammosomatotrophs in Porcine Anterior Pituitary
J. Lee, M. H. Stromer, L. L. Anderson; Department of Animal Science, Iowa State University, Ames, IA, Department of Biochemistry, Biophysics and Molecular Biology, Iowa State University, Ames, IA, Department of Biomedical Sciences, Iowa State University, Ames, IA, Department of Poultry Science, Mississippi State University, Starkville, MS
Prolactin (PRL) is synthesized in specific anterior pituitary secretory cells, mamatomatrophs or PRL cells (lactotrophs) and has diverse functions including growth, reproduction, lactation, osmoregulation, immunomodulation, and energy metabolism. The objective of this study was to identify spatial distribution patterns of mammatrophs in the newborn and prepubertal porcine pituitary using fluorescence immunocytochemistry. Immunoreactive mammatrophs were polygonal or irregular shape with stained nuclei and ranged from 10 to 15 μm in diameter in 1-45, and 90-day-old pigs. Clusters of mammutrophs consisting of 3 to 10 cells were found in day 45 and day 90 old pigs. Significant differences were observed among the total mammatrophs per 30,495 μm² across the three age groups (day 1; day 45 and day 90, P < 0.0001). Anterior lobes were sampled at 3 positions (a, b, and c) in each of 5 radial regions (1-5) in each of 3 levels (proximal, middle, and distal) perpendicular to the gland axis. There were changes in spatial distribution with different levels of the gland and this specific pattern in similar among different age groups. Mammatrophs were most numerous in positions a and b (57 ± 4.2; mean ± standard error of the mean per 30,495 μm²), and least numerous in position c at the proximal level (24 ± 5.2) in day 1, day 45, and day 90 indicating high population and immunointensity close to intermediate lobe. However, at the distal level, the pattern showed a bell shape with significant increase in the number of mammatrophs in region 3 at position c (P = 0.001). From these results, we suggest that there may be regional specificity of cellular differentiation and transformation to control PRL secretion to meet the need for endocrine regulation as the animal ages. Supported by research grant USDA/CSREES NRI 2003-35206-12817 (L.L.A., S.J., and C.G.S).

521 Role of Oxidative Stress on the Regulation of Na⁺−K⁺−ATPase Activity in Renal OK Cells
E. F. Silva, P. Soares da Silva; Institute of Pharmacology and Therapeutics, Faculty of Medicine University of Porto, Porto, Portugal
The present study aimed at evaluate oxidative stress in cells that retain characteristic of kidney proximal tubules plays a role in the regulation of Na⁺−K⁺−ATPase. Opossum Kidney (OK) cells were kept in culture from passage 36 to passage 80. Na⁺−K⁺−ATPase (OKA) activity was examined by electrophysiological methods. Hydrogen peroxide production and cell viability were determined with fluorescent assays, Amplex Red Hydrogen Peroxide/Peroxidase Assay Kit and Calcein-AM, respectively. NKA subunits expression was determined by western blotting and in cell western. NKA activity, measured as apical-to-basal ouabain-sensitive amphotericin B-induced increases in short-circuit current (μA/cm²), increased with the number of cell passages from 6.42 ± 0.99 in young cells (passage 36 to 50) to 47.51 ± 3.02 in aged cells (passage 60 to 80). The related increases in cell hematocrit and NKA subunits expression increased 5-fold between passage 36 and passage 80. Twenty four hour accumulation of hydrogen peroxide in the extracellular medium in aged cells (319±3.2 nM) was significantly higher than in young cells (256±5.2 nM). The rate of hydrogen peroxide production was of 5.21±0.02 nM/min in young cells and 7.37±0.02 nM/min in aged cells. Apocynin, at the concentration of 300 μM (non toxic concentration) abolished the increased production of hydrogen peroxide in aged cells and significantly decreased NKA activity (30% reduction). It is concluded that oxidative stress plays a role in the
long-term regulation of NKA activity, as evidenced by the fact that increases in hydrogen peroxide production in aged OK cells paralleled increases in NKA activity and inhibition of hydrogen peroxide production reduced NKA activity. Supported by grant POCTI/CBO/45767/2002.

522 Evaluation of Mullerian Inhibiting Substance Concentration Using ELISA and RT-PCR in ICR Mouse Y. Kim, J. Lee, D. Han, J. Kim, S. Kim, J. Jang, S. Park, D. Choi, H. Ko, Y. Lee, Y. Hwang, D. Kim; Biological Science, Gachon University of Medicine & Science, Incheon, Republic of Korea

MIS (Mullerian inhibiting substance) is a member of the TGFβ family whose members play key roles in development, suppression of tumor growth, and feedback control of the pituitary-gonadal hormone axis. MIS is expressed in a highly tissue-specific manner, restricted to Sertoli cells of the testis and granulosa cells of the ovary. It induces Mullerian duct regression, controls primordial follicle recruitment and regulates steroidogenesis and Leydig cell differentiation. In addition, its level is used as a marker for ovarian aging and breast, prostate, uterus, and ovarian cancers. To detect MIS serum level and expression of MIS messenger RNA (mRNA), we used ICR mice and sampled the blood and tissue from fetals, pregnant, postnatal male and female mice group. RT-PCR method was used to compare MIS mRNA expression level in reproductive organs tissues. We confirmed MIS serum level secretion by Enzyme-linked immuno-solvent assay (ELISA) using MIS/AMH antibody. We obtained MIS serum level data from fetus to adult (17 weeks). MIS serum levels have a remarkable difference between female and male fetuses during sex organ differentiation (both <0.1ng/ml). Its level of pregnant mouse changed markedly (4.5–12.2ng/ml). Postnatal female and male mice serum level changed (Male: <0.1–13.6ng/ml, Female: 5.3–103.4ng/ml) and the changing phase was diurnally opposed (Male: decreasing, Female: fluctuating). For further study, normal level of MIS is important. It would contribute to understanding of reproductive organ differentiation, and ovarian aging. We expect that our study would provide the basic information for the study of MIS interactions with reproductive organ disability, cancer, effect of other hormone or menopause; we forward if MIS is regularly injected to middle age women, menopause would be delayed.

523 Histomorphometric Analysis of the Sex Cords in the Testis of Gallus domesticus during Embryonic Development E. Soria; 1St. Gonzalez-Moran; 1Patología, Instituto Nacional de Cardiología, Distrito Federal, Mexico, 2Biología Comparada, UNAM, Distrito Federal, Mexico

In this study we evaluated the pattern of sex cords in the testis of the Gallus domesticus during embryonic development of the testis. They were studied on day 8 and 13 of embryonic development and the day of hatching. Left testes were obtained in all cases, and immediately fixed and embedded in Epon 812 and semi-thick-sections were morphometrically measured under light microscopy, using stereological methods. The results indicate that in the testes from 8-day-old embryos, the sex cords are larger and convoluted and the sex cords are elongated along the basement membrane. Results also reveal an increase in the total volume of sex cords, and in the number of Sertoli cells and spermatagonia, as well as enlargement of the individual Sertoli cells during embryonic development. Based on our results we concluded that the proportion of sex cords and the number of germ cells and Sertoli cells may differ markedly according to age.

524 Neuregulin 1-β-1 Induces Nuclear Bag Fiber Morphogenesis in a Defined In Vitro Culture System J. W. Runnemeyer, 1 M. Das, 2 J. Kang, 2 J. J. Hickman, 2 BioMolecular Sciences, University of Central Florida, Orlando, FL, 2Nanoscience Technology Center, University of Central Florida, Orlando, FL

Research into the factors affecting the differentiation of skeletal muscle myotubes into the intrafusal fibers of the muscle spindle during primary and secondary myogenesis is relatively unexplored. Additionally, in vitro systems designed to investigate this myogenesis are underdeveloped. Neuregulin 1-β-1 (Nrg1-β-1), secreted by sensory neurons, has been shown to influence transcription factor activation in developing muscle through ErbB2-4 signaling. In this study we investigated the role of the growth factor Nrg1-β-1 EGF domain for its ability to influence myotube fate specification in a defined in vitro culture system on the non-biological substrate DETA. Morphologically, Nrg1-β-1 EGF domain treatment of developing myotubes increases the ratio of nuclear bag fibers to total myotubes from 0.019 to 0.100. This increase of 8% is statistically significant using a Student’s t-test (P<0.001). After Nrg1-β-1 EGF treatment, nuclear chain fibers were also observed in culture. Nrg1-β-1 EGF treated nuclear bag and chain fibers were positive when evaluated immunocytochemically for alpha cardiac-like myosin heavy chain expression specific to spindle fibers. Additionally, the Nrg1-β-1 EGF treated nuclear bag and chain myotubes were characterized electrophysiologically. This data shows conclusively, in a serum-free defined culture system, that the growth factor neuregulin 1-β-1 is sufficient to drive the morphogenesis of forming myotubes to the nuclear bag phenotype.

525 Effects of Radiofrequency on the Connective Tissue of the Dermis in Sprague-Dawley Rats A. Zauta, 1 E. Beltran, 1 C. Ferrer, 1 S. Navarro, 2 C. Bernal-Mañas, 2 M. Canteras, 2 L. M. Pastor, 2 Cell Biology, Institute of Aging, University of Murcia, Murcia, Spain, 2Department I-D, Grupo Tahe, Murcia, Spain, 1Statistics, University of Murcia, Murcia, Spain

Many studies exist on the effect of radiofrequency on connective tissue, although no a histological evaluation has been made of the changes that take place after successive applications of low power radiofrequency. In this work studies such changes in the fibroblast, where its proliferation and biosynthetic activity. In this experiment 16 (8 treated and 8 control) 3 month-old Sprague-Dawley rats were divided into four groups, which were subjected to different session of radiofrequency (1, 2, 3 and 5) in the tail. All were sacrificed after the last treatment, except the 4th group, which was sacrificed 2 months later. Fibroblast per unit area were determined in all the animals. The proliferation rate and the expression of Heat Shock Protein (HSP-47) were assessed by Western blot and Northern analysis. HSP-47 expression was highly increased after radiofrequency treatment. In this study, we have used Ki-67 antibody to determine the rate of cardiac myocyte proliferation in the postnatal mouse heart. The protein profiles of 5-day- and 13-day-old hearts were established and compared. Eighteen protein spots were found to be differentially expressed at day 13. We focused our attention on 2 of the proteins identified by MALDI-TOF MS, cyclin I and p53 because they are both believed to be involved in cell cycle regulation. Western blot analysis confirmed that both proteins were positively up-regulated in the 13-day-old postnatal heart. To determine directly whether these proteins were associated with cell proliferation, we examined their expression patterns in H9c2 cardiomyocytes maintained in vitro. We established that cyclin I expression was low during the growing phase of H9c2 culture and high during the growth arrest/ differentiation phase. In contrast, p53 expression was unchanged during both phases. The various growth phases were confirmed by the presence of cyclin A and growth arrest specific 1 (gas1) proteins. We investigated whether silencing cyclin I expression using cyclin I siRNA could promote an increase in H9c2 proliferation. It was determined that silencing cyclin I could enhance a small, but significant, increase H9c2 cell proliferation. The results imply that the increased cyclin I expression detected in this study may be associated with cell growth arrest in the cardiomyocytes.

526 Cytokine like 1 (Cyt1) in Chondrogenesis and Cartilage Development J. Kim, S. Yang, J. Chun; Life Science, Gwangju Institute of Science and Technology, Gwang-ju, Republic of Korea

Cytokine like 1 (Cyt1) is known as a possible candidate of cytokine originally isolated from bone marrow-derived CD34 positive cells. We initially found that Cyt1 is predominantly expressed in cartilage and chondrocytes and, therefore, investigated in this study the expression and possible function of Cyt1 in cartilage development. Cyt1 expression was very low in mesenchymal
cells, dramatically increased during chondrogenesis, and highly expressed Cyt1 was decreased during hypertrophic maturation both in vivo (during limb development) and in vitro (during micromass culture of mesenchymal cells). The function of Cyt1 in chondrogenesis and hypertrophic maturation was examined by treating chondrifying mesenchymal cells with exogenous Cyt1 obtained from conditioned medium of L929 cells which express ectopic Cyt1. Cyt1 treatment promoted chondrogenic differentiation of mouse limb bud mesenchymal cells during micromass culture as determined by the increased synthesis of type II collagen and sulfated proteoglycan. Cyt1 treatment activated expression of protein kinase C-alpha, which is known to induce chondrogenic differentiation through extracellular signal-regulated protein kinase. In addition, Cyt1 stimulated proliferation of chondrifying mesenchymal cells, which is necessary for chondrogenesis. However, exogenous Cyt1 did not affect hypertrophic maturation of chondrocytes. Collectively, our results suggest that chondrocyte-specific expression of Cyt1 regulates chondrogenesis but not hypertrophic maturation during cartilage development.

Wound-healing Responses of the Marine Red Alga, Griffithsia monilia, Monitored with Time-Lapse Videography and FITC-conjugated Lectins
J. H. Han, G. H. Kim, J. H. Choi, I. Y. Jeon; Biology, Kongju National University, Kongju, Republic of Korea

When cells of the marine red alga Griffithsia monilia receive fatal wounding, the wound healing process occurs by a somatic cell fusion between the two neighbouring cells, called repair rhizoid and shoot cells, which extend from each side of the wounded thallus. Previous research by Waaland et al. suggested that the process of somatic cell fusion was mediated by a glycoprotein with a methyl-D-mannose binding site, named "Rhodomorphin", which was produced by the repair rhizoid cells. In this study, we showed that FITC-labeled ConA (Concanavalin A), which is specific to methyl-D-mannose, indeed labelled tip of the apical rhizoid cell, and these data, therefore, agreed with Waaland et al. However, our time-lapse videographic data were contradictory to Waaland et al. as follows. Was found, the repair shoot cell was the inducer for somatic cell fusion, and it promoted growth of rhizoid cells until cell fusion occurred.

Modulo Fibonaccial Model of Phylloaxis
C. P. Spears,1 J. J. Yan,2 M. Bicknell-Johnson; 1Fibonacci Phylloaxis, Inc., Davis, CA, 2Department of Electrical and Computer Engineering, University of California at Davis, Davis, CA, A

We recently presented a Matlab program for display of a Fp modulo Fm model of phylloaxis (12th International Conference on Fibonacci Numbers and their Applications, San Francisco, CA, July, 2006). The program assumes only an initial single cell cycle delay in division by daughter cells, before continuous binary division, and self-association of cells by age from birth. The program is shown to generate phylloactic patterns of growth consistent with diffusion models of directional auxin secretion, as well as biophysical, contact pressure, and minimal displacement models, for providing a basis for the occurrence of Fibonacci numbers and relations in plant development. The model predicts spatial stability of growth points and of structures based on age and generation identifiers. Cylindrical and rectangular displays of populations >20,000 cells shown by age and generation provide testable hypotheses for future discrete model correlates of apical meristem development.

Proteomics and Expressed Sequence Tag Analyses of the In Vitro-formed Protoplasts of the Marine Multinucleate Green Alga Bryopsis plumosa
G. Kim, T. Kloczková; Biology, Kongju National University, Kongju, Republic of Korea

When cell membrane of the marine coenocytic green alga Bryopsis plumosa is destructed, the protoplasm expelled in seawater generates numerous protoplasts in vitro. Protoplasts in masses are initially surrounded by a polysaccharide envelope, which acts like the cell membrane. New cell membrane develops within several hours and cell wall develops in 24-48 h after wounding. Then, the newly formed cells begin to grow into plants. We constructed two-dimensional polyacrylamide gel electrophoresis (2-DE) protein maps of the protoplasts at different stages of development (0, 3, 12, 24, and 48 h after wounding). There was about 50% increase in the number of protein spots over time intervals (from 1235 spots at 3 h to 1915 spots at 48 h after wounding). This increase may be due to recovery of the gene expression from extreme condition of cell rupture to normal cell differentiation. A dramatic change of proteome structure was observed during the protoplast development. When the proteomes of different stages were compared, 59.8% of proteins that were up-regulated at early stages (0-3 h) almost disappeared at late stages (24-48 h). About 70-80% of proteins detected at 48 h were not detected at the initial stage. 29 proteins, differentially regulated according to stages, were selected and analyzed using MALDI-TOF mass spectrometry. Among them, chaperon proteins involved in protein folding, chloroplast precursor proteins, and regulatory proteins were identified as up-regulated genes during the early stages of protoplast development. EST analysis of 3 h-old protoplast showed that 607 sequences (74%) were present in multiple copies of 77 genes, which likely reflects the need for a high amount of certain gene products at this stage. 252 unique ESTs were compared to those in Genbank cDNA. Protoplast formation in Bryopsis plumosa serves as a natural defense from life-threatening injuries and contributes to dispersal of this alga.

The Plasmodium Protein Network Diverges from Those of Other Eukaryotes
S. Suthram,1 T. Sittler,2 T. Ideker; 1Bioinformatics, UCSD, La Jolla, CA, 2Bioengineering, UCSD, La Jolla, CA

Plasmodium falciparum is the pathogen responsible for over 90% of human deaths from malaria. Therefore, it has been the focus of a considerable research initiative, involving complete DNA sequencing of the genome, large-scale expression analyses, and protein characterization of its lifecycle stages. The Plasmodium genome sequence is relatively distant from those of most other eukaryotes, with only 31% of the 5,334 encoded proteins having notable sequence similarity to other organisms. To systematically elucidate functional relationships among these proteins, a large two-hybrid study has recently mapped a network of 2,846 interactions involving 1,312 proteins in Plasmodium. This network adds to a growing collection of available interaction maps for a number of different organisms and raises questions about whether the divergence of Plasmodium at the sequence level is reflected in the configuration of its protein network. Here we examine the degree of conservation between the Plasmodium protein network and those of model organisms. Although we find 29 highly connected protein complexes specific to the network of the pathogen, we find very little conservation with complexes observed in other organisms (three in yeast, none in others). Overall, the patterns of protein interaction in Plasmodium, like its genome sequence, set it apart from other species.

Genome-Scale Network Analysis of Leishmania major, a Pathogenic Trypanosomatid
J. D. Whittemore, A. K. Chavali, J. A. Papin; Biomedical Engineering, University of Virginia, Charlottesville, VA

Leishmaniasis, caused by infections due to species of the genus Leishmania, affects over 350 million people worldwide (mostly in developing nations). Existing forms of treatment are either too expensive or have toxic side effects, and resistance to some treatments is on the rise. We reconstructed the metabolic network of the recently sequenced Leishmania major and accounted for the gene-protein-reaction relationships of a significant portion of the annotated genome. The reconstructed network consists of more than 300 reactions. Using flux balance analysis, we make predictions of growth dynamics in various cellular environments and analyze the lethality of gene knockouts, validating our results with experimental data. This work constitutes one of the first genome-scale network analyses of a pathogen responsible for an emerging and uncontrolled disease. The reconstructed Leishmania major network is additionally unique, in that it is the first metabolic reconstruction of a trypanosomatid protozoan. We present IDEAS (Infectious Disease Engineering, Analysis and Simulation) as a framework to build multi-level computational models that connect genome-scale metabolic network reconstructions with parasite epidemiology to generate potential therapeutic applications.

Transcriptional Regulation of Protein Complexes within and Across Species
K. Tan,1 T. Hirono,2 H. Feizi,1 T. Ideker,2 R. Sharan; 1University of California San Diego, La Jolla, CA, 2Tel-Aviv University, Tel-Aviv, Israel

Yeast two-hybrid and co-immunoprecipitation experiments have defined large-scale protein-protein interaction networks for many model species. Separately, systematic chromatin immunoprecipitation experiments have enabled the assembly of large networks of transcriptional regulatory interactions. To investigate the functional interplay between these two interaction types, we combined both within a probabilistic framework which models the cell as a network of transcription factors regulating protein complexes. This framework identified 72 putative co-regulated complexes in yeast, and allowed the prediction of 120 novel transcriptional interactions. Several predictions were tested using new microarray profiles, yielding a confirmation rate (53%) comparable to that of a direct immunoprecipitation experiment. Furthermore, we extended our framework to a cross-species setting, identifying 24 co-regulated complexes that were conserved between yeast and fly. These complexes demonstrate that transcriptionally-regulated complexes are conserved over large evolutionary distance and provided suggestive evidence that
protein-protein interaction networks may evolve more slowly than transcriptional interaction networks. Our results demonstrate how multiple molecular interaction types can be integrated toward a global wiring diagram of the cell, and provide new insights into the evolutionary dynamics of protein complex regulation.

535 Analyzing the Residue-Composition of Metal Binding Sites in the Whole Protein Data Bank Z. Szabadka, G. Ivan, V. I. Grolmusz; Computer Science, Eotvos University, Budapest, Hungary

The Protein Data Bank (PDB) is the largest depository of protein structural information, containing more than 37,500 structures. The form and the organization of the PDB seems to be perfectly adequate for gathering information from specific protein structures, by using the bibliographic references and the informative remark fields. On the other hand, however, it seems to be impossible to automatically review remarks and journal references for processing hundreds or thousands of PDB files. We re-structured the whole PDB, creating a new database, the RS-PDB, containing more than 330 million atoms. The new database made possible the reliable and redundancy-free collection of all the binding sites from protein-ligand complexes. Here we analyze the metal binding sites from the whole PDB for residue-composition. More than 30,000 metal-binding sites were found; this number was reduced to 16,900 after deleting redundancies. It was not a surprise that ASP and GLU were counted most frequently in metal binding sites. The next three most frequently appearing residues were HIS, GLY and ASN. In the case of specific metal ions, the list of most frequent residues sometimes differ: potassium ions bind most frequently to GLY and SER, and ASP is only the third most frequent residue. Zinc ions were detected relatively frequently in the PDB, mostly bound to HIS and CY5 and significantly less frequently to ASP and GLU. It is a remarkable finding that the residue composition of the binding site strongly depends on the number of the coordinated water molecules: zinc ions with one coordinated water are bound most frequently to HIS and GLU and less frequently to CY5. Magnesium and calcium binding sites were also analyzed and we found that the number of the coordinated waters has high impact on the residue-composition of the binding sites.

536 Protein-Protein Interactions Inference Environment (PIIE): Increasing Confidence by Integrating Evidence from Multiple Sources M. Singhal, K. Domico; Computational Biology and Bioinformatics, Pacific Northwest National Laboratory, West Richland, WA

Deciphering interaction networks (say protein-protein interactions) forms the first step in annotating unknown proteins with functions, determining protein complexes, target identification as well as drug discovery. Over the past decade a large number of databases, websites and prediction tools have emerged that assign confidence scores to individual interactions. Unfortunately this growth in availability of interaction data is not coupled with increase in availability of computational tools allowing conversion of this data into information. The lack of computational tools facilitating the integration of evidence from multiple prediction/experimental sources such as Gene Neighborhood-GN, Gene Cluster-GC, Phylogenetic Profiles-PP, Rosetta Stones-RS, BIND, and DIP etc is the motivation behind Protein Interactions Inference Environment (PIIE). The poster presents PIIE, a software tool developed as a plug-in to an open source tool - Cytoscape (www.cytoscape.org), as applied to the problem of protein-protein interaction networks. PIIE presents multiple coordinated views (scatter plots, matrix visualization, Cytoscape networks, filtering mechanism and an integrated view) to a user that facilitates visual analytics of protein-protein interaction networks obtained from multiple sources of evidence. This poster will demonstrate the use of this plug-in on experimentally observed protein-protein interactions in Shewanella oneidensis strain MR-1.

537 GPS: Prediction of Phosphorylation Sites Implemented in Group-based Phosphorylation Scoring Algorithm Y. Xiu, Y. Yao,1 Systems Biology of Phosphoproteome, Laboratory of Cellular Dynamics, Hefei, China, 2Physiology, Morehouse School of Medicine, Atlanta, GA

Protein phosphorylation is an essential reversible post-translational modification of proteins, and it orchestrates cellular dynamics and plasticity. Experimental identification of protein kinases (PKs) substrates with their phosphorylation sites is labor-intensive and often limited by the availability and optimization of enzymatic reactions. Recently, large-scale analysis of the phosphory-proteome by the mass spectrometry (MS) has become a popular approach. However it remains experimentally challenging to identify cognate kinase without in vitro reconstitution. In this regard the in silico prediction of kinase-specific phosphorylation sites with protein's primary sequences may provide guidelines for the further experimental design and the interpretation of PS phospho-proteomic data. Here we present a novel computational program named GPS: Group-based Phosphorylation Scoring platform. We formulated GPS that carries greater computational power with superior performance compared to two existing phosphorylation sites prediction systems, ScanSite 2.0 and PredPhospho. With database in public domain, GPS can predict substrate phosphorylation sites from 71 different protein kinase (PK) families while offer at most 30 PK families. Using PKA as a model enzyme, we first compared prediction profiles from the GPS method with those from ScanSite 2.0 and PredPhospho. In addition, we chose an important mitotic kinase Aurora-B as a model enzyme since ScanSite 2.0 and PredPhospho offer no prediction. However, GPS still offers satisfactory sensitivity (94.44%) and specificity (97.14%). Finally, the accuracy of phosphorylation on MCAK predicted by GPS was validated by experimentation, in which six out of seven predicted potential phosphorylation sites on MCAK (Q91636) were experimentally verified. Taken together, we have generated a novel predictor to predict phosphorylation sites, which offers greater precision and computing power over ScanSite 2.0 and PredPhospho. GPS has been implemented in PHP and is freely available at: http://973-proteinweb.ustc.edu.cn/gps/GPS_web.html.

538 Protein Subcellular Location Image Database for Comprehensive Image Retrieval and Automated Interpretation J. Hua, T. Zhao, Y. Hu, S. Chen, A. Shanbhag, J. Newberg, R. F. Murphy; 1Dept. of Biological Sciences, Carnegie Mellon University, Pittsburgh, PA, 2Machine Learning Department, Carnegie Mellon University, Pittsburgh, PA, 3Dept. of Biomedical Engineering, Carnegie Mellon University, Pittsburgh, PA

Fluorescence microscope images (FMI) are widely used for the determination of protein subcellular locations. Due to the growing volume of images collected, a multimedia database system is required for the storage of both image and meta-data, retrieval of interesting images and automated analysis of subcellular location patterns in these images. The Protein Subcellular Location Image Database (PSLID, http://pslid.cbi.cmu.edu/PSLID) is an open source database system which enables comprehensive retrieval and automated analysis of high resolution FMI. FMI of 2 through 5 dimensions as well as the associated experimental annotations are stored hierarchically in a relational database for hundreds of proteins in a number of cell types. Through a web-based interface, users can search images based on the experimental annotations, while the context search looks for images that display similar location patterns to query image(s). The analysis modules in PSLID include statistical inferences, such as image selection (TypIC) and image set comparison (SimIC), and machine learning algorithms for both classification and clustering, allowing proteins be grouped by their location (creating location families). These tools have been proven to be more accurate and efficient than human visual inspection. PSLID also provides a programmatic search interface for linking to genome and proteome databases. Queries can return images either for a specific protein or proteins which are in the same location family. PSLID is built on the Postgres database system and the Tomcat Java Server Page server on the Linux platform, both of which are open source.

539 Identification of Protein Subcellular Location Families by Large-scale Random GFP-tagging of 3T3 Cells J. Hua, T. Zhao, E. G. Osuna, N. W. Bateman, M. H. Fuhrman, J. W. Jarvik, P. B. Berger, R. F. Murphy; 1Dept. of Biological Sciences, Carnegie Mellon University, Pittsburgh, PA, 2Machine Learning Department, Carnegie Mellon University, Pittsburgh, PA, 3Dept. of Biomedical Engineering, Carnegie Mellon University, Pittsburgh, PA

The goal of location proteomics is the systematic and objective characterization of the subcellular locations of all proteins. Our lab has previously designed numeric Subcellular Location Features (SLF) which we can extract from protein subcellular location images of single cells and developed automated classifier to successfully recognize major subcellular location patterns in both 2D and 3D images. We have also described the use of clustering algorithms to group proteins by their subcellular location patterns, so that assignments of proteins to subcellular location classes can be done objectively and new patterns can be identified. We have recently updated automated microscopy to collect large numbers of fluorescence microscope images from over 350 clones of NIH-3T3 cells randomly tagged with GFP by CD-tagging. Statistically distinctive subcellular location groups, or location families, were identified from the dataset by K-means clustering using the SLF. A consensus subcellular location tree was also generated to show the hierarchy of these proteins. These image data being publicly available, these methods will be able to identify new, if not all subcellular location families, which will hopefully provide a framework of sufficient resolution for location prediction and cell modeling.

540 LOCATE: A Mammalian Protein Subcellular Localization Database J. Fink, M. J. Davis, K. Hanson, R. N. Aturaliya, R. D. Teasdale; Institute for Molecular Bioscience, University of Queensland, Brisbane, Australia
The membrane organization and subcellular localization of a protein can provide information about its functional role. Historically, these data have been difficult to produce on a large scale for higher eukaryotic organisms. Our recent advances in membrane organization prediction methods and development of a Location Proteome Platform to determine subcellular localisation have made it possible to generate these datasets. We present here LOCATE, a curated, web-accessible database that houses data describing the membrane organization and subcellular localization of proteins. LOCATE represents a catalogue of experimentally-verified subcellular location and membrane organization of mammalian proteins using a high-throughput approach and provides localization data for nearly 40% of the mouse proteome. As well as experimental images for a given protein, LOCATE integrates information from external sequence databases and protein function information with computer predicted membrane organization, subcellular localisation and protein domains. It is available at http://locate.imb.uq.edu.au. As an illustrative example of the LOCATE database we have investigated the differential use of endoplasmic reticulum signal peptides and transmembrane domains within the variable protein output of single genes. In summary, we found that the generation of protein isoforms that are targeted to multiple subcellular locations represents a major functional consequence of transcript variation within the mouse transcriptome.

The Shape of Things to Come: Quantitative Analysis of Cell Morphology
Z. Pincus, 1, 2 J. A. Theriot 3, 3Program in Biomedical Informatics, Stanford University School of Medicine, Stanford, CA, 2Department of Biochemistry, Stanford University School of Medicine, Stanford, CA, 3Department of Microbiology and Immunology, Stanford University School of Medicine, Stanford, CA
Quantitative measurement of cell shape is necessary for rigorous investigation of the biochemical and biophysical causes and correlates of morphological variation. Current approaches, which utilize ad hoc measures to capture particular morphological features, introduce biases based on the features selected and can blind investigators to novel variation. We have investigated data-driven approaches to quantifying morphological variation with quantitative but intuitive and biologically meaningful parameters. Given a cell-shape data set, we apply the principal components analysis to create a shape model that describes the average cell shape, the major modes of shape variation in the population (e.g. large vs. small, round vs. elongated, etc.), and the relative importance of those modes. Our experience with different cell types - multiple populations of bacterial cells, epithelial monolayers, and isolated crawling cells - indicates that the modes of shape variation so derived closely mirror qualitative descriptions used in the literature to describe a given cell type. In addition to recapturing descriptive terms, shape models have many quantitative uses. A cell can be measured in terms of the contribution of each shape mode to that cell's shape, and quantified populations can be statistically tested for morphological differences. The shape modes themselves can be visualized to provide a compact representation of the morphological variability of a population better than hand-picked "representative images," and entire populations can be plotted along the axes provided by the shape modes to uncover subtle trends in cell shape. We have used these tools to quantitatively examine the cytoskeletal role in Caulobacter shape, finding a link between cell shape and the localization of actin and tubulin homologues relative to a cell wall deposition protein. We have also investigated the stereotyped shape of ciliated keratocytes, finding three principal shape modes that are conserved across multiple data sets and can be experimentally manipulated independently.

Computer Modeling of Ultrastructure of Muscle Cells
J. Parulek, 1 I. Zahradník, 2 M. Novotová, 1 J. Michálko, 3 Lab Cell Morphology, Inst Molec Physiol & Genetics SAS, Bratislava, Slovakia
Understanding of biological processes at the cellular level requires a large scale synthesis of numerous data of different origin. This would be facilitated by a computer modeling tool allowing construction of three dimensional geometrical models of living cells and their organelles with very high spatial resolution. In this study we explore an original approach to construction of models of skeletal muscle cells and their organelles such as myofibrils, mitochondria, t-tubules, sarcoplasmic reticulum, lipid droplets and sarcolemna at the resolution of 1 nm and the size of about 1000 µm3. Construction of the model is based on the theory of implicit surfaces and of their binary operations. Geometry of the muscle fibre and of its constituents is defined by means of parallel modeling planes perpendicular to the fiber axis. In each modeling plane, the number, shape and topology of organelles is defined by means of skeletal elements and functionally represented polygons. The 3D model is obtained by implicit shape transformations of the defined objects between the modeling planes. This approach allows generation of the surfaces of organelles and explicit association of each model voxel with only one of the organelles. As a result, the condition of organelle exclusivity is fulfilled and the volume and surface densities of each organelle type in the model can be estimated. These features allow various applications such as a simulated electron microscopic experiment as the model allows generation of a set of random sections along any plane, and their projection to the image plane. Visualization of the model and its components can be achieved at various levels of detail and complexity. The software implementation with nowadays computational power allows creation of rather complex geometric models with all advantages of computer presentations and secondary processing like sectioning, zooming, and rotating. Supported by APVT - 51-31104.

Mobile Phone Radiation Affects Gene Expression in Human Endothelial Cell Lines
D. Leszczynski; Research and Environmental Surveillance, STUK-Radiation and Nuclear Safety Authority, Helsinki, Finland
Induction of biological and health effects by mobile phone radiation remains a controversial issue. We have earlier proposed (Leszczynski & Joenvääri, Nature Genetics 2001, 27; 67; Leszczynski, Lancet 2001, 358, 1733) and demonstrated (Leszczynski et al., Proteomics, 2004, 4, 426-431) that using genome-wide and proteome-wide screening techniques will help identification of genes and proteins responding to mobile phone radiation. Mobile phone research has shown that mobile phone radiation activates cellular stress response by increasing the expression and phosphorylation of stress protein Hsp27 (Leszczynski et al., Differentiation 2002, 70, 120-129) what has a physiological impact on cells by induction of stabilization of stress fibers (Leszczynski et al., Proteomics, 2004, 4, 426-431). Also, mobile phone radiation affects expression of vimentin (Nyland & Leszczynski, Proteomics 2004, 4, 1359-1365; research presented in the ASCB 2004 Year Book). In the present study, we examined were the effects of 900 MHz GSM mobile phone radiation on the expression of 1176 genes using cDNA Expression Array (Clontech, USA) and two closely related human endothelial cell lines - EA.hy926 and EA.hy926v1. Obtained gene expression data were further analyzed with Ingenuity Pathways Analysis (Ingenuity Systems, USA). The expression of over 100 genes has been altered in both cell lines but different genes were affected in each of cell lines. This was reflected in identification of various canonical pathways and gene sets. In conclusion, cell response to mobile phone radiation may depend on the repertoire of genes (and proteins) that are expressed at the time of exposure - genome-dependent (and proteome-dependent) response. Therefore, it is possible that different types of cells from different species might respond differently to mobile phone radiation; i.e. might have different sensitivity to this weak stressor.

Transient Anomalous Subdiffusion Due to Barriers
M. J. Saxton; Department of Biochemistry and Molecular Medicine, University of California, Davis, CA
Hindrances to diffusion may lead to transient anomalous subdiffusion, in which diffusion is anomalous at short times (mean-square displacement MSD = Dtα, α < 1) and normal at long times (MSD = Dt). The crossover from anomalous to normal diffusion is most clearly seen in a plot of log MSD versus log t. Transient anomalous subdiffusion has been observed by single-particle tracking experiments on Cajal bodies in the nucleus and receptors in the plasma membrane. Different mechanisms for transient anomalous subdiffusion differ in their sensitivity to thermalization. In Monte Carlo simulations, thermalization is accomplished by annealing, and in experiments on cells it is accomplished by treatment with metabolic energy inhibitors, with the caveat that metabolic energy depletion may affect obstacle structure and dynamics. Transient anomalous subdiffusion due to binding sites is removed by thermalization; that due to barriers is not; that due to a combination of binding sites and barriers, or an energy landscape model, is partially removed. A combination of binding sites and barriers is plausible for 2D diffusion in the plasma membrane and 3D diffusion in the cytoplasm and the nucleus. As a limiting case for the effect of barriers on diffusion, the bond percolation problem on the triangular lattice is examined. Here bonds are randomly chosen to be conducting or nonconducting. Monte Carlo simulations show how transient anomalous subdiffusion becomes more anomalous over longer times as the fraction of conducting bonds approaches the bond percolation threshold. Simulations also examine how many time points are required in a single-particle trajectory for the crossover to be detected reliably. Supported by NIH grant GM038133.

Enabling Data Collection, Processing, Analysis, and Management: The Bioinformatics Resource Manager
M. Singhal, A. R. Shah, K. Klicker, K. M. Waters; Computational Biology and Bioinformatics, Pacific Northwest National Laboratory, West Richland, WA
The biological sciences have experienced rapid growth in the amount of data generated. This growth is a result of increasing availability of sequencing data and the development of new techniques to generate large datasets, but also facilitate the integration and analysis of datasets in the context of functional annotation information from public sources. This poster presents the Bioinformatics Resource Manager (BRM), a computational tool that takes into account the disparate nature of biological data to provide users with data retrieval, management, analysis and visualization capabilities through all aspects of an experimental study. BRM addresses a host of requirements for biologists, incorporating emerging technologies and concepts, to facilitate analysis of high-throughput biological data. This poster presents example workflows of BRM.
Reversing Endosymbiosis: the Path to an Independent Mitochondrion

M. Legua, A. Vila-Sanjuán, B. Zamfir, C. Bastamante; Synthetic Biology, University of California Berkeley/Lawrence Berkeley National Laboratory, Berkeley, CA

Little is known about the genes that collectively define the living state and how their function(s) are spatially and temporally integrated. Developing a minimal cell carrying only the essential genetic content necessary for survival in a maximally supportive environment is key to identifying the essential genetic elements of the living state we are using mitochondria as a platform to build a minimal cell -defined as a viable collection of genes and an enclosing envelope, such that the system can self-replicate in a particular niche. Our goal is to reverse endosymbiosis, not for the purpose of re-engineering a living microbe, but to build the simplest cell possible. Our approach is to systematically move genes from the nuclear to the mitochondrial genome. We begin by building a transcriptionally-independent mitochondrial that does not depend on nucleus-encoded proteins for mitochondrial gene expression. Four genes required for mitochondrial transcription, namely the mitochondrial RNA polymerase (POLRMT) and the transcription factors TFAM, TFB1M and TFB2M, are modified to comply with the mitochondrial genetic code and introduced into the mitochondrial genome. Following this transfer, the nuclear copies of these genes are deleted from the host genome. Here we describe the steps undertaken towards this goal, including efforts to engineer a modified mouse mitochondrial genome that carries the nucleus-encoded mitochondrial transcriptional machinery. We also discuss efforts to deliver and express recombinant DNA in mitochondria. The construction of a minimal cell is the first step towards a functional definition of the living state and a pre-requisite for the construction of whole synthetic organisms in the laboratory. This work warrants insight into a variety of fields, including the origins of life, bacterial evolution, control of metabolism and mitochondrial physiology, as well as several practical applications, such as the production biofuels and biopharmaceuticals, and environmental remediation.

The Bcl-2 Family Protein N-Bak Induces Structural Changes in Mitochondrial and Endoplasmic Reticulum Membranes

M. Yabal, M. Jakobson, E. Jokitalo, U. Arumé, M. Makarow; 1 Institute of Biotechnology, University of Helsinki, Helsinki, Finland, 2Department of Applied Chemistry and Microbiology, University of Helsinki, Helsinki, Finland

Bcl-2 proteins are regulators of programmed cell death that mediate apoptosis by regulating the integrity of endoplasmic reticulum (ER) and mitochondrial membranes via their Bcl-2 homology (BH) domains. In this study we examined the localization and activity of a novel member of the Bcl-2 protein family expressed only in central and peripheral neurons, N-Bak. N-Bak is a splice-variant of the ubiquitously (except in neurons) expressed pro-apoptotic Bak protein which comprises BH domains 1, 2 and 3. N-Bak is a BH3-only protein with a novel transmembrane domain at the extreme C-terminus. In neonatal sympathetic neurons N-Bak has been demonstrated to be anti-apoptotic whereas in non-neuronal cells and in cortical, hippocampal, and cerebellar granule neurons, it is pro-apoptotic. In sympathetic neurons N-Bak has been shown to localize to an undetermined intracellular membrane. In this study we aimed to elucidate the membrane target of N-Bak. We employed in vivo biochemical assays, fluorescence imaging, and electron microscopy in the yeast Saccharomyces Cerevisiae as well as mammalian non-neuronal cells, and primary sympathetic neurons. We demonstrate that N-Bak is not toxic for yeast cells and we detected the protein on mitochondrial outer membranes: N-Bak behaved as a peripheral membrane protein. In yeast cells, the active protein induced mitochondrial swelling. In Hela cells, N-Bak associated with both mitochondrial outer membranes and endoplasmic reticulum membranes, and induced mitochondrial membrane degradation. In sympathetic neurons, N-Bak induced degradation of mitochondrial outer membranes and proliferation of the endoplasmic reticulum membrane. These ultra-structural changes were dependent on both an active BH3-domain and the presence of the hydrophobic C-terminus. These results suggest that N-Bak is a BH3-only protein that triggers apoptosis via interactions with longer BH1-4 proteins that are missing in yeast. Also membrane targeting of N-Bak is dependent on these protein interactions with ER membrane proliferation being a neuron specific event.

Role of Bax and Bak in Mitochondrial Morphogenesis

K. L. Norris, M. Karbowski, M. Celander, R. J. Youle; 1SNB, NINDS, NIH, Bethesda, MD, 2George Washington University, Washington, DC, 3Johns Hopkins University, Baltimore, MD

Bcl-2 family proteins are potent regulators of programmed cell death in several animal phyla. These proteins are known to localize to the mitochondria and endoplasmic reticulum, focusing research on this family towards these organelles. However, the function of these proteins remains unknown. Two Bcl-2 family members that induce cell death, Bax and Bak, change intracellular location during apoptosis to concentrate into focal clusters at sites of mitochondrial division, leading us to investigate their potential role in mitochondrial morphogenesis. Bax activates mitochondrial fusion in healthy cells, forming elongated tubules. Cells of various lineages lacking Bax and Bak activity due to genetic knockout or vMIA inactivation have shorter and less interconnected mitochondria than wild-type cells. Bax regulates sub-mitochondrial distribution and membrane mobility of the fusion protein Mfn2. These results show that Bax and Bak regulate mitochondrial dynamics in healthy cells and that Bcl-2 members may regulate apoptosis through morphogenesis machineries. In contrast to Bax/Bak double knockout cells, mitochondrial fragmentation due to vMIA-induced inactivation of Bax/Bak is not reversed by ectopic Mfn2. This is likely due to vMIA-dependent disruption of Mfn2 localization to the outer mitochondrial membrane. Protein interaction with wild-type but not vMIA-deficient Mfn2 appears cytosolic in cells expressing vMIA. However, fluorescence recovery after photobleaching analysis in cells expressing vMIA revealed a phenotype whereby Mfn2 was more mobile within the cell than normal membrane-bound Mfn2, yet less mobile than the soluble GFP protein. The implications of these results will be discussed.

Characterization of Charcot-Marie-Tooth Associated MFN2 Mutations in Patient-derived Fibroblasts and the Yeast Mitofusin FZO1

E. A. Amiot1, P. Pott, Y. Saint-Georges, K. Flanigan, V. Lawson, J. M. Shaw; 1Biochemistry, University of Utah, Salt Lake City, UT, 2Human Genetics, University of Utah, Salt Lake City, UT, 3Ecole Normale Superieure, Laboratoire de Génétique Moléculaire CNRS, Paris, France, 4Neurology, University of Utah, Salt Lake City, UT

Charcot-Marie-Tooth (CMT) disorders are a group of inherited peripheral neuropathies categorized as either demyelinating (CMT1) or axonal (CMT2) disorders. Genetic studies have determined that the most common axonal subclass, CMT2A2, is caused by mutations in MFN2, one of two human mitofusins genes homologous to the yeast mitochondrial fusion protein, Fzo1p. Mitofusins are evolutionarily conserved GTPases localized to the outer mitochondrial membrane and are required for proper maintenance of tubular mitochondrial morphology. When fusion is impaired, unopposed division leads to fragmentation of the mitochondrial network and impaired mitochondrial function. We obtained primary fibroblasts from skin biopsies of CMT2A2 patients carrying different MFN2 mutations and representing a range of clinical phenotypes, from mild to severe. Preliminary studies reveal that these fibroblasts have normal mitochondrial morphology, fusion competence, mtDNA content and integrity, and respiratory capacity. However, the equivalent mutations in Fzo1p, the yeast counterpart of Mfn2, lead to a variety of defects, ranging from subtle distortion of the mitochondrial network to disrupted fusion, complete fragmentation of mitochondria, and loss of mtDNA. Interestingly, the yeast phenotypes correlate with the clinical severity of patients. Yeast co-expressing WT and CMT mutant forms of Fzo1p exhibit normal mitochondrial dynamics, indicating that these mutations are not dominant-negative and possibly explaining the lack of observable phenotypes in the fibroblasts. The yeast results also suggest that Mfn2 mutations and representing a range of clinical phenotypes, from mild to severe. Preliminary studies reveal that these fibroblasts have normal mitochondrial morphology, fusion competence, mtDNA content and integrity, and respiratory capacity. However, the equivalent mutations in Fzo1p, the yeast counterpart of Mfn2, lead to a variety of defects, ranging from subtle distortion of the mitochondrial network to disrupted fusion, complete fragmentation of mitochondria, and loss of mtDNA. Interestingly, the yeast phenotypes correlate with the clinical severity of patients. Yeast co-expressing WT and CMT mutant forms of Fzo1p exhibit normal mitochondrial dynamics, indicating that these mutations are not dominant-negative and possibly explaining the lack of observable phenotypes in the fibroblasts. The yeast results also suggest that Mfn2 mutations carry a second mutation, FZO1. The majority of CMT-related MFN2 mutations are located within the GTPase domain of the protein. We show for the first time that Fzo1p is a bona fide GTPase and are currently testing whether CMT mutations in mitofusins disrupt GTP hydrolysis and whether this may be an underlying molecular cause of the CMT2A2 neuropathy.

Regulation of Mitochondrial Fission by the Mitochondrial Outer Membrane Protein hFis1

M. Serasinge, Y. Yoon; 1University of Rochester, Rochester, NY

Mitochondrial fission in mammalian cells is mediated by at least two proteins, DLP1/Dplp1 and hFis1. DLP1 mediates the scission of mitochondrial membranes through GTP hydrolysis, and hFis1 is a putative DLP1 receptor anchored at the mitochondrial outer membrane by a single transmembrane domain at the C-terminus. The cytosolic domain of hFis1 contains six α-helices (α1-6) that form two tetratricopeptide repeat (TPR) folds. The current study focuses on identifying hFis1-containing complexes and defining the mechanisms of complex formation. We have found that mutations in the hFis1 TPR folds lead to a dominant-negative effect, suggesting that the mutant may interact with endogenous hFis1 or other fission components to inhibit mitochondrial fission. Upon crossinglink of cells expressing full-length hFis1, we observed an appearance of only a small amount of dimeric-size hFis1. However, deletion of the N-terminal first α-helix (α1) greatly increased the formation of dimer and oligomer-size hFis1. These results suggest that hFis1 forms multimeric complexes and that α1 functions as a negative regulator of the
Multimer formation. Further deletions decreased the formation of hFis1 oligomers. Swollen ball-shaped mitochondria were prevalent in cells overexpressing α1-deleted hFis1, and the extent of hFis1 oligomer formation among different deletions was correlated with the ball-shape mitochondria formation. In vitro crosslinking of the purified hFis1 cytosolic domain (α1-α6) did not form any detectable dimer or other complexes. Interestingly, the deletion of α1 (α2-α6) was able to form hFis1-containing complexes distinct from dimeric and oligomeric forms, only in the presence of cell lysis, suggesting that other cellular factors are necessary for hFis1 complex formation. Abnormally elongated mitochondria markedly increased in cells overexpressing α2-α6, suggesting that this mutant contains essential fusion factors in the cytosol and inhibits mitochondrial fusion. These data indicate that hFis1 complex formation requires additional proteins and is regulated by the α1 helix.

Mutations of the Dynamin-like GTPase Drp1 That Affect Self Assembly and Mitochondrial Morphology
C. Chang, J. Stadler, C. Blackstone; NINDS, NIH, Bethesda, MD
The dynamin-related GTPase Drp1 is critical for mitochondrial fission. Previous studies have suggested that Drp1 monomers are assembled into oligomeric ring-like structures at mitochondrial fission sites to construct the outer membrane in a GTP-dependent manner. However, the mechanisms of fission complex assembly and regulation remain unclear, particularly in mammals. The Drp1 protein comprises four structural domains: N-terminal GTP-binding, middle, insert B, and C-terminal GTPase effector (GED) domains. The middle and GED domains are critical for stabilizing higher order structures in Drp1 and the S. Cerevisiae ortholog Dnm1. We have demonstrated that mutations within the middle domain of Drp1, G359D and G363D, alter its oligomerization status, impair its GTPase activity, and interfere with intramolecular associations between GED and middle-GTPase domains. Over-expression of these mutant Drp1 proteins causes tubulation of the mitochondria by inhibiting mitochondrial fission. These findings are consistent with, and extend, those evaluating corresponding mutations in yeast. Lastly, we have identified several sites of post-translational modification by protein phosphorylation and sumoylation in the C-terminal domains of Drp1, and are currently evaluating the effects of these modifications on Drp1 properties and function. Our results provide insights into the interactions and modifications of Drp1, which will clarify regulatory mechanisms of mitochondrial dynamics in cells.

A Conserved Role for Miro Proteins in Mitochondrial Distribution and Morphology
R. L. Frederick, K. Okamoto, J. M. Shaw; Department of Biochemistry, University of Utah, Salt Lake City, UT
The conserved family of Miro GTPases has been implicated in mitochondrial dynamics and distribution in yeast, insects, and mammals. Miro proteins contain two GTPase domains flanking a pair of calcium binding EF hand motifs. We previously demonstrated that yeast cells require the yeast Miro Gem1p to maintain a branched tubular mitochondrial network. In a wild-type yeast, mitochondria form globular structures; collapsed tubules, and grape-like clusters. Gem1p is a tail-anchored outer mitochondrial membrane protein with the GTPases and EF hand motifs exposed to the cytoplasm. Recent work has revealed that the fly and mammalian Miro family members bind the kinesin adapter protein Milton, possibly forming a linker between microtubules and mitochondria (Glater et al 2006, JCB; Fransson et al 2006, BBRC). Consistently, fly miro mutants lack synaptic mitochondria (Gao et al 2005, Neuron). Although the Miro family is conserved, yeast utilize the actomyoskeleton for mitochondrial movement and do not contain an identifiable Milton homolog. Budding yeast grow in a polarized manner and require faithful mitochondrial inheritance to survive, making them an ideal system to study polarized mitochondrial movements. To understand the relationship between Miro and other cellular pathways, we initiated a synthetic lethal screen in yeast. Synthetic genetic interactions between gem1Δ and mutations in other mitochondrial inheritance pathways suggest that the transport function of Miro may be conserved. Altering the distribution of mitochondria between the mother and daughter cells demonstrates that the absence of Gem1p does not impair other mitochondrial inheritance pathways. Thus, multiple overlapping pathways, including a Miro-dependent pathway, are likely required for mitochondrial inheritance. The properties of Miro proteins are currently investigated.

Mitochondrial Dynamics Participates in Overproduction of Reactive Oxygen Species and Cell Injury in Hypertension
T. Yu, 1 J. L. Robotham, 2 R. J. Fox, 1 Y. Yoon, 1 Department of Anesthesiology, University of Rochester, Rochester, Rochester, NY 3 Department of Anesthesiology, Pharmacology and Physiology, University of Rochester, Rochester, NY
Mitochondria in cells display a dynamic behavior, showing constant shape change. However, the functional implication of dynamic change of mitochondrial morphology is not well understood. We observed a rapid change of mitochondrial morphology in cells exposed to high glucose concentrations. Hyperglycemia is a main cause of diabetic complications, leading to oxidative stress through overproduction of reactive oxygen species (ROS) resulting from mitochondrial dysfunction. Therefore, in the present study, we investigated the role of mitochondrial dynamics in regulating mitochondrial function in the hyperglycemic setting. We found that, upon exposure to high glucose concentrations, mitochondria underwent rapid fragmentation and recovery within an hour, which coincided with increase and decrease of ROS levels. Preventing ROS increase in high glucose conditions still caused mitochondrial fragmentation. Remarkably, maintaining tubular mitochondria in high glucose incubation by DLPI-Κ38A, a dominant-negative mutant of the fission protein DLPI, prevented high glucose-induced ROS overproduction. These results demonstrate that mitochondrial fragmentation in high glucose conditions is a causal factor for ROS overproduction. Sustained incubation in high glucose concentrations, which may mimic untreated diabetic conditions, provoked a prolonged ROS increase for the second time after the initial transient increase. Again, the mitochondrial morphology change occurred concomitant with ROS increase. We found an increased cell death during the sustained high glucose incubation. The high glucose-mediated cell death was apoptotic, as the mitochondrial permeability transition pore (MPT), cytochrome c release, and caspase 3 activation were observed in these conditions. DLPI-Κ38A prevented the prolonged ROS increase during extended exposure to high glucose concentration, and thereby the MPT, cytochrome c release, caspase 3 activation, and cell death were subsequently decreased. These findings suggest that mitochondrial morphology controlled by membrane fission and fusion is an integral factor that regulates the mitochondrial ROS production and cell injury in high glucose conditions.

Mitochondrial Clustering Induced by Overexpression of the Mitochondrial Fusion Protein Mfn2 Causes Mitochondrial Dysfunction and Cell Death
P. Huang, 1 Y. Yoon, 1 Department of Pharmacology and Physiology, University of Rochester School of Medicine and Dentistry, Rochester, Rochester, NY 3 Department of Anesthesiology and of Pharmacology and Physiology, University of Rochester School of Medicine and Dentistry, Rochester, NY
Mitochondria change their shapes dynamically mainly through fusion and fission. Dynamin-related GTPases have been shown to mediate remodeling of mitochondrial membranes during these processes. Overexpression of GTPase-defective Mfn2, mfn2, is anchored to the outer mitochondrial membrane in the outer membrane. We found that overexpression of a mitofusin isomorph, Mfn2, drastically changes mitochondrial morphology, forming mitochondrial clusters. A GTPase-defective Mfn2 mutant, Mfn2-K109A, induced the formation of mitochondrial clusters indistinguishable from those seen with the wild-type overexpression, indicating that formation of mitochondrial clusters is independent of the GTPase activity of Mfn2, and that mitochondrial clusters are not the result of mitochondrial fusion. High-resolution microscopic examination indicated that the mitochondrial cluster consisted of small fragmented mitochondria
and overexpressed Mfn2 was concentrated at the interstitial region of mitochondrial aggregate. Inhibiting mitochondrial fission prevented the cluster formation, supporting the notion that mitochondrial clusters are formed by fission-mediated mitochondrial fragmentation. Fragmented mitochondria in the cluster showed slightly larger diameters than control mitochondria, indicating that they undergo mild fission. JC-1 and TMRM assays indicated that mitochondrial clusters displayed a decreased inner membrane potential, suggesting functional compromise of small fragmented mitochondria by Mfn2 overexpression. However, mitochondrial clusters still retained mitochondrial DNA. Greatly decreased cell survival was observed among cells containing mitochondrial clusters, suggesting cell death occurred. We found that cells containing clustered mitochondria lost cytochrome c from the mitochondria, indicating that the extensive mitochondrial fragmentation by Mfn2 overexpression caused cytochrome c release from mitochondria. Inhibition of caspase activity maintained cell survival at a steady level and caspase 3 was activated in cells transfected with Mfn2, indicating that cells containing mitochondrial clusters underwent caspase-mediated apoptosis. These results demonstrate that mitochondrial deformation impairs mitochondrial function, leading to apoptotic cell death and suggest the presence of an intricate form-function relationship in mitochondria.

556 Structural, Functional Features, and Significance of the Physical Linkage between SR/ER and Mitochondria
G. Csordas,1 C. Renken,2 C. Garcia-Perez,2 P. Varnai,1 L. Walter,1 T. Balla,1 C. A. Mannella,1 G. Hajneczky;1 Pathology, Anatomy and Cell Biology, Thomas Jefferson University, Philadelphia, PA;2Resource for Visualization of Biological Complexity, Wadsworth Center, Albany, NY;3Endocrinology and Reproduction Research Branch, National Institute of Child Health and Human Development, Bethesda, MD

Mitochondrial calcium signaling is commonly mediated at the sites of close associations between SR/ER and mitochondria. However, the microstructure of the ER-mitochondrial interface and its relevance for cell function remains elusive. Here we show that ER and mitochondria are physically coupled and directly visualize the tethering structures by electron tomography. The length of the tethers is ~10nm at the smooth-ER and ~25nm at the rough-ER. Limited proteolysis loses the ER-mitochondrial associations and disconnects mitochondrial Ca2+ uptake from the IP3 receptor-mediated Ca2+ release. Conversely, expression of a short ‘synthetic ER-mitochondrial linker’ (~5nm), leads to tightening of the ER-mitochondrial associations to permit the propagation to the mitochondria of Ca2+ release that normally would be unrecognized. Under these conditions, mitochondria become prone to Ca2+ overloading and ensuing membrane permeabilization. Tightening of the ER-mitochondrial associations also appears in cells exposed to some pro-apoptotic stimuli. Thus, the tether length controls the Ca2+ relay function of the ER-mitochondrial interface to support either cell survival or cell death mechanisms. Similarly, we observed SR vesicles tightly coupled with mitochondria in rat heart homogenate that preserved the potency to generate ryanodine receptor dependent Ca2+ increases in the mitochondrial matrix as measured by fluorescence imaging of the vesicles glued to coverslips. Western blot analysis of the lysates of rat heart mitochondria confirmed the presence of SR markers (phospholamban, calsequestrin, SERCA2a) which got reduced after limited trypsinization or exposure to high ionic strength (750 mM NaCl). The latter result suggests that a non-covalent protein-protein interaction may be important in the establishment of physical linkage between the SR and mitochondria. Thus, physical linkage appears as a unifying support/control mechanism for the local Ca2+ couplings between the reticular stores (both SR and ER) and mitochondria.

557 Oxa1 Directly Interacts with ATP9 and Mediates Its Assembly into the F1F0-ATP Synthase
L. Jia, M. H. Bi, R. Huang, A. Sturtevant, J. T. Brunger, and M. A. Wittingham;1 Department of Biological Sciences, Marquette University, Milwaukee, WI

Oxa1 is a member of conserved Oxa1/YidC/Alb3 protein family. In the yeast Saccharomyces cerevisiae, deletion of the Oxa1 gene causes loss of mitochondrial respiratory function due to the impaired biogenesis of three respiratory complexes, of which cytochrome c oxidase complex (COX) is the most affected. Oxa1 was identified to be essential for the co-translational insertion of COX. Our data suggest that interaction between Oxa1 and Atp9 following its synthesis by the ribosome is necessary to ensure the efficient and correct assembly of the Atp9 oligomers, and thus important for the stable assembly of the Fo-sector of the ATP synthase. We demonstrate that Oxa1 directly interacts with Atp9 following its synthesis by in organello translation and affinity purification. In the absence of Oxa1, although newly synthesized Atp9 forms oligomers, the organization is altered. Our data suggest that interaction between Oxa1 and Atp9 is necessary to ensure the efficient and correct assembly of the ATP9 oligomers, and thus important for the stable assembly of the Fo-sector of the ATP synthase.

558 Ubiquitin Mediated Protein Quality Control at the Mitochondria
S. Radke,1 X. Xu,2 Z. Pan,2 D. Germain;11 Oncology/Hematology, Mount Sinai School of Medicine, New York, NY;2Derald H. Ruttenberg Cancer Center and Department of Human Genetics, Mount Sinai School of Medicine, New York, NY

Protein quality control (PQC) is required for the proper folding of newly synthesized proteins. It is ensured by a complex of different proteins that may involve chaperones, co-chaperones, ubiquitin ligases and proteases like the proteasome. If the structure of a protein remains misfolded and cannot be properly folded with the help of the chaperone complex, its elimination can be induced via ubiquitination and proteasomal degradation. PQC has been reported in different cellular compartments including the endoplasmic reticulum and the nucleus. In the mitochondria, AAA-proteases control an ubiquitin independent PQC. Our data show that there is an additional ubiquitin-dependent PQC for proteins residing in the intermembrane space (IMS) of the mitochondria. We found that the IMS chaperone BAP37 interacts with the recently identified F-box protein Skp2B. Using in vitro ubiquitination assay, we demonstrate that Skp2B associates with a ubiquitin ligase activity. Both Skp2B and BAP37 bind to IMS proteins such as cytochrome C, smac and endonuclease G whose ubiquitination depends on Skp2B. However binding and ubiquitination of misfolded IMS proteins are markedly elevated compared to wild-type proteins. Furthermore, we show by electron microscopy and aggresome assay that overexpression of misfolded cytochrome c promotes mitochondrial aggresome formation with strongly aberrant morphology. This results in cytochrome C release and apoptosis. Skp2B overexpression reduces aggresome formation and conversely, Skp2B downregulation enhances the formation of these aberrant structures. In conclusion, our results indicate a novel role of the ubiquitin pathway at the mitochondria involving the chaperone protein Bap37 and the F-box protein Skp2B as necessary for the detection and ubiquitination of misfolded IMS proteins respectively. The elimination of accumulating misfolded proteins is crucial to avoid the formation of mitochondrial aggresomes and is therefore highly important for the integrity of the mitochondria.

559 Dynamics of Respiratory Chain Complexes in Mitochondria
K. B. Busch,1 J. Berete-Hahn,1 I. Wittig,1 H. Schagger,1 M. Jendrach1;1Cell Biology and Neuroscience, Kinematic Cell Research, Frankfurt, Germany;2Molekulare Bioerggetik, Universitaet Frankfurt, Frankfurt, Germany

Mitochondrial dynamics play a key role in cell life, ageing and death. It is hypothesized that here the rescue mechanism is provided to maintain a healthy chondriome by constant mixing of mitochondrial compounds. Improvement of mitochondrial compounds, in particular by ROS (reactive oxygen species), is a severe problem during the life span of a cell. Mitochondrial fusion may allow the exchange of constituents (proteins, lipids and mitochondrial DNA) and thus maintaining functionality. We address the question whether complexes of the respiratory chain are exchanged during mitochondrial fusion. The main complexes of the respiratory chain form superfamilies: Complexes I, III, and IV are probably organized in respirasomes or even respiratory strings (Wittig et al, 2006). Complex V has a distinct organization. The dynamics of Complex I were followed during fusion and fission. HeLa cells with differently labeled mitochondrial Complex I were fused and the re-localization of Complex I was monitored. The tagged complex I spread throughout the whole mitochondrial population within 3 to 6 h after induction of cell fusion, substantiating the view of a homogenous mitochondrial population due to constantly rearranging mitochondria. Mitochondria of fused cells displayed a patchy substructure where the differently labelled proteins occupied separate and distinct spaces (Busch et al., 2006), indicating the existence of long-lasting sub-mitochondrial structures. In young HUVECs cells, Complex I tagged by photoactivatable EGFP showed a fast transfer rate due to mitochondrial fusion. We propose that this is reduced in old (postmitotic) HUVECs mitochondria, which display decreased dynamics (Jendrach et al., 2005). Mobility studies with labelled Complex II and IV shall complement the current results.

560 Mitochondrial Magnesium Imaging with Novel Fluorescent Probe

Mitochondria are the organelles responsible for cell death and proliferation that also work as ‘magnesium’ stores. Mg²⁺ is considered to play important roles in the modulation of mitochondrial functions such as oxidative phosphorylation and apoptosis and also in mitochondrial disorder based neural diseases like migraine. Thus, we focused on the development of imaging probes and systems to monitor the dynamics of Mg²⁺ in mitochondria. Rhodamine-based Mg²⁺ fluorescent probes were designed, which localize in mitochondria. KMG-301 has a charged beta diketone Mg²⁺ selective binding site and rhodamine as a fluorophore in order to localize in mitochondria. KMG-301 showed successful Mg²⁺ specific fluorescent increase. Mitochondrial localization of KMG-301 was confirmed by double-staining with GFP-Mito. Mitochondrial Mg²⁺ dynamics were evaluated using isolated mitochondria. Isolation was confirmed by AFM and fluorescence image. FCCP induced Mg²⁺ release and fluorescence decrease of KMG-301 in mitochondria, showing that KMG-301 functions inside mitochondria. Further, intracellular and mitochondrial Mg²⁺ changes induced by FCCP were simultaneously imaged by double staining with KMG-104 (cytoplasmic Mg²⁺) and KMG-301 (mitochondrial Mg²⁺). Mitochondrial Mg²⁺ decrease was slightly faster than cytosolic Mg²⁺ increase. Thus, we can conclude that KMG-301 successfully measured intramitochondrial release of Mg²⁺ in a living PC12 cell. Here, we developed a novel rhodamine-based Mg²⁺ fluorescent probe (KMG-301) and a Mg²⁺ imaging system inside and outside of mitochondria. The correlation between the Mg²⁺ and the main of mitochondrial functions (oxidative phosphorylation, apoptosis) related to many neural diseases can be clarified by ‘mitochondrial magnesium imaging’.

Objective: To investigate functional heterogeneity within pancreatic β-cell mitochondria.

Background: In the β-cell, mitochondrial membrane potential (ΔΨm) increases in response to glucose. This results in the production of metabolites which serve as insulin secretory signals. It is not clear, matches to the most common mtDNA haplotypes in sub-Saharan Africa. Here we looked to further test these common African mtDNA haplotypes which belong to the L-subclade. These types

β cells were isolated from C57BL6 mice and plated on glass slide dishes, or the Optical LiveCell Array for confocal microscopy. Cells were loaded with the mitochondrial dye TMRE and Mito Tracker Green and imaged using a Zeiss confocal microscope. Mitochondrial matrix targeted photo activatable GFP (PA-GFP) was used to tag and track the ΔΨm of individual mitochondria over time. Results: β-cell mitochondria are functionally heterogeneous, displaying great heterogeneity in ΔΨm values. Tracking individual mitochondria over time reveals that ΔΨm differences between mitochondria persist and do not result in instability. Furthermore, when expressed as mV this range is considerably greater than the change in mV induced by fuel challenge. Upon acute glucose stimulation the range in ΔΨm narrows, indicating recruitment of previously inactive mitochondria into the active pool. Exploration of the mechanism behind heterogeneity revealed BAD, previously implicated in mitochondrial recruitment of glucokinesis, as a significant factor influencing the level of heterogeneity. Chronic exposure to a rich nutrient environment, in an in vitro diabetes model, leads to increased ΔΨm heterogeneity which is a result of increased mitochondrial fission and reduced network size. Conclusions: We suggest that mitochondrial ΔΨm heterogeneity in beta cells represents a metabolic reservoir that is recruited by increased levels of fuels and therefore may serve as a therapeutic target.

Integral membrane proteins are maintained at the plasma membrane by an intricate balance of secretion, endocytosis, recycling, and protein quality control in eukaryotic cells. We have used the trafficking of a model plasma membrane protein, the yeast arginine permease Can1, as a reporter to understand the mechanisms involved in membrane protein trafficking and quality control. Can1 is transported to the plasma membrane via the secretory pathway and can subsequently be internalized into an endosomal compartment via ubiquitin-dependent endocytosis. Once there, depending on nutrient conditions, Can1 is either actively recycled back to the plasma membrane or delivered to the vacuole for degradation via the multivesicular body (MVB) pathway, which is dependent on the function of three endosomal complexes required for transport (ESCRTs). We conducted a screen of the yeast nonessential gene deletion collection for mutants that exhibit either resistance or hypersensitivity to the toxic arginine analog canavanine. Genes that come through the screen function in several different cellular pathways including vesicular trafficking, protein quality control, lipid metabolism, cytoskeletal organization, and ubiquitin-mediated signaling and catabolism. Many of the known VPS genes, such as class E VPS genes that encode components of the ESCRT complexes, came through the screen as canavanine sensitive (CVS), while genes with protein products that function in recycling and secretion of Can1 came through as canavanine resistant (CVR). We identified Cvr22, a protein that localizes to endosomal compartments and interacts with known ESCRT complex components. We will report on the characterization of Cvr22 and its role in the MVB sorting pathway.

Did2 Coordinates Vps4-mediated Dissociation of ESCRT-III from Endosomes
D. P. Nickerson, M. C. West, G. Odorizzi; MCD Biology, University of Colorado, Boulder, CO
The sorting of transmembrane cargo proteins into the lumenal vesicles of multivesicular bodies (MVBs) depends upon the recruitment of Endosomal Sorting Complexes Required for Transport (ESCRTs) to the cytosolic face of endosomal membranes. The subsequent dissociation of ESCRT complexes from endosomes requires Vps4; a member of the AAA family of ATPases associated with a variety of cellular activities. We show that Did2 directs Vps4 activity to the dissociation of ESCRT-III but has no role in the dissociation of ESCRT-I or ESCRT-II. Surprisingly, vesicle budding into the endosome lumen occurs in the absence of Did2 function even though Did2 is required for efficient sorting of MVB cargo proteins into lumenal vesicles. This uncoupling of MVB cargo sorting and lumenal vesicle formation suggests that Vps4-mediated dissociation of ESCRT-III is an essential step in the sorting of cargo proteins into MVB vesicles but is not a prerequisite for budding of vesicles into the endosome lumen.

567
Regulation of Multivesicular Body Formation by Nvr1
C. Dimamo, C. B. Jones, M. Babst; Biology, University of Utah, Salt Lake City, UT
Endosomal compartments called multivesicular bodies (MVBs) facilitate the sorting of transmembrane proteins from the cell surface to the lumen of lysosomes/vacuoles for degradation. Class E Vps protein complexes including the ESCRT (-I, -II, -III) complexes and the AAA-ATPase Vps4 are recruited to the MVB membrane and cooperate to form cargo-containing vesicles for vacuolar delivery. Vps4 is known to play a terminal role in the vesicle-forming process at the MVB, but how Vps4 function is regulated is not well understood. We have previously shown that the class E protein Vti1 positively regulates Vps4 ATPase activity (Azmz et al., 2005). Here, we describe a novel regulator of Vps4 function that we have designated Nvr1 (for negative regulator of Vps4). We have determined that Nvr1 localizes to the endosomal membrane and interacts with Vps4 in the sorting process. Under normal growth conditions, Nvr1 is rapidly degraded by the proteosomal system. Stabilization or overexpression of Nvr1 prevents Vps4-dependent recycling of ESCRT complexes from the endosomal membrane, which results in MVB sorting defects. We have also found that Nvr1 directly binds to Vps4 thereby regulating Vps4 activity. Our findings indicate that the cellular levels of Nvr1 regulate MVB trafficking through the interaction of Nvr1 with Vps4. Progress toward the dissection of Nvr1 function will be presented.

Cell-free Reconstitution of Membrane Fission
L. Michailat, A. Mayer; Biochemistry, University of Lausanne, Epalinges, Switzerland
Most organelles in eukaryotic cells undergo membrane fission events in order to ensure correct organelle transmission, and homeostasis. Fission of membrane is often dynamin-dependent. In general, little is known about the fission mechanism, nor about other factors involved. The vacuole of budding yeast Saccharomyces cerevisiae is used as a model for membrane fission. Vesicles undergo constant fission and fusion, with an average of 1-3 vacuoles per cell in the steady-state. As lysosomal compartments, vacuoles play a role for the turnover of proteins and lipids, for storage and transport of ions and amino acids, and for osmoregulation. Fusion of vacuoles can be induced in vivo by application of an osmotic shock to the cells. Simple macroscopic inspection of cells has allowed the identification of numerous factors involved in vacuole fission. We have now reconstituted the process of fission in vitro, which permits to study the mechanisms involved in detail. Conditions to induce fission of purified vacuoles in vitro have been identified. In vitro fission reproduces the physiological requirements of the in vivo reaction, because it is sensitive to the same mutations and inhibitors as vacuole fission in living cells. The ability to study physiological membrane fission in vitro opens exciting perspectives because yeast vacuoles are big enough (1-3nm) to be conveniently visible in the light microscope. When combined with new technology to fix individual organelles on solid supports and/or to quantitate and kinetically dissect the fission process, e.g. by dynamic light scattering, our in vitro system generates a powerful tool to elucidate the molecular events in a membrane fission reaction.

Chemical Genetic Identification of Inhibitors of Membrane Traffic
M. C. Duncan, D. G. Ho, M. E. Jung, G. S. Payne; 1Biological Chemistry, UCLA-Medical School, Los Angeles, CA, 2Chemistry and Biochemistry, UCLA, Los Angeles, CA
The field of membrane trafficking has a long history with use of chemical inhibitors that can allow greater flexibility than genetic techniques such as knockout and knockdown strategies. The spectrum of membrane trafficking events with potent chemical inhibitors remains limited. However, the availability of large libraries of diverse compounds has opened opportunities for identification of small molecules altering currently untargeted events. Growth based screening provides several advantages: compounds identified are cell permeant and functional in metabolically active cells; screening requires simple plate readers, common reagents and little optimization. In general, reduced or enhanced growth is a non-specific phenotype. We recognized that synthetic lethal genetic interactions, a phenotype commonly investigated in genetic research, provides a facile strategy to confer specificity for particular cellular processes to a growth based assay. We made use of well characterized synthetic genetic growth phenotypes as a guide for selecting in vivo chemical induced growth phenotypes. A family of compounds identified by compound-specific lethal screening in yeast cause effects that mimic phenotypes of deletions of clathrin adaptor AP-1 substrates, a major component in vesicle traffic between the Golgi network (TGN) and endosomes. Importantly these effects are specific to traffic between the TGN and endosomes and do not appear to alter other membrane traffic pathways. These novel piparrazinyl compounds should be useful for further studies of membrane traffic in yeast, and potentially in other. Furthermore, the easily automated technology may be adapted to identify inhibitors of a wide variety of cellular processes.

Myotubularin Phosphoinositide Phosphatase Regulates Membrane Homeostasis in Drosophila Cells

M. Velickova, J. Dennis, A. Kiger; Cell and Developmental Biology, University of California at San Diego, La Jolla, CA

The regulation of specific phosphoinositide phosphatases (PIPs) provides spatial control for distinct cellular processes, including cytoskeletal organization, protein sorting, membrane trafficking and membrane homeostasis. Using RNAi in Drosophila Kc cells, we identified myotubularin (mtm), a predicted phosphoinositide phosphatase, with a function important for an induced change from a round to an elongated cell shape. PI(3)P and PI(3,5)P2, the predicted substrates of myotubularin phosphatases, have been localized throughout the endolysosomal system. To identify the PIP-depleted cell process required for cellular elongation, we examined mtm-depleted cells for defects in the function of membranous organelles in kinetic cell-based assays. Whereas no defects were detected in early endosomes (Rab5), RNAi knock down of mtm resulted in enlarged (3x) late endosomes and lysosomes (Rab7-GFP, LAMP1-GFP, LysoTracker), as indicated by quantitation of fluorescent images. The rate of fluid phase transport of fluorescent Dextrans was significantly delayed, further suggesting a role for mtm in endolysosomal homeostasis. Mtm depleted cells exhibited an accumulation of the PI(3)P reporter, GFP-2xFYVE, suggesting that PI(3)P is a substrate of mtm in Drosophila. To test whether mtm cellular roles are mediated through phosphoinositides, we assessed the consequence of modulating phosphoinositide levels by reducing the opposing phosphoinositide kinase function. Co-RNAi of mtm and the Drosophila PI(3)P kinases DIP60 or DIP45, resulted in reduced accumulation of PI(3)P, indicating a role for mtm in phosphoinositide recycling. We propose that myotubularin-mediated turnover of the PI(3)K65D generated pool of PI(3)P involved in regulation of membrane homeostasis of the endolysosomes, which subsequently may be important for cellular morphogenesis. Currently we are investigating the role of mtm for the formation of specialized cell types in Drosophila development. We are testing the spatial regulation of Mtm activity and its significance for phosphoinositide-dependent cellular functions in vivo.

Leishmania Parasitophorous Vacuoles Acquire the Capacity to Initiate Phosphoinositide-dependent Signaling by Interacting with VAMP7 Positive Vesicles

D. Abu Abdallah, 1 J. Benjack, 1 P. E. Kim; 1Microbiology and Cell Science, University of Florida, Gainesville, FL, 2Wright-Patterson Medical Center, Dayton, OH

Leishmania amazonensis parasites infect macrophages wherein they replicate in distended parasitophorous vacuoles (PV’s). Previous studies showed that macrophage infection with Leishmania results in sustained levels of activated Akt, a downstream kinase in the PI3K pathway. To determine whether Akt activation in infected cells occurs at the PV membrane (PVM), we tracked the recruitment of the pleckstrin homology domain of Akt fused to GFP (Akt-PH-GFP) in transfected cells. Within the first hour after infection, greater than 60% of nascent PVs were positive for Akt-PH-GFP. We confirmed that Akt-PH-GFP recruitment to PVs was dependent on the presence of phosphoinositides by reducing observed Akt-PH-GFP positive PVs in the presence of wortmannin. Also, a mutant Akt-PH-GFP construct whose phosphoinositide binding is disrupted, failed to be recruited to PVs. Beyond 1 hour post infection, there was a gradual diminution in the number of Akt-PH-GFP positive PV’s, down to approximately 20% by 8 hours post infection. This time course of Akt-PH-GFP association with PVs is unlike the time course of association of plasma membrane molecules that cycle off nascent PVs within 30 minutes post infection. Disruption of microtubules with nocodazole or colchinib inhibited Akt-PH-GFP recruitment to the PVM. One interpretation of this observation is that the capacity to generate phosphoinositides at the PVM requires the fusion of PVs with vesicles along microtubule tracks. Further investigation was obtained by assayings VAMP7 and VAMP8, which plays a role in the transport of vesicles along microtubules. Overexpression of dominant negative mutants of VAMP7 and VAMP8 minimal effects of Akt-PH-GFP recruitment to the PV, expression of VAMP7 (Ner1-120) significantly blocked Akt-PH-GFP recruitment to the PVM. Taken together, these studies show that PVs acquire the capacity to generate phosphoinositides to which signaling molecules that modify host cell processes are recruited and activated.

Rab GTPase-activating Proteins Define the Transport Pathway of Shiga Toxin

E. Fuchs, H. K. Alexander, S. Yoshimura, R. Kopajtic, F. A. Barr; Max Planck Institute of Biochemistry, Martinsried, Germany

Rab family GTPases are conserved regulators of membrane trafficking that cycle between inactive GDP- and activated GTP-bound states. A key determinant of Rab function is the lifetime of the GDP-bound state. Since Rabs have a low intrinsic rate of GDP-hydrolysis this is under the control of GTP-hydrolysis activating proteins (GAPs). RabGAPs are useful cell biological tools, since they can be used to specifically inactivate the endogenous pool of their target Rab, and thus interfere with the process this Rab is involved in. Here we have focused on the identification of RabGAPs that interfere with the transport of Shiga toxin between the cell surface and the Golgi apparatus. We have screened 35 human RabGAPs for their ability to block the uptake and transport of fluorescently labelled B-subunit of Shiga Toxin (STxB) to the Golgi. To confirm that effects on STxB transport are due to GAP activity we compared wild-type RabGAPs with catalytically inactive mutants. In addition, the integrity of the Golgi was monitored in RabGAP expressing cells, to ensure that the lack of a Golgi signal for STxB was not simply due to Golgi fragmentation. As a final control for specificity, we monitored the endocytosis of fluorescently labelled EGF, to eliminate RabGAP-causing a general block in endocytosis. Seven out of 35 RabGAPs blocked STxB transport to the Golgi dependent on their catalytic activity, while having no effect on the uptake of EGF. Overexpression of two of the positive RabGAPs lead to a fragmented Golgi, however, STxB accumulated in pre-Golgi structures, indicating these GAPs block STxB trafficking in addition to disrupting the Golgi. We therefore conclude that these seven candidate RabGAPs act specifically on the transport pathway utilised by STxB on its way from the plasma membrane to the Golgi, and will provide useful tools to further investigate this pathway.

A Syntaxin 10-containing SNARE Complex Distinguishes Protein Transport from Late and Early Endosomes to the trans Golgi Network

I. G. Ganeley, E. Espinosa, S. Pfeffer; Biochemistry, Stanford University, Stanford, CA

V-SNAREs on vesicles and t-SNAREs on target organelles mediate fusion between vesicles and their targets. We used soluble, recombinant SNARE proteins as potential dominant-negative inhibitors to identify SNARE proteins that are responsible for the fusion of late endosome-derived transport vesicles with the trans Golgi network (TGN). We show here that soluble v-SNAREs, VAMP3 and VAMP4, but not VAMP7 or 8, can inhibit the transport of mannose 6-phosphate receptors from late endosomes to the TGN in an in vitro system that reconstitutes this transport step. Similarly, the soluble t-SNAREs Syntaxin-10, 16 and Vti1a inhibited transport, but Syntaxins 6, 11, 12 and Vti1b did not. Overexpression of cytosolic SNARE proteins that inhibited transport in vitro triggered lysosomal enzyme mis-sorting from living cells, as monitored by the hyper-secretion of hexosaminidase from soluble SNARE protein-expressing fibroblasts. Furthermore, each of the requisite SNARE protein was found to bind GCC185 in cell extracts. GCC185 is a GRIP domain-containing, Golgin family member that binds to Rab9 and is required for mannose 6-phosphate receptor recycling (1). This study represents the first functional assignment for the Syntaxin10/Syntaxin16/Vti1a; VAMP3/VAMP4 SNARE complex. Moreover, the requirement for Rab9, GCC185, and Syntaxin 10, and the lack of a requirement for Syntaxin 6, distinguish late endosome export of mannose 6-phosphate receptors from the transport of proteins from early endosomes to the TGN. I. Reddy, J.V. et al. (2006) A Functional Role for the GCC185 Golgin in Mannose 6-Phosphate Receptor Recycling. Mol. Biol. Cell, in press

Rab11 Family Interacting Proteins (FIPs) Regulate the Differential Sorting of Membrane Proteins in Recycling Endosomes

J. Burden, J. Jing, C. Hopkins, R. Prekeris; 1Department of Biological Sciences, Imperial College, London, United Kingdom, 2Cell and Developmental Biology, UCHSC, Aurora, CO

Rab11 and Rab11p are the members of Rab11 family of interacting proteins (FIPs), a family characterized by their ability to bind Rab11 and phospholipids. We and others have previously shown that FIPs are involved in regulating various steps of endocytic sorting and recycling. However, their precise function remains to be elucidated. Using the combination of RNA interference, electron and fluorescent microscopy and a variety of biochemical techniques we have investigated the role of CPH and Rip11 in regulating endocytic sorting and transport. Firstly, we overexpressed Rip11-Rab Binding Domain (Rip11-RBD) dominant-negative construct to investigate the role of FIPs in endocytic transport. Rip11-RBD sequesters Rab11 and prevents it from interacting with proteins that are responsible for the fusion of late endosome-derived transport vesicles with the trans Golgi network (TGN). We show here that soluble v-SNAREs, VAMP3 and VAMP4, but not VAMP7 or 8, can inhibit the transport of mannose 6-phosphate receptors from late endosomes to the TGN in an in vitro system that reconstitutes this transport step. Similarly, the soluble t-SNAREs Syntaxin-10, 16 and Vti1a inhibited transport, but Syntaxins 6, 11, 12 and Vti1b did not. Overexpression of cytosolic SNARE proteins that inhibited transport in vitro triggered lysosomal enzyme mis-sorting from living cells, as monitored by the hyper-secretion of hexosaminidase from soluble SNARE protein-expressing fibroblasts. Furthermore, each of the requisite SNARE protein was found to bind GCC185 in cell extracts. GCC185 is a GRIP domain-containing, Golgin family member that binds to Rab9 and is required for mannose 6-phosphate receptor recycling (1). This study represents the first functional assignment for the Syntaxin10/Syntaxin16/Vti1a; VAMP3/VAMP4 SNARE complex. Moreover, the requirement for Rab9, GCC185, and Syntaxin 10, and the lack of a requirement for Syntaxin 6, distinguish late endosome export of mannose 6-phosphate receptors from the transport of proteins from early endosomes to the TGN. Phagocytic and Autophagic Pathways Are Actively Modulated by Phase II Coxiiella burnetii to Efficiently Replicate in the Host Cell

F. S. Romanò, 1 M. G. Gutierrez, 2 W. Beron, 1 M. Rabinovitch, 3 M. I. Colombó; 1HEIM-CONICET-Facultad de Ciencias Médicas, Universidad Nacional de Cuyo, Mendoza, Argentina, 2Departamento de Microbiología, Imanología e Parasiología, Escola Paulista de Medicina, UNIFESP, São Paulo, Brazil, 3Microbiology and Immunology, University of Michigan School of Medicine, Ann Arbor, MI

The etiologic agent of Q fever Coxiiella burnetii, is an intracellular obligate parasite that develops large vacuoles with phagolysosomal characteristics, containing multiple replicating bacteria. We have previously shown that Phase II Coxiiella burnetii replicative vacuoles generated after 24-48 h post infection are decorated with the autophagic protein LC3. The aim of the present study was to examine, at earlier stages of infection, the distribution and roles of the small GTPases Rab5 and Rab7, markers of early and late endosomes, respectively, as well as of the protein LC3 on C. burnetii trafficking. Our results indicate that: 1) Coxiiella phagosomes (CPs) acquire the two Rab proteins sequentially during infection; 2) overexpression of a dominant negative mutant form of Rab5, but not of Rab7, impaired Coxiiella entry, whereas both Rab5 and Rab7 dominant negative mutants inhibited vacuole formation; 3) Cph colocalized with the protein LC3 as early as 5 min after infection; acquisition of the protein appeared to be a bacterially driven process, since it was inhibited by the bacteriostatic antibiotic chloramphenicol; 4) C. burnetii delayed the arrival of the typical lysosomal protease cathepsin D to the CPs, a process that is increased by starvation-induced autophagy. Based on our results we propose that C. burnetii transits through the normal end/phagocytic pathway but actively interacts with autophagosomes at early times after infection. This intersection with the autophagic pathway delays fusion with the lysosomal compartment possibly favoring the intracellular differentiation and survival of the bacteria.

Vascular Trafficking Is Required for Maintenance of Lipid Bodies

K. M. Szymanski, J. M. Goodman; Pharmacology, University of Texas Southwestern Medical Center, Dallas, TX

Lipid bodies (lipid droplets, adiposomes) are dynamic organelles found in virtually all eukaryotic cells that store neutral lipids. They are surrounded by a single phospholipid leaflet that is deformed by the endoplasmic reticulum. Very little is known about factors that control size, number, and distribution of lipid bodies. To this end we screened a commercial knockout strain library of nonessential genes in Saccharomyces cereviseae. Cells were grown overnight in rich medium, and lipid bodies were visualized by fluorescence microscopy upon staining with Bodipy 403/503. The wild-type strain, BY4742, contained 5.05 ± 0.44 (SEM) lipid bodies per cell, most of which formed a “string of pearls,” the ultrastructure of which we recently described (Binnis et al., JCB 173:719, 2006). With 99% of the library screened, we found 69 strains with lipid bodies that were clearly altered in number, size, or distribution within the cell. Three typical morphological variants were found: those with few large lipid bodies (Class 1), such as abf2Δ with 2.50 ± 0.18 lipid bodies; normal number of large lipid bodies (Class 2); and multiple small and indistinct lipid bodies (Class 3), such as erd1Δ with 9.51 ± 0.79 lipid bodies. Although several families of genes were identified that are important for maintenance of normal lipid bodies, the largest group of strains (18) were lacking genes for the endosomal-vascular trafficking pathway. They include 9 VPS genes, 2 PEP genes and 6 genes of the vacuolar ATPase, the last representing both V0 and V1 assemblies. These strains typically were of the Class 2 phenotype. It is not yet clear whether endosomal-vascular trafficking per se affects lipid body morphology, or whether a defective pump is solely responsible for the phenotype in this group of mutants.

Lysosome Trafficking in Osteoblasts

N. Nahavi, R. Harrison; Department of Life Sciences, University of Toronto at Scarborough Campus, Toronto, ON, Canada

Osteoblasts are the principle cells responsible for bone deposition via secretion of organic proteins such as type I collagen, proteoglycans, glycoproteins, and carbohydrates proteins into the extracellular matrix (ECM). Osteoblasts are also responsible for controlling the levels of bone resorption through regulating osteoclastic activities; thus, they play a key role in the pathophysiology of osteoporotic diseases. The objective of our experiments is to investigate the morphology and function of undifferentiated and differentiated MC3T3 osteoblast cell line as well as primary cells through a number of experimental procedures including cell transfection, microinjection, epifluorescence and TRF microscopy. We observe a morphological change in differentiated osteoblasts as compared to undifferentiated cells. The differentiated cells show enhanced lysosome dispersion. Live imaging of LAMP-GFP transfected cells reveal a faster movement of lysosomes in ascorbate differentiated cells compared to undifferentiated osteoblasts. Lysosomal distribution is dependent on intact microtubules and blocking antibodies to microtubules interfere with lysosome distribution in cells before and after differentiation. Osteoblast lysosomes acquire Rab7-GFP but have negligible levels of Rab5-GFP and Rab11-GFP. It is suspected that osteoblast lysosomes may be involved in protein secretion or degradation of the ECM. The function of lysosomes in osteoblasts is currently under investigation.

Three-dimensional Pathways of Transport for Maternal Antibody Across the Epithelial Barriers in the Small Intestine of Suckling Rats Revealed by Electron Tomography

W. He, 1 C. Kivotik, 2 M. Morphey, 3 J. McIntosh, 3 G. Jensen, 1 P. Bjorkman; 1Division of Biology, California Institute of Technology, Pasadena, CA, 2Laboratory for 3D Electron Microscopy of Cells, University of Colorado, Boulder, CO, 3Laboratory for the Physical Sciences, College Park, MD, 4Department of Chemistry, University of Illinois at Urbana-Champaign, Urbana, IL

Before its own immune system is fully developed, the suckling rat is dependent upon the neonatal Fc receptor (FcRn) to transport maternal IgG from ingested milk into its bloodstream. Early conventional electron microscopy studies using IgG-Ferritin conjugates showed that the proximal small intestine of the neonatal rat selectively transports ingested antibodies into the blood. However, due to the large size and non-specific coupling of the labels that were used, these studies may not have revealed the true transport pathways. To accurately trace transport pathways during dynamic endocytic processes and to examine the configuration of FcRn-Fc complexes within different types of intracellular vesicles in the small intestine, we need a technique that allows us to trace fully functional antibody conjugates in an in vivo system. We are using 1.4 nm nanogold clusters, covalently attached to the reduced hinge region of rat Fc then purified on an FcRn affinity column, as a more reliable label to explore functional endocytic pathways. It is challenging, however, to visualize 1.4nm gold particles within thin sections prepared for electron microscopy. Therefore, we are combining techniques: improved gold-enhancement methods for chemically-fixed samples, a newly-developed freeze-substitution based silver-enhancement method for high pressure frozen samples, and electron tomography to visualize the labeled Fc molecules and trace the transport pathway in 3D. Our results clearly demonstrate that the neonatal rat proximal small intestine takes up antibodies through an FcRn-specific mechanism with most gold particles localized in tubular vesicles and coated vesicles; the conjugates are then discharged to the basolateral extracellular space. In the distal small intestine, which does not express FcRn, the gold particles are delivered to a lysosomal degradation pathway. Hence, these techniques are confirmed to be very useful for tracing 3D transport pathways and of analyzing dynamic events in transcytosis.

4D Imaging of Endosome Dynamics in Filter-grown Polarized MDCK Cells

Y. Kababiyah, J. Chu, J. Lippincott-Schwartz, I. M. Arias; CBMB, NICHD/NIH, Bethesda, MD

Live cell imaging techniques have been widely used to study cellular dynamics and processes in cells and organisms. However, live imaging of filter-grown, fully, polarized epithelial cells has been cumbersome and problematic due to extensive manipulation of the permeable filter inserts that could result in the loss of polarization and function. To develop a simple protocol for live cell imaging of filter-grown polarized Madin-Darby Canine Kidney (MDCK) cells, we cultured MDCK cells on the reverse side of permeable filter inserts. MDCK cells cultured in this inverted configuration formed structural and functional tight junctions. Furthermore, all morphological and functional features tested were similar to MDCK cells cultured in the conventional configuration. To evaluate the advantage of inverted culture system, live cell imaging was performed with FM4-64, a lysophilic fluorescent dye, commonly used to visualize endosomes dynamics. Using an inverted microscope, MDCK cells cultured in the inverted configuration permitted 4D tracking of FM4-64 positive endosomes dynamics, effectively allowing selective reagent application, and access to either the apical or the basolateral membrane surfaces. These results demonstrate that the inverted culture system provides a technique to analyze endosome dynamics in four dimensions with spatial and temporal resolution when provided with an inverted microscope.
lower eukaryotes. 

T. gondii is an obligate intracellular eukaryotic pathogen that relies on cell host invasion as a major survival strategy. Invasion related proteins are proteolytically processed during their transport to specialized secretory organelles (micronemes and rhoptries) that are sequentially discharged during cell entry. Using general and specific inhibitors we have found evidence that TgCPL, T. gondii cathepsin L-like enzyme, is involved in the proteolytic maturation of multiple microneme adhesin complexes. In the tachyzoite invasion form, TgCPL is located in a novel, photon lutein structure visible by phase contrast microscopy and positioned in the apical region between the rhoptries and apical secretory organelles. Serial sections of the same parasite shown by electron microscopy indicate that TgCPL is associated to the limiting membrane and internal vesicles of a large multi-vesiculated compartment, which is also occupied by a proton-pump, the T. gondii vacuolar protonophosphatase TgVPI. During intracellular replication the compartment is highly dynamic and is fragmented in multiple vesicles. We speculate that TgCPL is a multifunctional enzyme involved in both the proteolytic maturation of microneme protein complexes and the degradation of endogenous and exogenous substrates within the endocytic pathway.

Phenotype Analysis of Snapin Knockout Mice Reveals Its Essential Role in the Late Endosome-Lysosome Trafficking Pathway

L. Lu, J. Tian, Q. Cai, Z. Sheng; NIH, Bethesda, MD.

Our previous findings that a frameshift (p.E805fsX) and a relatively milder missense mutation (p.N3376S) located in the BEACH domain of Snapin KO mice in combination with genetic rescue experiments provide evidence that Snapin, a SNARE-associated protein, modulates neurosecretion by stabilizing the structural coupling of synaptogamy to the SNARE complex, a critical step for priming docked vesicles for fusion (Tian et al. 2005). In addition to established role in vesicle priming for synaptic vesicle exocytosis, recent evidence suggests that Snapin is potentially implicated in the trafficking of lysosome-related organelles (Starevcic and Dell'Angelica, 2004). By characterizing Snapin KO mice, we now report a novel role for Snapin in the trafficking of late endosomes to lysosomes. Snapin is enriched in the immunolocalized late endosomolysosomal SNAREs including syntaxin-8, VAMP-7, and Vti1b. Immunochemicalcytochemical staining reveals an increased density of the late endosomes in both cortical neurons and fibroblasts from snapin (-/-) mice, a phenotype that can be rescued by reintroducing the Snapin gene into the mutant cells. Furthermore, the deletion of Snapin in fibroblasts blocks the degradation of internalized EGF-EGRF via the endosome-lysosome pathway and accumulates internalized Dextran in the late endosomes instead of lysosomes. Finally, maturation of lysosomal enzymes is impaired in the Snapin mutant cells. Taken together, our study reveals a novel role for Snapin in the fusion of late endosomes with lysosome, probably by interacting with the endosomal SNAREs and synaptotagmins. Thus, Snapin, like many other SNARE regulatory proteins, is involved in both synaptic vesicle exocytosis and the intracellular membrane trafficking (Supported by the NINDS intramural research program).

GPNMB Is a Newly Defined Melanosomal Protein

C. M. Trantow,1 G. E. Petersen,1 L. A. Ammono,1 T. Hararszi,1 M. G. Anderson1; 1Physiology and Biophysics, University of Iowa, Iowa City, IA, 1Institute of Physical Chemistry, University of Heidelberg, Heidelberg, Germany

Melanosomes are the intracellular organelle of melanin synthesis. Melanosomes normally play an important role in regulating the color of our hair, skin, and eyes. Unfortunately, melanosomal defects have been implicated in a number of diseases, including a variety of ocular diseases. One gene suggested to play such a role is Gpnmb. In inbred DBA/2 mice, a naturally occurring Gpnmb mutation contributes to a pigment dispersing iris disease that ultimately results in a form of pigmentary glaucoma. The Gpnmb gene is predicted to encode a type I transmembrane protein that also contains a pre-melanosomal sorting signal. The objective of this experiment was to test the hypothesis that GPNMB is indeed a melanosomal protein. As expected for a melanosomal protein, we find that Gpnmb transcripts are abundant in the iris, and that the mutation of DBA/2 mice results in an approximate 18 fold down-regulation compared to wild type. Using immunohistochemistry, we find that GPNMB is specifically expressed in a punctate cytoplasmatic pattern throughout pigmented tissues of the eye, including the iris, ciliary body epithelium, and choroid. To test whether this labeling may correspond to melanosomes, we performed Western blots of sucrose gradient purified ocular melanomas and demonstrate the presence of GPNMB immunoreactivity. The function of GPNMB within melanosomes remains unknown. Unlike many known genes encoding melanosomal proteins, Gpnmb mutation does not seem to detectably alter melanin synthesis nor does it affect the expression of the vast majority of other known genes encoding melanosomal proteins. However, spectromicroscopic analysis of purified melanomas using scanning transmission X-ray microscopy demonstrates that DBA/2 irides mutant for Gpnmb do contain multiple chemical differences in comparison to wild-type C57BL/6J melanosomes. In sum, these results indicate that GPNMB is a newly defined melanosomal protein. Our ongoing experiments aim to further elucidate the precise functions of this important disease-causing protein.

Chediak Higashi Syndrome: A Genotype-Phenotype Correlation in the Human and Cell Biological Level

W. Westbrook,1 D. Adams,1 A. Koshofer,1 A. Helip-Wooley,1 R. Kleta1,2 A. Helip-Wooley,1 W. A. Gaht1,2; 1Medical Genetics Branch, NHGRI, NIH, Bethesda, MD, 1Department of Dermatology, University of Cincinnati College of Medicine, Cincinnati, OH

Chediak Higashi syndrome (CHS) is a rare autosomal recessive disorder caused by mutations in the CHS1 gene. Clinical characteristics include skin, hair and eye hypomelanosis, recurrent infections, a mild bleeding diathesis and late-onset progressive neurological impairment. We report two unrelated patients, CHD4 and CHD6. CHD4, suffering from the severe childhood form of CHS, presented with infections, a mild bleeding diathesis and late-onset progressive neurological impairment. We found evidence that TgCPL, Toxoplasma gondii cathepsin L-like enzyme, is involved in the proteolytic maturation of multiple microneme adhesin complexes. In the tachyzoite invasion form, TgCPL is located in a novel, photon lutein structure visible by phase contrast microscopy and positioned in the apical region between the rhoptries and apical secretory organelles. Serial sections of the same parasite shown by electron microscopy indicate that TgCPL is associated to the limiting membrane and internal vesicles of a large multi-vesiculated compartment, which is also occupied by a proton-pump, the T. gondii vacuolar protonophosphatase TgVPI. During intracellular replication the compartment is highly dynamic and is fragmented in multiple vesicles. We speculate that TgCPL is a multifunctional enzyme involved in both the proteolytic maturation of microneme protein complexes and the degradation of endogenous and exogenous substrates within the endocytic pathway.

Dissection of a Complex Phenotype: Conditional Inactivation of the Chloride Channel CIC-7

L. Wartosch, J. C. Fuhrmann, P. F. Lange, T. J. Jentsch; AG Jentsch, Max-Delbrueck-Center, Berlin, Germany

One common denominator in the function of intracellular CLC chloride channels and transporters is their role in the acidification of the vesicles in the endocytic pathway, where they provide an electrical shunt for the pumping of vesicular H+-ATPases. The chloride channel CIC-7 resides in late endosomes and lysosomes where it colocalises with the specific lysosomal marker protein Lamp-1. Recently we could show that CIC-7 requires Ostm1 as a beta-subunit. In addition, CIC-7 is localised in a specialised plasma membrane domain of osteoclasts facing the resorption lacuna. The latter is the exclusive site of bone resorption and consequently mutations in the CIC-7 gene cause osteopetrosis in mice and men, an inherited disorder characterised by a failure of osteoclasts to resorb bone. As a consequence Clic7 knockout mice show retarded growth, anaemia, extramedullary haematopoiesis and hepatosplenomegaly. Furthermore, degeneration of the central nervous system showing features of lysosomal storage disease, as well as retinal degeneration was observed. Clic7 knockout mice do not live longer than 45 days. In addition CIC-7 is highly expressed in kidney cortex. Lysosomal storage material accumulates in proximal tubules of Clic7 ko mice. In C7-knock out mice the increased activity of lysosomal beta-Hexosaminidase could be detected. This study reveals an altered Lamp-1 distribution in enlarged lysosomal compartments of CIC-7 ko proximal tubules that are positive for Dextran instead of lysosomes. Finally, maturation of lysosomal enzymes is impaired in the Clic7 mutant cells. These findings in CHD6 might be attributable to the endosomal SNAREs including syntaxin-8, VAMP-7, and Vti1b. Immunochemicalcytochemical staining reveals an increased density of the late endosomes in both cortical neurons and fibroblasts from snapin (-/-) mice, a phenotype that can be rescued by reintroducing the Snapin gene into the mutant cells. Furthermore, the deletion of Snapin in fibroblasts blocks the degradation of internalized EGF-EGRF via the endosome-lysosome pathway and accumulates internalized Dextran in the late endosomes instead of lysosomes. Finally, maturation of lysosomal enzymes is impaired in the Snapin mutant cells. Taken together, our study reveals a novel role for Snapin in the fusion of late endosomes with lysosome, probably by interacting with the endosomal SNAREs and synaptotagmins. Thus, Snapin, like many other SNARE regulatory proteins, is involved in both synaptic vesicle exocytosis and the intracellular membrane trafficking (Supported by the NINDS intramural research program).

Regulation of Acetylcholine-evoked H+-MPP+ Release by Short-Term Exposure to Somatostatin or Muscarinic Agonists in Bovine Adrenal Chromaffin Cells

L. Ribeiro, F. Martel, I. Azevedo; Biochemistry Department, Faculty of Medicine, University of Porto, Porto, Portugal

The aim of this work was to investigate the effect of a short-term exposure to somatostatin (SS), its receptors (SSTR) selective agonists as well as muscarinic receptors agonists upon acetylcholine-induced release of H+-MPP+ from bovine adrenal medullary cells. Acetylcholine (ACH, 100, 500 μM) was found to increase the release of H+-MPP+ by these cells (to 175 and 171% of basal release, respectively). ACH-elicited H+-MPP+ release was significantly reduced by hexamethonium (100 μM) and atropine (100 μM), selective nicotinic and muscarinic acetylcholinergic receptor antagonists. Whole mount electron microscopy of normal and patients' platelets found evidence that TgCPL, Toxoplasma gondii cathepsin L-like enzyme, is involved in the proteolytic maturation of multiple microneme adhesin complexes. In the tachyzoite invasion form, TgCPL is located in a novel, photon lutein structure visible by phase contrast microscopy and positioned in the apical region between the rhoptries and apical secretory organelles. Serial sections of the same parasite shown by electron microscopy indicate that TgCPL is associated to the limiting membrane and internal vesicles of a large multi-vesiculated compartment, which is also occupied by a proton-pump, the T. gondii vacuolar protonophosphatase TgVPI. During intracellular replication the compartment is highly dynamic and is fragmented in multiple vesicles. We speculate that TgCPL is a multifunctional enzyme involved in both the proteolytic maturation of microneme protein complexes and the degradation of endogenous and exogenous substrates within the endocytic pathway.

2006 ASCB Annual Meeting Abstracts

108
antagonists, respectively. Previous exposure to any of two muscarinic agonists, oxotremorine or pilocarpine, led to a significant reduction of [3H-MPP+] release in response to 100 μM ACH, to about a maximum of 51% and 78% of control, respectively. SS (0.01-0.1 μM), previously applied to the preparation, depressed ACH-elicted [3H-MPP+] release by 25-27%, but only when a 500 μM ACH concentration was used. The inhibition exerted by SS upon ACH-evoked [3H-MPP+] release appeared to be mediated by its SSTR: (1) SSTR2, 3 and 4 subtype agonists mimicked the effects seen with SS, and (2) the SSTR non-selective antagonists, cyclo-SS, counteracted the SS inhibitory effect. When SS was tested in the presence of any of the muscarinic agonists, oxotremorine or pilocarpine, its inhibitory effect on 500 μM ACH-induced [3H-MPP+] release was no longer detectable. These results, showing a somewhat similar effect of short-term exposure to SS and muscarinic agonists over ACh-induced release of [3H-MPP], as well as the loss of effect of SS by the presence of the muscarinic agonists, suggest that these compounds may share signalling pathways. Supported by FCT (POCI, FEDER and Programa Comunitário de Apoio)

587  Selective Activation of Somatostatin Receptor Subtypes Differentially Modulates [3H-MPP+] Release from Primary Cultures of Bovine Adrenal Chromaffin Cells

L. Ribeiro, F. Martel, I. Azevedo; Biochemistry Department, Faculty of Medicine, University of Porto, Porto, Portugal

Somatostatin (SS), a neuropeptide widely distributed in the central and peripheral nervous systems, acts through five specific cell surface receptors (SSTR1-5) to elicit different biological functions. Using reverse transcription followed by PCR amplification (RT-PCR), we have identified in bovine adrenal chromaffin cells the expression of the SS gene. The purpose of this study was to investigate the effect of SS and SSTR2-5 selective agonists on adrenal catecholamine release, using model substrate [1H-1-methyl-4-phenylpyridinium ([1H]MPP+)] release from primary cultures of bovine adrenal chromaffin cells. The effects of SS (0.01-1 μM) upon ACH (100-500 μM, 10 mM)-evoked [1H]MPP+ release differed between different cultures, allowing us to distinguish two types of cell cultures: type A- cell cultures, in which SS decreased ACH-induced [1H]MPP+ release, and type B- cell cultures, in which SS increased ACH-induced [1H]MPP+ release. The SSTR2, 4 and 5 agonists mimicked the inhibitory effects elicited by SS upon ACH-induced [1H]MPP+ release in type A cell cultures, whereas the SSTR2, 3 and 5 agonists mimicked the excitatory effect of SS upon ACH-induced [1H]MPP+ release on type B cell cultures. On the other hand, while SS (0.01-1 μM) and the SSTR3 and 5 agonists significantly augmented the release of [1H]MPP+ from type A cell cultures, neither SS nor its SSTR selective agonists did significantly affect this release from type B cell cultures. Interestingly, type A and B cell cultures were not only heterogeneous in relation to the response to SS and SSTR agonists, but also did differ regarding AD/NA cellular ratio, [1H]MPP+ uptake capacity, basal [1H]MPP+ release, and [1H]MPP+ response to ACH. In summary, our data indicate that: (1) adrenal chromaffin cells respond differentially to SS and SSTR agonists as to basal and ACH-stimulated [1H]MPP+ release, and (2) endogenous SS might modulate adrenal catecholamine secretion through its specific receptors.

589  An Established Anitriot Pituitary Progenitor Cells (BPC-1) Could Produce Several Inflammatory Cytokines by the Stimulation through Its II-18 Receptors

Y. Nagai, H. Ogasawara, H. As0, Y. Taketa, Y. Yamaguchi; Animal Biology, Graduate School of Agricultural Science, Tohoku University, Sendai, Japan

In an anterior pituitary gland, inflammatory mediators regulate the cell function through immuno-endocrine pathway. Our previous study showed that proinflammatory cytokine, IL-18, was mainly expressed in the hormonal cells of anterior pituitary. Further study also showed that IL-18 was localized in the cell layer of Rathke’s pouch that has been proposed to embody stem/progenitor cell compartment in the postnatal pituitary. In this study, we attempted to establish a stem/progenitor cell line bearing IL-18 receptor from bovine anterior pituitary gland, and investigated its immunomodulatory function. The bovine pituitary cell line from bovine anterior pituitary cloned by limited dilution methods was designated as bovine pituitary cell 1 (BPC-1). BPC-1 grew stably by repeated passages, and expressed IL-18 and IL-18 receptors. The cell line expressed mRNA of stem/progenitor cell-associated factors and components of Notch signaling pathway such as nestin, Oct-4, Notch1 and Hes1. BPC-1 was positively immunoreactive for β-catenin in its nucleus, and also showed rapid growth in EGF and BFGF containing medium. RT-PCR showed that BPC-1 expressed mRNA of IL-1α, IL-6, IL-7, IL-12 and IL-15 in normal cultures. IL-18 induced IL-1α, IL-1β, IL-6 and IL-8 mRNA in BPC-1. Immunohistochemistry and cytochemistry showed that IL-18 and vimentin were expressed in BPC-1 and also in the layer of Rathke’s pouch in anterior pituitary gland. In addition, IL-18-positive cells of the layer were not colocalized with GH. These results suggest that BPC-1 is a stem/progenitor cell and regulates anterior pituitary cell function through immuno-endocrine pathway associated with IL-18.

589  Genomic and Proteomic Analysis of Myofibroblasts: α-Smooth Muscle Actin-EGFP Transgenic Mouse Model

C. Bertolotto, 1 V. Krause, 1 N. Khoury, 2 H. Hencidi, 3 Y. Uba, 1 B. Bassilain, 1 J. Xu, 1 C. Wang, 1 P. Whitelegg, 3 K. F. Faul, 4 C. F. Simmons 1-2; 1Pediatrics/Neonatology, Cedars-Sinai Medical Center, Los Angeles, CA, 2Pediatrics, David Geffen School of Medicine, UCLA, Los Angeles, CA, 3Psychiatry & Biobehavioral Sciences/Clinical & Biochemical-Molecular Spectroscopy, David Geffen School of Medicine, UCLA, Los Angeles, CA, 4Endocrinology, Cedars-Sinai Medical Center, Los Angeles, CA, 5Psychiatry & Biobehavioral Sciences, David Geffen School of Medicine, UCLA, Los Angeles, CA

Background: Myofibroblasts are specialized contractile fibroblasts that express alpha smooth muscle actin. Myofibroblasts demonstrate tissue specific phenotypes that promote normal tissue development and local disease processes of inflammation, fibrosis, and calcification. To facilitate in vivo identification and purification of myofibroblasts, we have developed a transgenic mouse line that expresses EGFP under the control of an alpha smooth muscle actin enhancer promoter element. Design/Methods: Linearized alpha smooth muscle actin - EGFP reporter construct was injected into FVB fertilized mouse ova. Founder mice were bred and tissue specific expression of EGFP was analyzed by fluorescence microscopy and compared with expression of native alpha smooth muscle actin by immunofluorescence microscopy and quantitative image processing. Tissue membrane and placental primary cell cultures were transfected with a temperature sensitive SV40 large T plasmid, and cloned by limiting cell dilution. Resultant myofibroblast cell lines were analyzed by genomic and proteomic analysis utilizing microarray and gel electrophoresis/mass spectrometry approaches before and after exposure to regulatory cytokines. Results: EGFP was readily detected in myofibroblasts, vascular and visceral smooth muscle cells of multiple organs including the tympanic membrane, and correlated with native expression of alpha smooth muscle actin. Myofibroblasts exhibited 10-100 fold greater EGFP fluorescence than fibroblasts; smooth muscle cells exhibited 100-500 fold greater EGFP fluorescence than fibroblasts. Several myofibroblast cell lines were immortalized, each expressing both nuclear and cytoplasmic EGFP. Immortalized myofibroblast cell lines exhibited cytochrome regulated expression of contractile proteins, extracellular matrix proteins, cytokines, and transcription factor genes and proteins. Conclusions: The 3.1 kb upstream regulatory region of the mouse α-smooth muscle actin gene directs the proper spatial and temporal regulation of EGFP in myofibroblasts, vascular and visceral smooth muscle. This mouse model system will provide new experimental platforms for understanding the cellular and molecular mechanisms of fibrosis and calcification in the tympanic membrane and placenta.

590  Hmgbl Expression in Mouse Tongue Cancer and Muscle Fiber Characteristics in the Surrounding Normal Muscle Tissues

K. Sakiyama,1 O. Okubo,2 K. Kurokawa,1 S. Abe,1 Y. Ide1; 1Anatomy, Tokyo Dental College, Chiba, Japan, 2Sports Dentistry, Tokyo Dental College, Chiba, Japan

Recently, it has been suggested that dysphagia caused by excision of tongue cancer may be affected by the hypofunction of the surrounding normal muscles, as well as by a tissue defect. However, there is no report concerning how the muscle fiber characteristics change in the normal regions surrounding the lesion after excision of tongue cancer. In this study, to demonstrate the muscle fiber characteristics of the surrounding normal muscles tissue of tongue cancer, we investigated myosin heavy chain (MyHC) isoforms at immunohistochemical and genetic levels. High mobility group box 1 (HMGB1) was used as a marker to examine whether tongue cancer actually developed. As a result, considerable HMGB1-2a was observed in the surrounding normal muscle of tongue cancer, unlike in the normal tongue muscle. Thus, excision of tongue cancer changed the muscle fiber characteristics of the surrounding normal muscle, demonstrating that postoperative dysfunction of the muscles are caused not only by tissue loss.

591  Differentiation of Myoblasts in Three-dimensional Culture Conditions

M. L. Marquette,1 L. Vergara,2 D. Byerly,2 M. A. Sognier1; 1Neuroscience and Cell Biology, University of Texas Medical Branch, Galveston, TX, 2NASA Johnson Space Center, Houston, TX

Differentiation of anchorage-dependent myoblast cell cultures: 1) can be induced by serum deprivation or changing serum types; and 2) is thought to require adhesion to a substrate. We previously reported the appearance of large multinucleated cells in myoblasts cultured in Synthecon’s Rotary Cell Culture System (RCCS). This study assessed if these multinucleated cells exhibited additional characteristics of differentiating muscle cells. A murine myoblast cell line, C2C12, was cultured as three-dimensional aggregates (without support structures) in both the RCCS and Petri dishes coated to prevent cell adhesion. Cells were cultivated in proliferation medium with no replacement of serum type or serum deprivation. Differentiation was defined by: 1) fusion of single myoblasts to form multinucleated syncitium; and 2) expression of myosin, a muscle specific protein. Cell aggregates were fixed at day 3 and 7, embedded, and sectioned. Evaluation of H & E stained sections revealed greater numbers of syncitia in the RCCS cultured cells than Petri dish suspension controls at both time points (i.e., mean number 7.64 in RCCS vs 1.75 in controls at day 7). Quantification of muscle specific myosin using immunofluorescence revealed that RCCS cultured aggregates exhibited: 1) myosin distribution over greater areas;
were stained with monoclonal antibodies to cytochrome c. The cell aggregates localized at the cell periphery were transformed to discrete grains separated from each other. Grain transition might serve to diminish damage effect by disassembling the separate mitochondria from the cytosol during stress periods to sustain mitochondrial homeostasis. Cytochrome c evidently substrate entry into mitochondria was blocked at this early stage. We speculate that decrease in mitochondrial membrane permeability caused reversible respiration decline serves to occur when cells reached confluent, medium was exchanged to adipogenic medium containing 50 ng/ml insulin, 0.25 μM dexamethasone, 2 mM octanoate, and 200 μM oleate. Medium was exchanged every other day for 8 days after stimulation, and the adiopogenic ability of each factor was judged by the cytosolic TG accumulation and Oil red O staining. Octanoate significantly accelerated the cytosolic TG accumulation. When cells were exposed to both octanoate and oleate, the large amount of lipid droplets were observed 8 days after stimulation, and the cytosolic TG increased over 13 fold compared with the cells maintaining growth medium. Insulin and dexamethasone themselves could not stimulate the accumulation of TG, but when treated together with both octanoate and oleate, induced further accumulation of the cytosolic TG over 25 fold higher than the cells maintaining growth medium. Moreover, both octanoate and oleate induced the cytosolic TG accumulation in the concentration dependent manner (0.5 to 10 mM octanoate and 20 to 200 μM oleate). Next, the PPARγ mRNA expression was investigated by semi-quantitative RT-PCR. Both octanoate and oleate induced significantly the PPARγ mRNA expression, but neither insulin nor dexamethasone. Especially, oleate could increase the expression of the PPARγ mRNA much more than oleate.

Differences in the Response to the Toxic Effect of Ceramide in Tumour Cells from Human Cervix-uterine Cancer Infected and Non-infected with Papillomavirus
G. Gutiérrez Iglesias,1,2,3 E. Gutiérrez Iglesias,1 A. Parra Barrera,1 E. Reyes Maldonado,2 R. López-Marure,3 1Physiology, National Institute of Cardiology, México, D. F., Mexico, 2Physiology, Instituto Politecnico Nacional, México, D. F., Mexico, 3Urology and Ginecology, Hospital Infantil de México, México, D. F., Mexico
Ceramide is a potentially important mediator of a number of natural and pharmacological agents that affect cell growth, viability, etc. This lipid is derived from sphingomyelin hydrolysis, or is produced by the de novo synthesis. We previously demonstrated that ceramide promotes the death of cell lines from human cervical cancer infected with human papillomavirus (HPV) type 16 and 18 (CaKi and CaLo cells, respectively), but cervical cancer cells without HPV (ViBo cells) are not affected. The mechanism of resistance for ViBo to ceramide is unknown. In this work we evaluated the differences in the cell morphology, potential and activity of the mitochondria in CaLo, Caski and ViBo cells. Production of free radicals (ROS) as a consequence of the toxic effect of the ceramide also was evaluated with the purpose to describe possible molecular differences in response to the ceramide. Hematoxylin stain was used to observe morphological changes, reduction of MTT for mitochondrial activity, DCF to free radicals and rhodamine 123 stain for mitochondrial membrane potential. Morphological changes related to death were observed in CaLo and Caski cells, however, ViBo cells showed resistance to death by ceramide. CaLo conserved the mitochondrial activity and Caski and ViBo augmented it. While in Caski and ViBo ceramide decreased the potential of the mitochondria, ceramide induced the production of free radicals. C6 did not have effect on potential of mitochondria and diminished in 56% free radicals production in ViBo cells. The results revealed remarkable differences between CaLo, Caski and ViBo cells to antiproliferative effect induced by ceramide, indicating that ViBo cells are more resistant to the toxic effect of ceramide possibly by using an efficient mitochondrial and antioxidiant system.

TNF-induced Apoptosis in Lymphoid U937 Cells Mitochondria Early Changes
E. Feltsova,1 A. Avetisyan2,1 1Moscow State University, AN Belozersky Institute of Phys.-Chem. Biology, Moscow, Russian Federation, 2Department of Bioenergetics, A.N.Belozersky Institute of Phys.-Chem. Biology, Moscow, Russian Federation
We investigated mitochondria-mediated TNF-α induced apoptosis in lymphoid U937 cells to reveal possible changes in mitochondria function that contributed to apoptosis development. Cells were stained with monoclonal antibodies to cytochrome c. Apoptosis was determined by staining with Hoechst 33342. Mitochondrial change was determined by TMRE staining. Confocal and fluorescent microscopes were used. Oxygen consumption was measured with Clark-type electrode. Cellular ROS and ATP levels were measured with H2DCF-DA (FACS - analyzed) and luciferin-luciferase reagent correspondingly. In 30 min after apoptosis induction rapid increase in mitochondrial transmembrane potential, rates of respiration, and ATP-generation level occurred. In 1.5-2 hr after TNF addition respiration declined to 50%-60% of the control. Respiration decline could be restored by in vitro addition of penetrating respiratory substrates. Evidently substrate entry into mitochondria was blocked at this early stage. We speculate, that decrease in mitochondrial membrane permeability caused reversible respiration decline serves to separate mitochondria from cytosol during stress periods to sustain mitochondrial homeostasis. Cytochrome c-staining revealed mitochondria to undergo "brain transition". Tightly-located aggregates localized at the cell periphery were transformed to discrete grains separated from each other. Grain transition might serve to diminish damage effect by disassembling the mitochondrial system and to lighten redistribution of mitochondria inside the cell. "Brain transition" was possibly a morphological manifestation of reversible respiration decline. It strongly resembled so called "thread-grain transition" described for mitochondrial reticulum of fibroblastic and epithelial cells as a step of mitoptosis and apoptosis. Later progressively increasing cell death with diffuse extramitochondrial localization of cytochrome c appeared. In 4 hr after TNF addition in parallel with extramitochondrial localization of cytochrome c there were many apoptotic cell characterized by simultaneous nuclear fragmentation and mitochondrial localization of cytochrome c. Evidently at the early stage of nuclear fragmentation at least part of cytochrome c retained its mitochondrial localization

Effects of Capsaicin on Rat Bone Marrow Stromal Cells
F. Aikawa, S. Kumebe, M. Nakatsuka, T. Okamura, Y. Iwai; Oral Anatomy, Osaka Dental University, Hirakata-shi, Japan
[Purpose] Chemical stimuli like growth factors and dexamethamone, and physically extending stimuli, are said to lead to apoplosis and cell proliferation. When the stimulus is modest, it would accelerate cell proliferation and cell differentiation. But when the stimulus is over the threshold, it would restrict cell proliferation or lead to apoptosis. In this study, we focused on capsaicin that is considered as a nociceptive stimulus, and examined the expression of capsincin receptor and transient receptor potential vanilloid-1 receptor (TRPV1) in cultured rat bone marrow stromal cells (RBMSCs). [Material and method] RBMSCs were obtained from the rat femora, and the RBMSCs were subcultured by 3 passages. Then the RBMSCs were cultured in Dulbecco’s Modified Eagle Media (DMEM) or with or without capsaicin for 2weeks in 24 well plates. Then each cDNA of cultured cell was extracted and the expression of TRPV1 mRNA was examined by RT-PCR. Also, we performed II-E staining on each well for the histological examination. [Result and discussion] TRPV1 mRNA was only expressed in the RBMSCs that
cultured with capsaicin. TRPV1 is a nonselective cation channel, and can be activated not only by capsaicin but also by heat (>43°C), various acid and lipids. For years, it is said that the expression of TRPV1 was restricted to sensory neurons and discrete areas of the central nervous system (CNS). While, a number of recent studies have demonstrated TRPV1 in a variety of non-neuronal tissues, including bladder and urethral epithelium, bowel, lung, kidney, etc., there is no studies that have demonstrated TRPV1 in the bone marrow. The present study demonstrates the expression of TRPV1 in the rat bone marrow, and this suggests additional of capsaicin in DMEM leads the expression of TRPV1 in RBMSCs.

**Culture Medium Supplemented with Bovine Serum Albumin Effects on the Proliferation of Human Dental Pulp Derived Cells**

T. Okamura, S. Kambale, M. Nakutake, F. Akawa, Y. Iwasai, Oral Anatomy, Osaka Dental University, Hirakata, Japan

[Purpose] Culture medium is insufficient nutrition for several reasons, such as proliferation and differentiation; therefore, fetal bovine serum (FBS) is added. On the other hand, because a composition of serum is very complex, it is difficult to analyze the result of an experiment. In addition, a causation of transplantation of a formed tissue into the human body could be infection and immune reaction. For these reasons, we examined the possibility of the medium that added bovine serum albumin (BSA) instead of FBS using human dental pulp derived cells in this study.

[Materials and Methods] Human dental pulp cells were obtained from first premolars that were extracted for the orthodontic treatment. Then cultured in Dulbecco’s modified Eagle’s medium (DMEM) with 10% FBS by the third passage. The cells cultured in 96 well plates on following 6 conditions; only DMEM, DMEM supplemented with 10%, 20%, and DMEM with 1%, 5%, 10% BSA. The cell proliferation was measured by bromodeoxyuridine (BrdU) cell proliferation assay kit chronologically. [Result and discussion] The cells cultured only DMEM showed low proliferation at any time. The cells cultured in DMEM with FBS showed better proliferation than DMEM only. The cells cultured with BSA showed remarkable proliferation in the first 2 hours of culture. There were few adhesive cells when cultured in DMEM with BSA. This study suggests that the difference of the medium composition have a big effect on the behavior of cell proliferation.

**In Vitro Evaluation of the Cytotoxic Potential of Brickellia Cavanillessi (Asteraceae) Using HepG2 Cells**

R. Villas, W. Gao, E. Smith; Environmental Toxicology, The Institute of Environmental and Human Health, Lubbock, TX

Our long term goal is to characterize the potential toxicity and biological mechanisms of alternative herbal medicine. In this study we used an *in vitro* cell culture approach. Experiments were designed to evaluate an aqueous extract of the Latin American tea “prodigiosa” (*Brickellia Cavanillessi*), a member of the Asteraceae botanical family. *Brickellia C.* is traditionally consumed as an herbal remedy to treat diabetes and other chronic diseases in several underdeveloped countries. HepG2 hepatocellular carcinoma cells were submitted to both a dose- (IC50) and a time-dependent toxicity evaluation in the presence or absence of Fetal Bovine Serum (FBS). Herbal extracts (1-35%) were used for the IC50 study. In the time course study, cells were exposed to 1-10% extract solutions of *Brickellia C.* for 48hrs. Cell viability was determined with the MTT assay. The estimated IC50 was determined to range from 5-10% in the absence and presence of FBS. At doses exceeding 10%, cellular viability decreased significantly (p<0.05) relative to controls. Furthermore, there is a clear indication of a time dependent decrease in cell viability. No significant differences were observed when cells were cultured with or without FBS. These results suggest that the cell viability effects from tea extracts are not influenced by FBS. The preliminary data from this study indicates that *Brickellia C.* extracts negatively influence HepG2 cell viability. Further studies will be necessary to characterize the bioactive components of the extracts, to determine the postulated therapeutic value of *Brickellia C.* at lower concentrations, and to study the mechanisms of action.

**Establishment and Characterization of a Human Neonatal Hepatocyte Cell Line**

J. P. Gaddipati, D. Yadav, J. Mundock, J. Kantor, Y. Reid, Cell Biology, ATCC, Manassas, VA, 1Neogenx Oncology, Rockville, MD

Primary hepatocytes have been extensively used in a wide variety of experimental studies, however, limited lifespan as well as restricted availability are major constraints for such studies. Immortalization of primary cells extend their replicative capacity and would provide for continuous, unlimited availability. Immortalized hepatocytes with a stable phenotype that mimics the original tissue would constitute very attractive experimental models for use in toxicological and pharmaceutical studies. Ectopic expression of human telomerase reverse transcriptase (hTERT) is one of the major strategies used in developing immortalized cells and allows for the retention of the original cellular characteristics to a large extent and avoids some of the problems associated with other approaches. In the present study we developed a cell line, NeHepLxHT, from human neonatal hepatocytes by transduction with a retroviral expression vector containing the hTERT gene. The cell line was continuously cultured for more than twenty five passages without senescence whereas the parental cells senesced within three passages. Thus, induction of stable expression of hTERT in the neonatal cells led to immortalization of these cells. Analysis of telomerase activity, by telomeric repeat amplification protocol (TRAP) assay, indicated elevated levels of telomerase activity in these cells compared to the parental cells. The immortalized cell line maintained a diploid karyotype and expressed gene product profiles similar to normal human neonatal hepatocytes. The data suggest that this immortalized cell line preserved the normal biological characteristics of neonatal hepatocytes and may therefore be useful model in in vitro studies.

**Purified Schwann and Perineurial Primary Cell Cultures**

O. Vivas, C. M. Moreno, E. Bernal, C. M. Spinel; Departamento de Biología, Universidad Nacional de Colombia, Bogota, Colombia, 1Laboratorio de Biofisica, Centro Internacional de Fisica, Bogota, Colombia

OBJECTIVE Obtain highly purified Schwann cells cultures from dorsal root ganglia and perineurial cells from sciatic nerve in mice at short time. METHODS ICR mice were sacrificed by over-anaesthesia. Dorsal root ganglia (DRG) were took out and plated. In another essay the ganglia capsule was removed by microdissection. Ganglia were dissociated firstly with collagenase type II (280 U/ml) and then with mechanical dissociation. The dissociated tissue was plated with the aim of obtain Schwann cells. By microdissection, sciatic nerve was divided in its three connective tissues, the epineurium, the perineurium and the endoneurium. Perineurium and endoneurium were separately cultured to obtain perineurial cells and Schwann cells, respectively. Endoneurium culture was firstly treated with collagenase type II (400U/ml) before plated. In another experiment, nerves, without microdissection, were cut in 1 mm long pieces and plated. RESULTS Without microdissection, DRG cultures gave arise a mixed cultured of sensory neurons, capsular cells and abundant Schwann cells. We were able to obtain Schwann cell cultures with purity of 94% in only ten days without passages, based on the microdissecting capsule. Pieces of 1mm long of sciatic nerves that were neither microdissected nor collagenase-dissociated show a mixed culture of Schwann cells, fibroblasts and a few number of perineurial cells while after microdissection, endoneurium culture produced Schwann cells and fibroblasts and the perineurium culture showed perineural cells in 30 days without other kind of cells. Additionally, during these experiments we noted an important similarity in shape and morphology between DRG capsular cells and perineurial cells from sciatic nerve. CONCLUSION Microdissection is a technique that improves and facilitates the isolation and purification of Schwann cells from DRG and perineural cells from sciatic nerve.

**Mkk6 Phosphorylation Regulates Production of Nos-2-derived Superoxide by Acting as a Rac-GAP**

M. M. Harraz, A. Park, W. Zhou, Y. Zhang, J. F. Englehardt; Anatomy and Cell Biology, University of Iowa, Iowa City, IA

Phagocytes utilize NADPH oxidase to generate reactive oxygen species that mediate killing of microbial pathogens. Rac is a small GTPase essential for NADPH oxidase activity. While the mechanisms leading to NADPH oxidase activation are fairly well studied, the mechanisms that control down-regulation of this enzyme complex remain unclear. We hypothesized that reactive oxygen species produced by NADPH oxidase may autoregulate the complex by inhibiting Rac activity. To this end, we searched for binding partners of Rac1 that were induced by redox-stress of RAW cells and identified a tyrosine-phosphorylated fragment of Mkk6 that bound to Rac1 under these conditions. Constitutively active Mkk6 interacted directly with Rac1 in vitro and this interaction was enhanced when Mkk6 was phosphorylated on tyrosine 219. Both Rac1 and Rac2 immunoprecipitated an Mkk6 fragment under conditions that elevate cellular peroxide levels in 293 and RAW cells, respectively. Constitutively active Mkk6 and Rac1 co-immunoprecipitated and its expression inhibited phorbol myristate acetate (PMA) induced NADPH oxidase activity in RAW cells. In contrast, overexpression of the constitutively active Y219F Mkk6 mutant did not alter PMA-induced NADPH oxidase activity in these cells. Our findings suggest that Mkk6 down-regulates NADPH oxidase activity by acting as a novel Rac-GAP.

Establishment and Characterization of a Human Telomerase Catalytic Subunit-transduced Fetal Bone Marrow-derived Osteoblastic Cell Line

M. Feng; Institute of Zoology, Chinese Academy of Sciences, State Key Lab of Biomembrane and Membrane Biotechnology, Beijing, China

The fate of human hematopoietic stem cells (HSCs)/progenitor cells (HPCs) is influenced by bone marrow (BM) stromal cells. To investigate the role of stromal cells in the hematopoietic support, we have transduced human fetal BM stromal cells (FBMSCs) with human telomerase catalytic subunit (hTERT). One of the resultant cell lines was identified as osteoblasts, because it contained mineral deposits and constitutively expressed osteogenic genes osteocalcin, osteopontin, collagen type I, osteoblast marker alkaline phosphatase, but not marrow stromal cell marker STR-1 and CD105. The hTERT-transduced fetal BM-derived osteoblastic cells (FBMOB-hTERT) can actively maintain the capacity of self-renewal and multipotency of HSCs/HPCs at least partly through transcriptional up-regulation of hematopoietic growth factors such as stem cell growth factors (SCFs) and Wnt5A signaling. Moreover, the FBMOB-hTERT cells seem superior to primary FBMSCs in supporting hematopoiesis, because they are more potent than primary FBMSCs in supporting the in vivo expansion and LTC-IC activity of HSCs. The FBMOB-hTERT cell line has been maintained in vitro more than 125 population doublings (PDs) without tumorigenicity. The results indicate that the FBMOB-hTERT is useful for the study of molecular mechanisms by which osteoblasts support hematopoiesis.

DNA Barcodes for Definitive Species Identification of Cells in Culture

J. K. Cooper, 1 N. V. Ivanova, 2 P. Ikonomi, 1 R. Hanner; 1 ATCC® (American Type Culture Collection), Manassas, VA, 2 Biodiversity Institute of Ontario, University of Guelph, Guelph, ON, Canada

Cell line authentication is crucial for the accuracy and reproducibility of scientific research, though cultures are often maintained for extended periods of time without being assayed for species identity. Traditional isoenzymological identification tools suffer from a limited taxonomic scope and are not easily replicated among laboratories. We evaluated a sequence-based approach for the species level identification of animal cell lines, targeting variation in ~650 bp of the 5' region of the mitochondrial cytochrome c oxidase subunit 1 (COI) gene as a molecular diagnostic tool or “DNA barcode.” ATCC® characterized the COI barcode region from 67 cell cultures representing 44 distinct species. The data was analyzed using the Barcode of Life Data (BOLD) systems, a collaborative on line database that aids in the collection, management, analysis and application of DNA barcodes. Cell lines derived from the same species had virtually identical sequences (0.4% mean divergence) whereas cell lines from different species showed great divergence (25.9% mean divergence) even when the two species shared a common genus (17.1% mean divergence). To test the reproducibility of this method among labs, we spotted 28 of the analyzed samples on FTA Whamman® cards and sent them to the University of Guelph for independent blind COI sequence analysis, where matching genetic profiles were obtained using a different analytical platform and chemistry. We conclude that DNA barcoding can successfully identify a wide range of species from various animal taxa in cell culture, making fine distinctions among congeneric species. This technique is easily replicated among laboratories and because the BOLD database contains reference sequences derived from morphological voucher specimens, it provides a reliable means of validating a putative species identification accompanying a cell line submitted to, and distributed by, collection centers. Such authenticated cultures can also serve as standard reference materials or as controls in forensic barcode analysis.

Detection of Interspecies Cross-Contamination in Cell Culture: A Highly Sensitive Multiplex PCR Based Approach

J. K. Cooper, S. King, K. Cottrill, M. Crissup, G. Sykes, P. Ikonomi; ATCC® (American Type Culture Collection), Manassas, VA

Extensive cross-contamination of human and animal cell lines with a variety of human and animal cell lines is a long-standing problem in biomedical research. Although awareness dates back to the 1950s, the problem has not diminished; submission of cell lines to major repositories indicates that up to 20% of the cultures may be contaminated. Currently, isoenzymology is the favored method for species identification and detection of interspecies contamination in cell lines but it suffers from two major limitations. First, the technique is cumbersome and therefore not widely practiced. Second, its sensitivity for the detection of cross-contamination is low (10-20%). To overcome these limitations we developed a multiplex PCR-based assay to detect cross-contamination and for species identification of cell lines used commonly in research laboratories. The assay is based on the mitochondrial cytochrome c oxidase 1 (COI) gene as a target. Species-specific primer pairs were designed based on sequence information both from public databases as well as sequencing of COI from ATCC® cell cultures. Each primer set was designed to produce a distinct amplicon that can be easily resolved by agarose gel electrophoresis or by other separation methods. This feature allowed the primers to be multiplexed. Additionally, we designed an internal control for the verification of the assay. The assay described above can detect cross-contamination when the contaminating species is present at less than 1% in a test cell culture. We have confirmed the species identity and checked for the presence of inter-species contaminants in 100 different cell lines. Further sensitivity analyses of the assay are currently being conducted. Our results show that this assay is sensitive, easy, cost effective, requires no dedicated equipment, and can be used in any research laboratory as a practical tool for species identification and confirmation of cell cultures.

Effects of Mycoplasma Infection in Cell Culture Systems and Tool for Routine Mycoplasma Screening

Q. Li, K. Cottrill, G. Sykes, M. Fisher, T. Correa; P. Ikonomi; American Type Culture Collection, Manassas, VA

Contamination of cell cultures is a problem that affects many laboratories. Regular screening of cell cultures for mycoplasma infection remains the only protection. We present here quantitative analyses of the effect of mycoplasma infection in two cell culture systems and offer a PCR-based method as a tool for regular screening mycoplasma infection in cell cultures. Two commonly used cell lines-HeLa and PC3 were infected with Mycoplasma hominis and Mycoplasma fermentans. While no significant changes were observed in overall cell growth, infection of mycoplasma had a significant effect on the cell proliferation assay. Mycoplasma infection of HeLa and PC3 cell lines reduced efficiency of transcription and reporter gene expression by 40% and 80% respectively. Quantitative PCR analyses of the expression of various cytokines and other endogenous genes at 6, 24, 48 and 72 hours after infection suggested that infection of mycoplasma, even at significantly low levels, drastically affects the results of comparative analyses of the transcriptome. We then describe a novel PCR-based assay capable of detecting low levels of infection of 49 mycoplasma species, including the mycoplasma species commonly found in cell cultures. The assay targets the nonconserved intergenic region of 16S-23S rDNA operon of mycoplasma, allowing for speciation of the mycoplasma infection either by size discrimination of the amplicons or via endonuclease digestion. The efficiency and the sensitivity of the assay are shown using six additional cell lines infected with mycoplasma and purified mycoplasma DNA from several species. Our results clearly showed the effects of mycoplasma infection has in skewing results acquired in studies conducted with cell line models. The PCR-based mycoplasma detection method offers a practical and sensitive tool for routine screening for mycoplasma infection as a requirement for the accuracy and the reproducibility of scientific research using animal cell culture.

Morphological Observations of Cell-Clusters in Hemolymph of Mamestra brassicae

P. R. Mangatikla, T. Kawamoto, K. Iwabuchi; Applied Entomology, Tokyo University of Agriculture and Technology, Tokyo, Japan

Hemocytes isolated from the larval hemolymph were classified into several types; plasmatocyte, granulocyte, spherulocyte, oenocytoid and prohemocyte. In addition, we observed cell-clusters. In short-term culture, the morphology of cell-cluster did not change, although change when co-cultured with fat body tissues or cultured under supplement with fat body extract or larval plasma. However, there was no effect in heat-treated plasma, protease-k treated plasma and co-cultured with hemocyte, suggesting that the fate of the cell-cluster is regulated by some factor(s) in larval plasma and fat body.

Heat Shock Protein of 70 kDa Family in Viable Paleacanthamoebae Acanthamoeba sp. and in Contemporary Amphilozite Representitive of the Same Genus

Y. I. Podlipaeva, 1 L. Shmakova, 1 I. Dykova, 1 A. Goodkov; 1 Institute of Cytology Russian Academy of Sciences, St. Petersburg, Russian Federation, 2 Institute of Physicochemical and Biological Problems in Soil Science, Pushchino, Moscow Region, Russian Federation, 3 Institute of Parasitology Academy of Sciences of Czech Republic, Ceske Budejovice, Czech Republic

The viable cysts of paleacanthamoebae belonging to the genus Acanthamoeba were isolated from samples of permafrost aging 30000-35000 years (eastern sector of the Arctic region, Kolyms Lowland and the Laptev Sea coast). After excystation trophozoites (Acanthamoeba sp. strain Am8) were cultivated in the laboratory at the room temperature. Method of immunoblotting using monoclonal anti-HSP70 antibodies was applied to reveal heat shock proteins of this family. Previously in some strains of Ameoba proteus the HSP of 70 kDa MW, termed as constitutive, was...
revealed by the same antibodies. In intact Am8 trophoectoderm extremely high level of HSP of about 60 kDa MW was revealed. We failed to cause induction of this protein in Am8 cells by heat (37 °C, 1 h) and cold (8 °C, 1 h) shocks; both shocks were resulted only in decreasing of constitutive HSP level. When comparing with contemporary representatives of the same genus (*Acanthamoeba* sp. strain 4465, the Department of Eukaryotic Organisms Infecting Fish, Inst. Parasitol., Acad. Sci. Czech. Rep.) it appeared that no zones were revealed on blot after staining with the same antibodies, and with the same amount of protein on the start gel. The preliminary data on temperature preferences of studied strains point that paleoamoebae (strain Am8) is much more thermostolerant than *Acanthamoeba* sp. strain 4465. Unusually high constitutive level of HSP in the cells of paleoamoebae might indicate the high potencies for their surviving, even in terms of geochronology.

608 Endotoxin-induced Fetal Toxicity Can Be Prevented by Pretreatment with Flavonoid Extracts in the Rat Model
E. E. Ntam, D. Hill, T. Charles, R. Howell, M. Baker, T. Martin, C. Reese; Department of Biology, Morgan State University, Baltimore, MD

Environmental contaminants have been well documented for their adverse effects on embryonic/fetal development. Endotoxin (environmental contaminant) has been associated with various developmental toxicities including embryo-resorption, degenerated tissue integrity, altered organ maturation, fetal-growth suppression and fetal lethality. Studies have indicated that endotoxin injury can be mediated by immune-effector cell activity. This is conceivable that decreases in effector-cell activity could alter the degree of endotoxin-induced toxicity. Natural flavonoid extracts (silymarin) can decrease immune-cell activation, scavenge reactive radicals and protect liver tissues from contaminant-induced injury. However, the feto-protective activity of flavonoid extracts requires further investigation. Therefore, the present study was designed to address the hypothesis that *in utero* pretreatment with flavinoid extracts affords protection against altered fetal tissue/organ development after exposure to endotoxin. Pregnant rats were pretreated with a flavinoid extract (25 mg/kg/day; gestational days 7 - 17). Exposure to endotoxin (50 μg/kg/day) occurred from gestational days 12 through 17. On gestational day 18, fetuses were removed to analyze gross fetotoxicity. On the parameters of fetotoxicity included crown-rump length, tail length, fetal viability/lethality, limb development and visible-tissue alterations. The results demonstrated that *in utero* exposure to endotoxin caused decreases in normal crown-rump length, tail length and fetal viability while limb and digit development remained unaffected. Endotoxin exposure also produced overt abdominal coagulation, sub-dermal hematomas and incomplete closure of the abdominal cavity. Pretreatment with flavinoid extracts afforded protection against endotoxin-induced lethality. Moreover, the flavinoid pretreatment regimen protected the abdominal tissues from endotoxin-induced injury. Supported by NIEHS R22ES00330, DOE E63580.

609 Differentiation of Non-Adherent Hematopoietic Stem Cells from Umbilical Cord Blood Cells into Adherent Hepatocytic Lineage
R. Peters, M. M. Mock, B. Steiger; Department of Medicine, University Hospital, Zurich, Switzerland

The liver has an enormous regenerative capacity. However, after severe liver injury, this capacity is not sufficient for regeneration and treatment of liver failure with hematopoietic progenitor cells might be a therapeutic option. It has been shown that umbilical cord blood (UCB) mesenchymal stem cells (MSC) are capable of differentiation into mesenchymal and non-mesenchymal lineages. However, only about 20% of frozen and either separated or unseparated UCB will give rise to MSC. We have developed the technology generate MSC from all frozen (3/3 tested) UCB. Here we show that the incubation of thawed UCB mononuclear cells and non-selected CD34+ cells in the presence of SCF, MGDF, FL-3 IL-6 and human serum in stroma-free liquid culture generated long-term expansion of UCB non-adherent hematopoietic stem cells (HSC) and long term expansion of MSC (adherent cells). Adherent cells were enriched by medium changes followed by trypsinization and subsequent culture and passing on fibronectin. Mesenchymal non-fibroblast liquid cultures were tested for the production of HSC as well as MSC over a period of 15 weeks and MSC kept increasing through out expansion of HSC. Expanded MSC between 35th to 5th passages were plated using MesenCult®. After 14 days, very large and small colony forming fibroblasts colonies were continuously detected throughout expansion. In order to test the capacity of these MSC to differentiate into a hepatocytic lineage, cells were cultured in DMEM supplemented with dexamethasone and HGF, which was replaced with Oncostatin M after day 14. This lead to the appearance of cells with hexagonal, hepatocyte-like appearance. These cells expressed mRNA for albumin, the basolateral bile salt uptake system NTCP and the canalicular bile salt export pump BSEP as assessed by RT-PCR. These data demonstrate the presence of pluripotent stem cells in UCB with the capacity to differentiate into a hepatocytic lineage.

610 Expression of 14-3-3 Proteins in the Human Cornea
J. Shankardas, D. Dimitrijevich; UNT Health Science Center, Fort Worth, TX

**Background:** 14-3-3 is a highly conserved, ubiquitously expressed family of proteins. At least seven mammalian isoforms ([β, γ, ε, ζ, τ and η] are known. These proteins associate with over 200 different target molecules and activate a number of downstream signaling cascades involved in the regulation of metabolism, cell cycle, apoptosis, protein trafficking, transcription, stress responses and malignant transformations. We are interested in the role of these proteins in the mechanisms regulating homeostasis and pathologies in the human ocular surface. **Purpose:** To determine the expression of the 14-3-3 proteins in the human cornea, the conjunctiva and the primary cells comprising these tissues. **Methods:** Using immunofluorescence, we determined the expression of 14-3-3 isoforms in the paraffin sections of the human cornea and conjunctiva. Using indirect immunofluorescence and western blot analysis we also determined the expression of these isoforms in primary corneal and conjunctival epithelial cells, keratocytes and endothelial cells. Furthermore, expression in primary epithelial cells was compared with that in several human corneal and conjunctival cell lines. Western blot analysis was used to confirm the presence of 14-3-3 isoforms in the culture medium from corneal epithelial cells and cell lines. **Results:** All the 14-3-3 isoforms were expressed in the corneal and conjunctival epithelia and the primary epithelial cells and cell lines. Expression of 14-3-3-ε was confined to epithelial cells and was secreted into the culture medium of the primary cells and cell lines. **Conclusions:** We have determined that all the mammalian 14-3-3 isoforms are expressed in the human cornea, conjunctiva and the component cells, and that the 14-3-3-ε isoform is found to be secreted into epithelial cell culture medium. We propose that the intracellular and extracellular presence of 14-3-3 ε supports its involvement in the epithelial specific signaling pathways.

611 Wound-induced ATP Release and Epidermal Growth Factor Receptor Activation in Epithelial Cells
J. Yin, K. Xu, J. Zhang, A. Kumar, F. X. Yu; Ophthalmology & Anatomy & Cell Biology, Wayne State University, Detroit, MI

Wounding of human corneal epithelial cells (HCECs) has been shown to elicit epidermal growth factor receptor (EGFR) transactivation through epidermal shedding of heparin-binding EGF-like growth factor (HB-EGF). However, the initial signal to target these signaling events in response to cell injury remains elusive. In the present study, we investigated the role of adenosine triphosphate (ATP) released from the injured cells in EGFR transactivation and in the activation of its downstream effectors phosphatidylinositol-3-kinase (PI3K)/AKT and extracellular signal-regulated kinase (ERK) pathways in HCECs as well as in BEAS 2B cells, a bronchial epithelial cell line. Wounding of epithelial monolayers of both cell types increased the ATP concentration in the culture media. The wound-induced rapid activation of PI3K and ERK in HCECs as well as in BEAS 2B cells, a bronchial epithelial cell line. Wounding of epithelial monolayers of both cell types increased the ATP concentration in the culture media. In order to test the capacity of these MSC to differentiate into a hepatocytic lineage, cells were cultured in DMEM supplemented with dexamethasone and HGF, which was replaced with Oncostatin M after day 14. This lead to the appearance of cells with hexagonal, hepatocyte-like appearance. These cells expressed mRNA for albumin, the basolateral bile salt uptake system NTCP and the canalicular bile salt export pump BSEP as assessed by RT-PCR. These data demonstrate the presence of pluripotent stem cells in UCB with the capacity to differentiate into a hepatocytic lineage.

612 The Cyclic Dependent Kinase 5 Inhibitor Olomoucine Promotes Corneal Epithelial Wound Closure In Vivo
B. K. Tripathi, M. A. Stepp, P. S. Zelenka; Laboratory of Molecular and Developmental Biology, National Eye Institute/National Institutes of Health, Bethesda, MD, 1Department of Anatomy and Cell Biology, The George Washington University Medical Center, Washington, DC

The prolinc-directed kinase, CDK5, regulates adhesion and migration of corneal epithelial cells in culture. Moreover, olomoucine, a CD5 inhibitor, accelerates corneal derbridement wound closure in organ cultured eyes of normal mice. This study was undertaken to test the effect of olomoucine on corneal derbridement wound closure in vivo in normal mice. A 1.5 mm central derbridement wound was made in corneas of anesthetized mice. The treatment group received 20 μl of 15 μM olomoucine in phosphate-buffered saline (PBS) containing 0.1% dimethyl sulfoxide (DMSO), applied as drops to the wound area immediately after wounding (0 h) and again after 6 h. The control group received similar applications of PBS containing 0.1% DMSO. Eighteen hours after wounding mice were euthanized, eyes were removed, fixed in 4% paraformaldehyde, stained with Richardson’s stain and photographed. The remaining wound area was measured with image processing software. Images were coded during measurement to prevent experimenter bias. Measurements of 28-30 mice in each group indicated that the remaining wound area in the control group was approximately 2-fold greater than that of the olomoucine treated mice (p=0.001). Two weeks after wounding, reepithelialization of the cornea was identical in

2006 ASCB Annual Meeting Abstracts

113
both olomoucine treated and control groups and neither group showed evidence of inflammation or stromal disorganization. These findings indicate that Cdk5 inhibitors promote corneal epithelial cell migration in vivo as in vitro and suggest that this class of compounds may be therapeutically useful for treatment of corneal epithelial erosions.

613 Maintenance of Corneal Epithelia in Pax6+/− Mice
J. Ou, R. Kucera, L. Leiper, P. Walczynko, J. M. Collinson; School of Medical Sciences, Institute of Medical Sciences, Aberdeen, United Kingdom

Pax6 encodes a transcription factor, which is vital to morphogenesis and functioning of the eye. Human and mice heterozygous for the gene have complex lens, iris and cornea abnormalities, including corneal opacity (aniridia-related keratopathy - ARK). We studied the etiology of such cornea abnormalities. By incubating the eyes with a cell impermeable fluorescent dye - lucifer yellow, we showed that unlike wild-type, the corneas of Pax6+/− mice are often permeable to diffusion of small molecules, presumably due to breakdown of tight junctions between superficial cells. Proteomic analyses revealed that Pax6+/− corneas have less keratins than wild-type. Pax6+/− corneas are deficient in several enzymes involved in detoxification. These results implied that Pax6+/− corneal epithelia are vulnerable to environment hazards and may subject to chronic cycles of damage and regeneration. We studied if molecular pathways controlling corneal epithelial cell migration are defective in Pax6+/− mice. Recently we reported that primary cultures of Pax6+/− mouse corneas have defective Ca2+ signalling in response to wounding. Subsequently, we showed by immunoassaying that phosphatidylinositol 4, 5-biphosphate, a multipotent 22nd messenger, may mediate Ca2+-signalling defects and abnormal actin assembly in Pax6+/− corneal epithelia. Extracellular-signal regulated kinase 1 and 2 (ERK 1/2) are abnormally activated, while other MAP kinases are poorly activated in Pax6+/− corneal epithelia; in an ex vivo epithelial model, inhibition of ERK1/2 activation slowed epithelial migration in both wild-type and Pax6+/− corneas. Different MAP kinases were suggested to be activated by different small GTPases. Therefore, MAP kinases and their respective small GTPase regulators may play distinct but coordinated roles of migration in regenerating mouse corneas; defective migration of the Pax6+/− corneal epithelium may result from cumulative effects of aberrant signaling of PI3P and MAP kinases.

614 Genetic Control of Corneal Epithelial Cell Migration by Pax6
R. Kucera, B. Reid, M. Collinson; Cell and Developmental Biology, Institute of Medical Sciences, University of Aberdeen, Aberdeen, United Kingdom

Cell migration is essential for tissue repair and wound healing. The factors that drive directional cell migration are incompletely understood. We have tested the role of endogenous electric fields (EFs) for guiding cell migration and wound healing. Ion transport across the corneal epithelium creates a potential difference (PD) such that the basal layer of the corneal epithelium is +25mV compared to the tear film. After the wounding, the PD collapses to 0mV at the wound site, resulting in a standing voltage gradient directed from the basal layer of intact epithelium into the wound. Cells are meant to respond to this standing voltage gradient by migrating cathodally into the wound. We have directly measured the wound induced electric current in current of mice heterozygous for the Pax6 transcription factor using vibrating, self - referencing microelectrode. Pax6+/− eyes showed normal outward current compared to Pax6+/− eyes of which 43% showed an inward current and the others showed small outward current. Ion replacement experiments suggest defective sodium pumps and channels in Pax6+/− epithelial cells. The wound-healing rate of corneal epithelium of both genotypes was measured and quantified. Surprisingly, all epithelia healed at approximately equal rates irrespective of genotype or (for Pax6+/−) the direction of wound-induced electric current. We tested the ability of the cultured mouse corneal epithelium cells to respond to in vitro applied EFs. The results showed that on average Pax6+/− cells migrate to the anode. Whole eye organ culture and electric current measurements, revealed no significant correlation between wound healing rate and the direction and magnitude of EF in Pax6+/− and Pax6+/− cells. We suspected that although applied EFs can modulate the wound healing process, endogenous EFs are unlikely to be major essential guidance cue for corneal epithelial cell migration.

615 Desmoplakin Regulates Rho Signaling through GEFD1
A. P. Miera; Cell Biology, Georgetown University, Washington, DC

Desmoplakin’s (DP) primary function is to link intermediate filaments to desmosomes. This function has been confirmed by conventional and tissue specific knockout studies. However, recent evidence from our lab strongly suggests that desmoplakin may also have a signaling function. We employed a novel high-throughput proteomics assay termed luminescence-based mammalian interactome mapping (LUMIER) whereby Luciferase-tagged DP cDNA bait was co-expressed with over 500 Flag-tagged prey cDNAs, followed by immunoprecipitation with a flag antibody and detection using the luciferase assay. We found three guanine exchange factors (GEFs) directly associated with DP. We analyzed the effects of the GEFD1/DP interaction focusing on RhoA activity and its downstream targets in human embryonic keratinocytes. Immunoprecipitation studies revealed that GEFD1 directly associates with DP in a spatio-temporal manner during early time points of terminal differentiation. Knocking down DP prior to inducing terminal differentiation and desmosome formation resulted in diminished RhoA activity, which was restored upon DP siRNA degradation and re-expression of DP protein. Using a fluorescent reporter that measures RhoA activity, we temporally and spatially confirmed the GEFD1/DP dependent-activation of RhoA at cell junctions during differentiation. Consequently, GEFD1/DP interaction is needed for normal RhoA activity in keratinocyte differentiation. To map the region on DSP that interacts with GEFD1, we generated a series of luciferase-tagged LUMIER vectors and analyzed their interaction with GEFD1. This revealed that the plakin domain of DP bound GEFD1. We then expressed each of these DP domains in Heka cells and examined cortical actin network (CAN) formation and GEFD1 localization. Of all the domains tested, only expression of the plakin domain caused mislocalization of GEFD1 and this correlated with disruption of the CAN. Consequently, our data supports a model in which DP is directly linked to actin reorganization by affecting the GEF/D/Rho/ROCK signal transduction pathway.

616 Deficiency of Protein 4.1R in Mice Results in Epidermal Hyperplasia
R. A. Hughes, X. An, C. Liu, N. Mohandas; Red Cell Physiology, New York Blood Center, New York, NY

Protein 4.1R (4.1R), originally identified as a major component of erythrocyte membrane, is also widely expressed in non-erythroid cells. In order to explore the function of 4.1R in non-erythroid cells, we have generated 4.1R knock-out mice. In the present study, we evaluated the functional role of 4.1R in skin. Interestingly, histological examination revealed a thickened epidermal layer, accompanied by an increase in the number of mitotic cells. The wound-healing rate of corneal epithelium of both genotypes was measured and quantified. Surprisingly, all epithelia healed at approximately equal rates irrespective of genotype or (for Pax6+/−) the direction of wound-induced electric current. We tested the ability of the cultured mouse corneal epithelium cells to respond to in vitro applied EFs. The results showed that on average Pax6+/− cells migrate to the anode. Whole eye organ culture and electric current measurements, revealed no significant correlation between wound healing rate and the direction and magnitude of EF in Pax6+/− and Pax6+/− cells. We suspected that although applied EFs can modulate the wound healing process, endogenous EFs are unlikely to be major essential guidance cue for corneal epithelial cell migration.

617 Assessment of p53 Protein Expression in Human Skin Models
R. L. Warters, B. Zhuplatov, D. L. Williams, C. D. Pond; 1 Radiation Oncology, University of Utah Health Sciences Center, Salt Lake City, UT, 2 Pharmacology and Toxicology, University of Utah Health Sciences Center, Salt Lake City, UT

The purpose of this study was to compare the regulation of the p53 stress response of cultured keratinocytes with keratinocytes in intact human skin. Neonatal human skin was obtained from the LDS Hospital Newborn Clinic. Primary, low passage number keratinocytes were recovered from Diapase II-treated neonatal skin and cultured in serum free keratinocyte medium (SKFM) (In Vitrogen). Skin epidermis was peeled away from skin that was heated at 60°C for 60 seconds and dissolved into RIPA buffer. Equal amounts of protein from cultured cells or the epidermis were separated through 4-12% gradient acrylamide gels, electroblotted onto membranes and western analyzed. Per equal g of protein recovered from cultured keratinocytes, we observed significant levels of the p53 DNA damage stress response, in cultured keratinocytes relative to keratinocytes in the intact human skin. In the epidermis the levels of p53 may be kept low through Mdm2 ubiquitilation of the p53 protein. This appears not to be the mechanism of regulating p53 levels in cultured keratinocytes. This work was supported by Department of Energy grant number DE-FG03-01ER63240.

Characterization of Sex-specific Expression of Airway Epithelial Proteins in the Mouse Lung

L. S. Van Winkle, J. Y. Wong, P. C. Edwards, D. Anderson, K. M. Sutherland, M. A. Isehll; Vncape/che, UC Davis, Davis, CA

Men and women are differentially affected by several major lung diseases that arise from the conducting airways including adenocarcinoma, COPD and asthma, regardless of smoking history. Defining the proteomic differences between males and females is key to understanding the sex differences in conducting airway biology. Our preliminary studies have shown that there is a difference in the epithelial proteome of the female vs male mouse conducting airway. We separated airway epithelial proteins obtained via 2 methods: lysis lavage (LL) and airway microdissection (MD) using 2-D gel electrophoresis. Both methods detected unique spots by sex but the total number of protein spots after correcting for background and noise was much greater on the LL samples (average of 1026) compared to the samples prepared by MD (average of 580). For this study we defined the effect of estrous cycle on the female mouse proteome. Estrous cycle stage was determined using vaginal cytology. Unique and common protein spots were identified using Phoretix gel imaging software (on 3 gels). Of these spots, there was one protein common to both male and female lysis lavage that mobilized laterally only on 2D gels from female mice, consistent with changes in the estrous cycle. MALDI-TOF/TOF identified this protein as peroxiredoxin-6. We conclude that 1) we can detect sex-specific expression of proteins and protein modifications using this approach and 2) that peroxiredoxin 6 is modified, possibly oxidized, in female mice coordinately with changes in the estrus cycle. Supported by grants from NIEHS (ES 012720 and ES05707) and TRDRP 14RT-0132.

Expression and Sub-cellular Localization of Protein 4.1 Homologs in Human Bronchial Epithelial Cells

Q. Kang, A. Xulii, N. Mohandas; Red Cell Physiology Laboratory, New York Blood Center, New York, NY

Protein 4.1 family of proteins act as adapter proteins linking the actin-based cytoskeleton to various transmembrane proteins. The four members of this family, 4.1R, 4.1G, 4.1N, and 4.1B, are encoded by four homologous genes, which undergo extensive alternative splicing. Members of protein 4.1 family are widely expressed in various cells but their specific function in these cells remains largely unexplored. As a first step in defining the function of protein 4.1 homologs in epithelial cells, we systematically examined the expression and localization of these proteins in human bronchial epithelial (HBE) cells by western blot analysis and immunofluorescence confocal microscopy using antibodies highly specific for each of the four 4.1 protein homologs. Western blot analysis revealed that two 4.1B (210 kDa and 53 kDa), three 4.1G (120 kDa, 90 kDa and 75 kDa), two 4.1N (110 kDa and 53 kDa) and three 4.1R (75 kDa, 60 kDa and 53 kDa) isoforms are expressed in these epithelial cells. Immunofluorescence confocal microscopy revealed distinct sub-cellular localization of various 4.1 isoforms. For example, while the 210 kDa 4.1B isoform is localized mainly to Golgi apparatus, the 53 kDa 4.1B isoform is associated with the plasma membrane and the mitotic spindle pole. Similarly, the 75 kDa 4.1G is detected in the nucleus, the 110 kDa 4.1N is associated with the lateral domain and the 53 kDa 4.1R is localized to the endoplasmic reticulum. These findings imply that all 4 protein 4.1 homologs are expressed in a single cell type. Furthermore, the diverse cellular distribution of various homologs and their isoforms indicate multiple roles for 4.1 proteins in epithelial cell biology.

IL-13 Induces a Bronchial Epithelial Phenotype That Is Inherently Profibrotic

N. K. Malaviya,1 R. A. Panarettes,2 S. C. George,1 Biomedical Engineering, University of California—Irvine, Irvine, CA, 2University of Pennsylvania, Philadelphia, PA

Introduction. The role of the epithelium in orchestrating subepithelial structural changes in asthmatics is of key interest. In embryo genesis the epithelium dictates’ mesenchymal differentiation and growth. In asthma there exists an altered epithelium phenotype characterized by hyperplasia and excessive mucus production. This altered phenotype may reawaken subepithelial tissue differentiation and growth by influencing numerous cells including the fibroblasts. While it is known that mechanical perturbations can cause release of profibrotic factors (eg TGFB-2 and Th-2 cytokines eg IL-13) induce goblet cell hyperplasia it is not clear whether the two perturbations cause different effects on epithelial-mesenchymal communication. We hypothesized that the phenotypic changes induced by IL-13 create an epithelium that is inherently profibrotic; that is, an IL-13 treated epithelium would induce changes in the subepithelial fibroblast consistent with fibrosis in the absence of IL-13. Methods. Fully mucociliary differentiated normal human bronchial epithelial cells (NHBE) were treated with IL-13 (0, 0.1, 1, 10 ng/ml) for fourteen days during the differentiation period. IL-13 was then withdrawn, and the NHBE were co-cultured with normal human lung fibroblasts (NHLF) for three or ten days. Results. IL-13 induced increasing levels of MUC5AC protein and a corresponding decrease in tubulin IV protein in the NHBE that persisted in the absence of IL-13. Elevated levels of TGFB-2 in the NHBE-NHLF co-culture persisted over the course of 10 days. Collagen I, III, Iysyl oxidase, and alpha-smooth muscle actin gene expression was upregulated in the NHLF, accompanied by increased deposition of collagen in the extracellular matrix. Conclusion. IL-13-treated NHBE creates a phenotype that is biased towards subepithelial fibrosis, which may be driven by epithelial-derived TGFB-2. Once established, this phenotype does not require IL-13 to eliciting these effects. We propose that a persistent state of epithelial mucus cell hyperplasia may account for key features of airway remodeling observed in chronic lung disease.

Peroxisome Proliferator-Activated Receptor-γ Regulates Airway Epithelial Bicarbonate Transport

M. Duszyk, N. Madsen, D. Nahirney; Physiology, University of Alberta, Edmonton, AB, Canada

This study examines the role of peroxisome proliferator activated receptor γ (PPARγ) in the regulation of human airway ion transport. Identification of molecules that can alter the normal response of airway epithelial cells to various stimuli may be therapeutically beneficial in a variety of airway diseases. PPARγ has emerged as crucial factor controlling gene expression in response to nutritional, pharmacological and metabolic stimuli. However, the effects of PPARγ activation on transepithelial ion transport have not been studied in the human lung. Therefore, we investigated the effects of various PPARγ agonists (such as pioglitazone, L-tyrosine-based agonists, N-[9-fluorenylmethyloxycarbonyl]-L-Leucine, and the short-circuit current (Isc) was measured in normal, HCO3− or Cl−-free Krebs-Henseleit solutions (KHS). Cells treated with pioglitazone exhibited a reduced forskolin- or carbachol-activated Isc. Interestingly, other thiazolidinediones, such as troglitazone, had no effect on either forskolin or carbachol responses. In HCO3−-free KHS, pioglitazone did not affect forskolin-activated Ic, but decreased carbachol-activated Ic. Pioglitazone had no effect on either forskolin- or carbachol activated Ic in Cl−-free KHS. Differential regulation of cell metabolism of PPARγ agonists in different transport systems in the apical and basolateral membranes. Real time PCR revealed that PPARγ agonists affected expression of CFTR Cl channels and Na+/HCO3− cotransporter (NBC1). The decrease in airway bicarbonate transport may provide a possible explanation for the increased upper airway infections observed in subjects participating in clinical trials of PPARγ agonists.

An SEM Study of the Effects of RU486, Used as a Postcoital Contraceptive, on the Rat Uterus during Early Pregnancy

K. E. Scholtz,1 C. Penny,2 M. J. Hosie1; 1Anatomical Sciences, University of the Witwatersrand, Johannesburg, South Africa, 2Medicine, University of the Witwatersrand, Johannesburg, South Africa

The window of receptivity is a narrow range of time in which the blastocyst can attach to the uterine surface and is under the strict control of the ovarian hormones, progesterone and oestrogen. To prime the uterus for blastocyst attachment, the plasma membrane of the uterine epithelial cells undergoes a remarkable change in structure, collectively referred to as ‘the plasma membrane transformation’ of early pregnancy that is mediated by the ovarian hormones. RU486, the controversial abortion drug marketed as Milfigyne™, has a high affinity for progesterone receptors, blocking binding of progesterone. However, normal human bronchial epithelial cells were treated with PPARγ agonists such as pioglitazone, L-tyrosine-based agonists, N-[9-fluorenylmethyloxycarbonyl]-L-Leucine, and the short-circuit current (Isc) was measured in normal, HCO3− or Cl−-free Krebs-Henseleit solutions (KHS). Cells treated with pioglitazone exhibited a reduced forskolin- or carbachol-activated Isc. Interestingly, other thiazolidinediones, such as troglitazone, had no effect on either forskolin or carbachol responses. In HCO3−-free KHS, pioglitazone did not affect forskolin-activated Ic, but decreased carbachol-activated Ic. Pioglitazone had no effect on either forskolin- or carbachol activated Ic in Cl−-free KHS. Differential regulation of cell metabolism of PPARγ agonists in different transport systems in the apical and basolateral membranes. Real time PCR revealed that PPARγ agonists affected expression of CFTR Cl channels and Na+/HCO3− cotransporter (NBC1). The decrease in airway bicarbonate transport may provide a possible explanation for the increased upper airway infections observed in subjects participating in clinical trials of PPARγ agonists.

Immunohistochemical Characterization of Cell Types Expressing the Cellular Prion Protein in the Small Intestine of Cattle and Mice

Ubiquitination of the Gastric Microsomal H,K-ATPase

G. K. Nagatani, C. T. Okamoto; Pharmaceutical Sciences, University of Southern California, Los Angeles, CA

Ubiquitin is a small hydrophobic protein that plays a key role in the downregulation of proteins through its covalent linkage to the ε-amino group of lysine residues and less commonly the N-terminal amino group. This posttranslational modification can play multiple roles depending on the extent of ubiquitination including targeting the protein for proteasomal degradation. Here we determine whether the α and β subunits of the gastric H,K-ATPase, the enzyme responsible for gastric acid secretion, are endogenously ubiquitinated serving to regulate its turnover. H,K-ATPase-rich gastric microsomes from rabbit and hog were purified through standard subcellular fractionation techniques. Microsomes were labeled with fluorescein isothiocyanate (FITC), and proteins were separated by SDS-PAGE. The gel was scanned for the FITC signal on a Typhoon 8610 Variable Mode Imager. An ubiquitin enrichment kit (Pierce) was used to enrich endogenously ubiquitinated proteins from microsomes according to the manufacturer’s protocol. These proteins were separated by SDS-PAGE and probed for H,K-ATPase-rich endogenous ubiquitinated proteins from microsomes regardless of the species. Western blots of the enriched ubiquitinated proteins showed reactivity with 2-26, an HKα antibody. Weak reactivity can be seen with an anti-HKα antibody leaving open the possibility for HKβ ubiquitination. Underway are attempts at identifying: 1) whether or not HKα is in fact ubiquitinated; 2) other ubiquitinated proteins associated with the HK-ATPase and/or gastric microsomal membranes; 3) the enzymes responsible for ubiquitination of the HK-ATPase; and 4) the proteins that bind to ubiquitinated targets. The ubiquitination of the gastric H,K-ATPase could be crucial to its downregulation by regulating the degradation of the HK-ATPase.

Development and Characterization of a New Model for Inflammatory Bowel Disease: Chemical and Bacterial Induction/Part 2

I. Abdallah, 1 A. R. Jurus, 1 A. Badawi, 1 K. Barada, 1 M. H. Mostafa 2; 1Faculty of Medicine, American University of Beirut, Beirut, Lebanon, 2Faculty of Sciences, Beirut Arab University, Beirut, Lebanon

There is no single mechanism to explain the pathogenesis of ulcerative colitis, however, evidence suggests that endogenous luminal bacterial play a critical role. The present study reports and characterizes a novel model of chronic ulcerative colitis induced in rats using a combination of iodoacetamide and E.coli. Male Sprague-Dawly rats (n=158) were divided weekly into the descending colon with 4 different combinations: (a) a control group inoculated with 1% methylcellulose, (b) iodoacetamide-treated group inoculated with 100 µl of 6% iodoacetamide, (c) bacteria-treated group inoculated with 6% iodoacetamide followed by bacteria after 2 days, and (d) combined-treatment group inoculated with 6% iodoacetamide followed by bacteria after 2 days. Thirty days post treatment, each group was divided into two subgroups and inoculation was stopped for one. Colitis was evaluated by the clinical course of the disease, the macroscopic and microscopic alterations, activity of myeloperoxidase (MPO), inflammatory signaling by cyclooxygenase-2 (COX-2) and tumor necrosis factor (TNF-α) gene expression. The clinical course of the disease, in the iodoacetamide-treated continued injection subgroup and both combined-treatment subgroups expressed symptoms and signs resembling human colitis: slow rate of weight increase, diarrhea, and bloody stools. The score of macroscopic alterations for the severity of inflammation were (2-3)/4 in the iodoacetamide-treated continued injection subgroup, and (3-4)/4 for both subgroups in the combined treatment. All animals in the combined treatment group had very high histopathological scores of (10-14)/16 indicating an excessive inflammatory reaction in the colon. MPO activity was consistently elevated (7-fold) in the combined treatment group. TNF-α and COX-2 gene expression were upregulated in the iodoacetamide-treated continued injection and the combined-treatment subgroups. In conclusion, the chronic experimental ulcerative colitis model reported in this study resembles, to a great extent, human ulcerative colitis.

Requirement for Epidermal Growth Factor Receptor Signaling in Stretch-activated Exocytosis of Bladder Umbrella Cells

E. M. Balestreire, G. Apodaca; Medicine/Renal, University of Pittsburgh, Pittsburgh, PA

The superficial umbrella cells that line the bladder lumen are able to dynamically insert and remove membrane to modulate the apical surface area while maintaining a highly impermeable barrier. Membrane turnover occurs in response to mechanical stimuli, such as changes in pressure and volume, which vary during the micturition cycle. This study examines the hypothesis that epidermal growth factor receptor (EGFR) tyrosine kinase signaling is an integral part of the mechanotransduction pathway that mediates an increase in umbrella cell apical surface area in the stretched bladder. A modified Ussing chamber was used to monitor bladder uropathelium capacitance, a measure of surface area, upon stretch stimulus. In control bladder tissue, filling induced a 50% increase in surface area over 5 hours. Addition of the EGFR inhibitor AG-1478 significantly reduced this response to ~25% over 5 hours, while inhibitors of tyrosine kinase pathways that are involved in mechanotransduction in other cell types caused no effect. Immunofluorescence staining demonstrated the presence of EGFR on the umbrella cell apical surface, and its ability to bind to EGF presented from the mucosal side of the tissue. The addition of EGF ligands caused an increase of surface area in the absence of stretch, in a dose-dependent manner, with greater potency when added from the apical surface. Using a pharmacological approach in the Ussing chamber system, various inhibitors demonstrated the requirement for matrix metalloproteinase activity, protein synthesis, and MAPK signaling pathways in the response of the tissue to stretch and EGFR stimulation. These data indicate that EGFR tyrosine kinase signaling from the apical surface is required in the mechanotransduction pathway that mediates a surface area increase in umbrella cells. The exploration of EGFR signaling in bladder mechanotransduction will help us understand bladder physiology while improving our appreciation of cellular responses to mechanical stimuli.
apoptotic protein Bim was suppressed by Muc4 in A375 cells. Determination of ErbB2 protein and phosphorylation levels during detachment indicated that ErbB2 was degraded during cell detachment; Muc4 was able to attenuate ErbB2 degradation in MCF7 and A375 cells. Muc4 expression also resulted in an increased ErbB2 phosphorylation during cell detachment. Specific inhibitors for the proteosome and lysosome pathways were employed to determine which pathway is involved in degradation of ErbB2. ErbB2 degradation in non-adhesive MCF7 cells without Muc4 expression is blocked by lysosome inhibitors, but not by proteosome inhibitors. Detachment caused localization of ErbB2 to the lysosome. In cells with over-expressed Muc4, ErbB2 localized on the cell membrane after detachment. These results indicate that ErbB2 is degraded through the lysosome pathway during detachment.

629 Gab2 Requires Membrane Targeting and the Met Binding Motif to Promote Lamellipodia Formation, Cell Scatter, and Epithelial Morphogenesis Downstream from the Met Receptor

M. M. Frigault, 1 C. M. Kuzmochka, 1 M. A. Naujokas, 1 C. M. Brown, 2 M. Park; 1 Molecular Oncology Group, McGill University, Montreal, PQ, Canada, 2 Life Science Complex Imaging Facility, McGill University, Montreal, PQ, Canada

Gab1 and Gab2 are conserved scaffolding proteins that amplify and integrate signals stimulated by many growth factor receptors including the Met receptor tyrosine kinase. Gab1 acts to diversify the signal downstream from Met through the recruitment of multiple signaling proteins, and is essential for epithelial morphogenesis. However, whereas Gab1 and Gab2 are both expressed in epithelial cells, Gab2 fails to support a morphogenic response downstream from Met. Using structure function studies, we identify elements of Gab1 that are required to confer epithelial morphogenesis downstream from Gab2. Addition of the Met Binding Motif, that mediates direct recruitment of Gab1 to the Met receptor, as well as membrane targeting of Gab2, through the addition of a myristoylation signal, are required to confer a morphogenic signaling response to Gab2. The morphogenesis competent Gab2 mutant, switches the transient response activated by the Met receptor downstream from Gab2 to a sustained and robust activation of signaling pathways involving MEK and AKT and JNK required for lamellipodia formation and scatter. Moreover the overexpression of Gab2 mutant rescues the ability of cells to form membrane ruffles, and localize activated ERK1/2 to the leading edge of the cell in response to Met activation. Hence subcellular localization of the Gab2 scaffold, as well as the ability of Gab2 to interact directly with the Met receptor, are both essential components of the morphogenic signaling response. The Gab family of docking proteins are currently in studies to be completely understood by bio imaging techniques indicating that these family members localized in the nucleus are not necessarily the only targets of Gab2 signaling. The Gab family of docking proteins are currently being studied by live imaging techniques in order to completely understand the dynamics of the subcellular localization of Gab1 and Gab2 downstream of the Met Receptor.

630 The Role of Ap-1 in Fluoride-induced Down-regulation of MMP-20 In Vitro

Y. Zhang, Otorhinolaryngology, University of California, San Francisco, San Francisco, CA

OBJECTIVE: Enamel is the hardest mineralized tissue in humans. Enamel formation is altered with excessive chronic intake of fluoride, resulting in enamel fluorosis, characterized by a delay in the removal of amelogenins as the enamel matures. In this study, we investigated how fluoride interferes with the expression of MMP-20, a matrix enzyme which initially hydrolyses amelogenin. METHODS: Human fetal tooth organ ameloblast lineage cells were cultured and exposed to 10 µM of fluoride. The changes in amelogenin, MMP-20 and TIMP-2 proteins in the presence of fluoride, were assessed by Western blot. Molecular relays mediated down-regulation of MMP-20 by fluoride was investigated via enzyme-activity blocking, Western blot, and protein-DNA affinity assays. RESULTS: MMP-20 synthesis decreased in the presence of fluoride, while amelogenin and TIMP-2 were not altered. Fluoride also decreased the transcription of a luciferase reporter gene driven by the MMP-20 promoter. Down-regulation of MMP-20 by fluoride was related to suppression of JNK and c-Jun phosphorylation. Three c-Jun binding motifs on the MMP-20 promoter were identified and proved to be occupied by c-Jun as MMP-20 expression was induced. CONCLUSIONS: These in vitro findings suggest that fluoride induced down-regulation of MMP-20 transcription occurs through the JNK/c-Jun signaling pathway. Altered MMP-20 expression could disturb the balance between MMP-20 and its amelogenin protein substrate, contributing to the formation of enamel fluorosis.

631 Mosaic Eyes Stabilizes Delta and Restricts Notch Activity to Rhombomere Boundaries

K. Rand, M. Joth, S. Yeo, G. Palardy, A. B. Chitnis; Laboratory of Molecular Genetics, NICHD NIH, Bethesda, MD

Mind bomb (Mib) is an E3 ligase that promotes Delta ubiquitylation and endocytosis, an essential step for its function as a Notch ligand. Interaction between Mib and Mosaic Eyes (Moe), a FERM domain protein, was identified in a yeast two-hybrid screen and subsequently confirmed with immuno-precipitation experiments. Moe is typically associated with the cell surface and in co-transfection experiments it alters Mib’s cellular distribution, reducing Mib in the cytoplasm and stabilizing it at the cell surface. In zebrafish embryos, knock-down of mow with morpholinos affects brain morphology, particularly in regions where expression is typically restricted to rhombomere boundaries is deregulated and spread throughout the hindbrain. While morphogenesis of rhombomere boundaries is disturbed, rhombomere-specific expression of various genes is not affected suggesting a specific problem with boundary formation, not early neural patterning that defines individual rhombomere compartments. Restriction of Notch activity is thought to be essential for morphogenesis of rhombomere boundaries, and cells with relatively high Notch activity segregate to these boundaries. In more morphants Notch activity is no longer restricted to boundaries and the Notch target gene her4 is expressed throughout some rhombomeres. Paradigmatically, deregulated Notch target gene expression is accompanied by an apparent disappearance of DeltaD protein, even though transcription of genes encoding Notch ligands seems unaffected. A truncated Moe, AN-Moe, lacking the N-terminal fragment responsible for surface localization, prevents Mib from being localized at the cell surface in transfected cells. Remarkably, co-transfection of DeltaD with AN-Moe and Mib reduces DeltaD stability suggesting that functional Moe protein is required to ensure stability of Delta in cell culture, just as in the embryo. We are now investigating how Moe determines DeltaD stability and limits Notch activity to rhombomere boundaries. These studies provide novel insights into Notch’s enigmatic role in morphogenesis of tissue compartment boundaries in the embryo.

632 Nerve Growth Factor and a Conditioned Medium Differentially Regulate the Appearance of Axons and Dendrites in PC12 Cells

M. V. Longart, L. L. Garcia; Unidad de Neurobiologia Molecular, Instituto de Estudios Avanzados, Caracas, Venezuela

Neurite formation, a process extending from the cell body and led by a growth cone, is a primary morphological event in neuronal differentiation. Neurotrophins like Nerve Growth Factor (NGF) are key regulators of neuronal differentiation. NGF, and other factors, are released by target tissues, initiates neurite generation and promotes synapse formation. Axonal and dendritic growths are fundamental to establish neuronal connectivity in the brain. However, the mechanisms that govern their morphogenesis remain to be elucidated. To investigate the role of neurotrophic factors on neurite specification, we used NGF and a conditioned media from sciatic nerve (CM) to differentiate PC12 cells into neuron-like cells. Both treatments caused cell differentiation and the percentage of cells with long neurites was 15 and 30% for CM and NGF, respectively. Using antibodies that specifically recognize axons and dendrites, we found that both conditions are able to induce the formation of dendrites at 24 hours, being the NGF more effective than the CM. At 7 days in culture, the ratio of dendrites/cell induced by NGF was 1.7, while by the CM was 1. At day 10, we observed that CM produced an increase in that ratio to 1.3. On the other hand, only NGF induced the appearance of axons from 7 days in culture in 48% of the differentated PC12 cells. The expression of the axonal marker always appeared towards the tip of the neurites and reached their proximal segments in older cultures (10 days). Despite the axonal marker was initially double labeled with the dendritic marker (7 days), always appeared in only one of the processes and its time increasing expression was accompanied by the disappearance of the dendritic marker. This phenotype could resemble pre-polarization of neurons. PC12 cells, differentiated with NGF, could serve as an excellent model to study the mechanism of neurite specification.

633 Solo/trio8, a Membrane-associated Short Isoform of Trio, Modulates Endosome Dynamics and Neurite Elongation

S. Aoki, Y. Sun, K. Nishikawa, H. Yuda, H. Osaka, Y. Wang, N. Fukazawa, K. Wada; Dept. of Degenerative Neurological Diseases, National Institute of Neuroscience, Tokyo, Japan

Using RNAi, we have identified a gene termed Solo, that is downregulated in the cerebellum of Purkinje cell degeneration (pcd) mutant mice. Solo is a mouse homologue of rat Trio8, one of multiple Trio isoforms recently identified in rat brain. Solo/Trio8 contains N-terminal sec14-like and spectrin-like repeat domains followed by a single GEFI domain, but it lacks the C-terminal GEF2, Ig-like and kinase domains that are typical of Trio. Solo/Trio8 is predominantly expressed in Purkinje neurons of the mouse brain, and expression begins following birth and increases during Purkinje neuron maturation. We identified a novel C-terminal membrane-binding domain in Solo/Trio8 that is required for EFGP/Solo/Trio8 localization to early endosomes (positive for both early endosome antigen 1 (EEA1)-) and Rab51 in COS-7 cells and primary cultured neurons. Solo/Trio8 overexpression in COS-7 cells augmented the EEA1-positive early endosome pool, and this effect was abolished via inactivation of the GEF domain or deletion of the C-terminal membrane-binding domain. Moreover, primary cultured neurons transfected with Solo/Trio8 showed increased neurite elongation that was dependent on these domains. These results suggest that Solo/Trio8 acts as an early endosome-specific upstream activator of Rho family GTPases for neurite elongation of developing Purkinje neurons.
Mechanical Force Locally Adjusts Accumulation of Synaptic Proteins at Axon Terminal

S. Stechen, J. Sun, S. Yang, F. Carrero-Martinez, T. Sai, A. Chiba; Cell and Developmental Biology, University of Illinois, Urbana, IL

Previous work has identified various chemicals such as NGF, NO, BMP and WNT as retrograde signals at synapses to adjust neurotransmission. Here, we provide evidence that mechanical force serves as a "retrograde signal" at Drosophila neuromuscular synapses and plays a critical role in locally adjusting their function in a usage-dependent manner. Within 30 minutes of contacting its target muscle, each motoneuron axon builds a 2 μm tension. Laser ablation before the axon reaches the terminals causes a very rapid 12 μm retraction. The use of nanofabricated MEM (micro-electro-mechanical) force sensor further reveals the constant contact to its target muscle, each motoneuron axon builds a 2 nN tension. Laser axotomy before the axon reaches the terminals results in a negligible retraction of the cut axon, whereas the same treatment after the axon-terminal contact is made causes a very rapid 12 μm retraction. The use of nanofabricated MEM (micro-electro-mechanical) force sensor further reveals the constant resistance tension being actively maintained with a time constant of 3 minutes. During the first 120 minutes, the tension exerted at the synapse terminals changes continuously due to, first, myogenic (neurotransmission-dependent) and, later, increasingly neurogenic (neurotransmission-dependent) contractions of the target muscles. Synaptotagmin-I and BRP (neurotrophin-2) are released from the terminals, which are essential for neurotransmitter release at the axon terminals during this period. If the muscle contraction is blocked genetically, those proteins fail to accumulate. However, this can be rescued by exogenous stretching or relaxing the neuron terminals, thereby increasing Ca^2+ influx and decreasing the amount of Synaptotagmin-I accumulation, suggesting the synapses' ability to accommodate a range of force-induced adjustment. The amount of synaptic proteins at the terminals is adjusted within 30 minutes and the effect lasts for at least 120 minutes. In all experiments, untreated neighboring synapses remain unaffected. Remarkably, the combination of atrophy (physical uncoupling of axon from the cell body) and micropipette patch (restoration of tension) demonstrates a local autonomy of the force-induced synaptic adjustment. We propose a novel mechanism that adjusts synaptic function according to its prior usage, locally through a mechanical signaling.

Asymmetric PtdIns(3,4,5)P_3 Signaling Mediates Chemoattraction of Nerve Growth Cones

S. Henle, E. Yang, E. Liang, G. Wang, M. Wu, M. Poo, R. H. Herley; Physical & Biomed Sciences, Stanford University, Stanford, CA, 2Mol and Cell Biology, UC Berkeley, Berkeley, CA

Pathfinding by growing axons in the developing nervous system is directed by extracellular gradients of attractive and repulsive chemotrophic factors that guide the nerve growth cone. We previously reported that the cellular action of many chemotrophic factors is mediated by a cytoplasmic gradient of Ca^2+ signals, but the link between surface receptor activation and Ca^2+ signaling was largely unknown. In migrating leukocytes and amoeboid cells, polarized elevation of the plasma membrane lipid PtdIns(3,4,5)P_3, is known to mediate the detection of a gradient of chemotractant and initiates cytokinetic rearrangements required for directed chemotaxis. Here we report that a gradient of axon guidance factors, brain-derived neurotrophic factor (BDNF) and netrin-1, can also induce polarized PtdIns(3,4,5)P_3 signals in growth cones of cultured spinal neurons, as revealed by translocation of the fusion protein Akt-PH-GFP to the plasma membrane. Activation of both PtdIns(3) kinase and Akt was required for chemotrophic factor induced attraction, and asymmetric application of exogenous PtdIns(3,4,5)P_3 was sufficient to induce attractive growth cone turning. Furthermore, focal application of exogenous PtdIns(3,4,5)P_3, rapid expansion of TRP receptor potential) channels in the growth cone plasma membrane, leading to Ca^2+ influx, which also depended on the activities of PtdIns(3) kinase and Akt. Our findings suggest that asymmetric PtdIns(3,4,5)P_3 signals at the growth cone membrane may serve to link focal guidance receptor activation with TRP channel activity and Ca^2+ signaling during chemoattractive axon guidance.

Dephosphorylation of Collapsin Response Mediator Proteins (CRMPs) Induced by Hypoxia-ischemia in Neonatal Mice through Down Regulation of Cdk5/p35

Y. Zhou, I. Bhata, P. He, P. Cheung, J. Chu; Department of Anatomy, The University of Hong Kong, Hong Kong, 2Department of Pediatrics and Adolescent Medicine, The University of Hong Kong, Hong Kong

Collapsin Response Mediator Proteins (CRMPs) are a family of cytosolic proteins involved in neuronal differentiation and axonal guidance. The expression of CRMPs are up-regulated during the peak period of axonal growth and down-regulated afterwards. By using proteomic approach (2D-MS) to study the alteration and modification of proteins in neonatal mouse brain tissues upon 24-hour hypoxia-ischemia (HI) treatment, we found that CRMP2, CRMP4 and CRMP5 proteins were post-translationally modified after HI treatment. MS and Western Blot analyses confirmed that these proteins are dephosphorylated on several sites. Because CRMP2 has previously demonstrated to be one of the substrates of cyclin dependent kinase 5 (cdk5), a neuronal specific kinase that plays pivotal roles in neuronal development and is critically involved in the regulation of neuronal survival, we further analyzed the expression level and activity of Cdk5 and its activator p35. We observed that the dephosphorylation of CRMPs was correlated with underexpression of p35 and significant reduction of Cdk5 kinase activity. Our findings suggest one molecular mechanism through which CRMPs are dephosphorylated during HI treatment. Further investigations are required to elucidate the pathological significance of CRMP dephosphorylation in HI-induced neuronal apoptosis and HI-related neurodegenerative diseases.

Role of the 5-HT7-Receptor in Synaptogenesis, Synaptic Plasticity

F. Koebe, D. Hess, M. Muller, D. W. Richter, E. G. Ponimaskin; Neuro- and Sensory Physiology, University of Goettingen, Goettingen, Germany

5-HT_7 receptor agonist 8-OH-DPAT (5-HT_7 agonist) plays an essential role in multiple events in the CNS. Recently we demonstrated that in mouse hippocampal neurons, activation of endogenous 5-HT_7 receptors significantly increased neurite length, whereas stimulation of 5-HT_7 receptors led to a decrease in the length and number of neurites. We showed that the 5-HT_7 receptor is coupled not only to the heterotrimeric Gs, but also to G13 protein. Activation of this signaling pathway results in RhoA-mediated modulation of gene transcription and in reorganization of the actin cytoskeleton. We also demonstrated that serotonin receptor 5-HT_7 can activate heterotrimeric G12 protein, leading to the selective activation of small GTPases RhoA and Cdc42. Agonist-dependent activation of the 5-HT_7 receptor induced pronounced filopodia formation via a Cdc42-mediated pathway paralleled by RhoA-dependent cell rounding. (1,2) This molecular model for 5-HT_7 and 5-HT_4 receptor mediated signalling provides a link between receptor activation and a subsequent change in morphology. We also asked whether these serotonin mediated morphological changes could be directly correlated to the modulation of synaptic plasticity. We investigated the 5-HT_7 receptor-mediated formation of presynaptic clusters (synaptoplasty), filopodia, spines and the spontaneous synaptic activity in primary culture of mouse hippocampal neurons. Furthermore we looked into changes in long-term potentiation related to the 5-HT_7 receptor mediated activity of pacemaker currents in the cultured neurons. Our data suggests that serotonin plays a prominent role in regulating the neuronal cytoskeleton and synaptic plasticity in addition to its classical role as a neurotransmitter. 1) Kuchavena E, Liu G, Dityateva G, Schachner M, Voyno-Yasenetska TA, Ponimaskin EG J Neurosci, Vol. 25, (2005) 2) Ponimaskin EG, Heine M, Joubert L, Sebben M, Bickmeyer U, Richter DW, Durnuis A J Biol Chem, Vol. 277, (2002)

Efficient Co-Packaging and Co-Transport of Neuromodulators Associated with Synaptic Plasticity

J. E. Lochner, E. Spangler, C. S. Schuttner, B. A. Scallett; Chemistry, Lewis & Clark College, Portland, OR, 2Physics, Lewis & Clark College, Portland, OR

Long-term memory formation is accompanied by enduring changes in synaptic efficacy, which are triggered in part by the secretory and subsequent activity of neuromodulators. Brain-derived neurotrophic factor (BDNF) and tPA, which is a component of the tPA-BDNF signalling pathway, are functionally linked to synaptic plasticity. We have constructed two fluorescent hybrid proteins, tPA-enhanced green fluorescent protein (tPA-EGFP) and proBDNF-mCherry, and we have effectively expressed both hybrids simultaneously during learning and memory. For example, mature BDNF (mBDNF) augments synapse density and elicits long-lasting enhancement of synaptic transmission. In contrast, precursor BDNF (pBDNF) is a weak growth factor that plays pivotal roles in neuronal development and is critically involved in the regulation of neuronal survival, we further analyzed the expression level and activity of Cdk5 and its activator p35. We observed that the dephosphorylation of CRMPs was correlated with underexpression of p35 and significant reduction of Cdk5 kinase activity. Our findings suggest one molecular mechanism through which CRMPs are dephosphorylated during HI treatment. Further investigations are required to elucidate the pathological significance of CRMP dephosphorylation in HI-induced neuronal apoptosis and HI-related neurodegenerative diseases.
Abnormally synchronized synaptic transmission in the brain causes epilepsy. Most inherited forms of epilepsy result from mutations in ion channels. However, one form of epilepsy, autosomal dominant partial epilepsy with auditory features (ADPEAF), is characterized by mutations in a secreted neuronal protein, LGI1. We show that ADAM22, a transmembrane protein that when mutated itself causes seizure, serves as a receptor for LGI1. The mutated form of LGI1 fails to bind to ADAM22. ADAM22 links extracellular LGI1 to the postsynaptic density-95 (PSD-95) cytoskeletal scaffold containing stargazin and AMPA-type glutamate receptors. LGI1 enhances AMPA receptor-mediated synaptic transmission in hippocampal slices and surface-expression of AMPA receptors in hippocampal neurons. This study identifies LGI1 as a new ligand for ADAM22 that controls synaptic transmission and human epilepsy.

Calcineurin, Calpain, and Cytoskeleton in Low Frequency Depression of Synaptic Transmission

L. B. Silverman Gavrila, M. P. Charlton; Physiology, University of Toronto, Toronto, ON, Canada
Low frequency depression (LFD) of transmitter release at phasic synapses of crayfish neuromuscular junctions is regulated by protein phosphorylation (Silverman-Gavrila et al., 2005). The permeant calcineurin inhibitors FK-506 or calcineurin autoinhibitory peptide abolished LFD. To determine if the site of action of calcineurin is pre or post synaptic we pressure injected impermeant calcineurin autoinhibitory peptide into presynaptic axons or postsynaptic muscle cells and measured the amplitude of the intracellularly recorded excitatory postsynaptic potential (EPSP) evoked by stimulating the phasic axon at 0.2 Hz. LFD was decreased only when calcineurin was inhibited in the presynaptic nerve terminal. The drugs have no postsynaptic effects since FK-506 or permeant peptide did not affect amplitude distribution of spontaneous miniature EPSPs; therefore they target presynaptic calcineurin, the activity of which is necessary for LFD. Neither drug affected high frequency depression caused by 20 Hz stimulation. Since moderate calcium buffering by injected BAPTA-based Ca2+ indicators did not inhibit LFD, the activation of calcineurin may occur very close to Ca2+ channels where a large Ca2+ signal is available. Calcineurin inhibition blocked LFD, suggesting that a limited proteolysis of calcineurin might be involved in its activation during LFD. To examine changes in phosphoproteins during LFD, we removed motor axons and nerve terminals after the induction of LFD or treatment with various phosphorylation regulators, extracted their proteins, separated them by SDS-PAGE, and stained them with phosphospecific stains to identify bands for analysis by mass spectrometry. Actin and tubulin phosphorylation was decreased during LFD. Western blot analysis and immunostaining showed calcineurin, actin and tubulin at presynaptic axons and terminals. Anti-calcineurin drug cytochalasin and the microtubule stabilizer taxol inhibited LFD, while the actin stabilizer jasplakinolide and the tubulin depolymerizing drug nocodazole accelerated LFD with no postsynaptic effects. In conclusion, dephosphorylation of presynaptic actin and tubulin by calcineurin regulate LFD.
significant concentrations of YC 1.360 such that activity could be recorded. While expression was almost exclusive in astrocytes, a number of other cell types which express S100β, such as large motor neurons in the brain stem and some of the NG2 and CNP positive oligodendrocyte progenitor cells (OP cells), also were fluorescent with YC 3.60. Using a variety of known in vivo assays, we found that stimuli known to elicit Ca²⁺ signals in astrocytes (glutamate application, electrical stimulation of neural pathways) caused substantial and rapid Ca²⁺ signals in the YC 3.60 expressing astrocytes. These results, for the first time, show that genetically encoded reporter is capable of recording activity dependent Ca²⁺ signals even in the very fine terminal processes of astrocytes that wrap individual synaptic boutons.

A Drug Screen for Fragile X Promoter Activation
L. Jabhour, D. Guo, R. Chen, A. M. Tartakoff; Pathology, Case Western Reserve University, Cleveland, OH
In the Fragile X Syndrome, trinucleotide expansion of the 5'UTR of the FMR1 gene inhibits its transcription. Its product, FMRP, is correspondingly reduced or absent. FMRP is a cytoplasmic protein which binds selected RNAs and is part of the RISC complex, thereby implicating it in translational regulation. Its presence enhances long-term depression at synapses and its titration can be rapidly increased upon stimulation of synaptic activity (Gabel et al. J. Neurosci. 24, 10579 (2004)). In anticipation of attempts to reverte the trinucleotide-expanded FMR1 promoter, we generated a plasmid which makes it possible to drive the expression of GFP using the normal FMR1 promoter. This plasmid was used to produce stable transfectants of COS7 cells. Using this fluorescent target cell, we then tested a panel of 1040 FDA-approved drugs (the NINDS custom collection -Heemskerk et al. Trends Neurosci., 25, 494 (2002)) in order to learn whether any of them - as expected if they stimulate the FMR1 promoter - would increase fluorescence levels. This involved the replication of plate cell cultures in microtiter wells, followed by addition of each drug at 10 nM, continued culture for two days, and quantitation of fluorescence using a fluorescent plate reader. Since replicate cultures did not show significant stimulation of fluorescence, continued work will use cDNA libraries for related studies. Supported by the Fondation Jerome Lejeune.

Role of Vascular Permeability in Brain Tumor Infiltration
C. V. Lund, 1 M. T. N. Nguyen, C. A. Kruse, B. E. Torbett, B. P. Eleciri1; 1La Jolla Institute for Molecular Medicine, San Diego, CA, 2The Scripps Research Institute, La Jolla, CA
Malignant brain tumors, such as glioblastomas, are characterized by extensive angiogenesis and permeability of the blood-brain barrier (BBB). The infiltration of glioma cells away from the primary tumor mass is a pathological characteristic of glial tumors. The infiltrating tumor cells represent a significant factor in tumor recurrence following surgical debulking, radiation, and chemotherapy treatments. Vascular endothelial growth factor (VEGF)-mediated vascular permeability (VP) has been associated with the progression of glioma growth and infiltration into surrounding normal brain parenchyma. While VEGF induces robust VP response in control mice (src+/+ or src–/–), the VP response is blocked in src–/– mice that demonstrate a "leakage-resistant phenotype" in the brain. We used the Src-deficient mouse model to determine the role of Src in the maintenance of the BBB following orthotopic implantation and growth of glioma cells in the brain. Although solid tumor growth was the same in control and src–/– mice, the infiltrating component of glioma growth was reduced in src–/– mice. CD31-labeled vasculature of the primary tumors were unchanged in the tumor models of wildtype and src–/– mice, however, indirect immunofluorescence of the extracellular matrix (ECM) protein fibrinogen showed reduced accumulation in the tumor of src–/– mice compared to wildtype. To identify Src-mediated changes in protein expression and phosphorylation in vivo, additional proteomic studies of brain lysates from wildtype and src–/– mice containing glioma tumors were performed and mass spectrometry analysis of protein changes identified. We hypothesize that phosphorylation of focal adhesion kinase (FAK) is required for VEGF-induced VP. By using VEGF-expressing glioma cells to induce VP in a xenograft tumor model of glioma growth, we can determine whether Src-regulation of FAK is essential in the maintenance of blood vessel integrity in the brain during brain tumor growth.

Abi1/Hsh3bp1 Regulates c-Abl Tyrosine Kinase Activity and c-Abl-dependent Cell Proliferation and Spreading
X. Xiong, P. Cui, B. Warner, S. Hossain, X. Guo, X. An, L. Kotula; Laboratory of Cell Signaling, New York Blood Center, New York, NY
Bcr-Abl is a validated target for drug development in the treatment of chronic myelogenous leukemia (CML). The initial success of Gleevec (imatinib mesylate) in the treatment of CML has been hampered by identification of kinase mutations resistant to the drug. In vitro screen to identify possible mechanisms of the drug resistance as well as data from functional studies lead to the conclusion that Alb ligands or its substrates may be an important factor in regulating Bcr-Abl kinase activity in addition to the autoinhibitory mechanism of the kinase. The presence of SH3 and SH2 domains in Bcr-Abl and c-Abl indicate that the mechanism of kinase regulation involving these domains is conserved. Here we report identification of an allosteric non-ATP-competitive mechanism of c-Abl kinase inhibition by phosphopeptides derived from Abi1/Hsh3bp1. The mechanism involves high affinity binding of the phosphotyrosine from Abi1 to the SH2 domain and the Abi1/Hsh3bp1's PXXP motif to the Abi1 SH3 domain. The critical role of Abi1/Hsh3bp1 in regulation of c-Abl kinase activity in vivo is supported by inhibition of cell proliferation and cell spreading expression of Abi1/Hsh3bp1 in cells deficient in Abi1/Hsh3bp1 due to loss-of-function mutation. The Y to F replacement of the regulatory tyrosine of Abi1 or the mutation in its PXXP motif did not inhibit c-Abl kinase activity supporting the role of these regions in the regulation of c-Abl. Our findings suggest a novel mechanism by which Abi1 kinases are regulated in cells and provide a novel strategy for anti-leukemic drug development.

Studies of Ferrite Based Magnetic Nanoparticle Transport Mechanisms and Magnetocytolysis Effects on a Model Cell Culture
H. L. Rodriguez, A. Herrera, C. Rinaldi, M. Torres; Chemical Engineering, University of Puerto Rico Mayaguez, Mayaguez, Puerto Rico
Suspended magnetic nanoparticles, such as ferrites, are known to dissipate energy under an oscillating magnetic field. Such energy dissipation could be employed to locally raise the temperature inside a tumor to 41-46 °C, promoting cell death. This technique is promising in the development of a novel cancer treatment with potentially fewer side effects, compared to radio and chemotherapy. Cytotoxicity experiments, transport analysis, and magnetocytolysis experiments were performed in Caco-2 cells (human colon adenocarcinoma epithelial cells) using dextran coated ferrite nanoparticles. Cytotoxicity was examined by exposing the cells to various concentrations of nanoparticles for 2, 24, 48 hours. Cell viability was analyzed using a fluorometric assay which measures cell metabolism. These studies indicate that viability of the cells was not affected by the nanoparticles in the concentration range 0.08-0.2 mg/mL. Nanoparticle suspensions with a concentration of 0.144 mg/mL were applied to the cells and the system was exposed to a magnetic field of 3.1 kA/m, and a frequency of 1 kHz. It was found that viability of the cells decreased to 40% of the negative control. Additionally, with the purpose of investigating the exact transport mechanism of the ferrite nanoparticles, these were coated with cross-linked fluorescein isothiocyanate dextran (FITC Dextran). Cells were exposed to the fluorescent labeled nanoparticles and then examined using a confocal laser scanning microscope. Preliminary results suggest that nanoparticles were transported through the cell membrane, invading the cytoplasm of the cells. This fluorescent label will allow further investigation of the nanoparticle transport mechanism through the cells.

Localization of a Mutant p53 Response Element on the Tissue Inhibitor of Metalloproteinase-3 Promoter: Mutant p53 Activities Are Distinct from Wild-Type
S. Thomas, D. Reisman; Biological Sciences, University of South Carolina, Columbia, SC
Missense mutations in the p53 gene have been observed in greater than 60% of all human tumors. Recent evidence indicates that some mutations in p53 arise as the cancer progresses from a benign tumor to a metastatic tumor and that these mutations in p53 actively contribute to the process of cancer progression. Earlier work that found the expression of the gene encoding the tissue inhibitor of metalloproteinase-3 (TIMP-3) is repressed in cells expressing codons 248 and 281 mutant p53 (Telles). The ability of tumor-derived p53 mutants to inhibit TIMP-3 expression provides a novel mechanism for understanding how p53 mutations might contribute to tumorigenesis. Since mutant p53 is often expressed at elevated levels in a variety of cancers, the generation of cells in a tumor carrying certain mutations in p53 would cause inappropriate reduced expression of TIMP-3 and lead to elevated matrix metalloproteinase activity. We present the results of experiments that begin to determine the mechanism by which mutant p53 represses TIMP-3 gene expression. By generating deletion derivatives of the TIMP-3 promoter and testing them for expression and by performing DNA protein binding assays on the regions determined to be required for repression, we have identified elements that are essential for mutant p53-mediated transcriptional repression. These elements respond specifically to mutant but not wild type p53. While mutant p53 itself does not bind to the TIMP-3 promoter, we provide evidence for the presence of DNA binding proteins whose activity is enhanced in the presence of mutant p53.
DNA-dependent Activation of ATM Kinase in Chromatin-free Nuclear Extracts

Y. Tsai, L. Liu; Pharmacology, University of Medicine and Dentistry of New Jersey, Robert Wood Johnson Medical School, Graduated School of Biomedical Sciences, Piscataway, NJ

A chromatin-free nuclear extract capable of supporting ATM activation in response to DNA double-strand breaks (DSBs) was developed. Addition of short duplex DNA fragments (e.g. 30-mer) incapable of forming nucleosomes was shown to efficiently activate ATM kinase in the nuclear extract, as evidenced by the stimulation of ATM autophosphorylation at Ser-1981, and phosphorylation of ATM substrates such as 53BP1, Chk1 (Ser-317), Chk2 (Ser-33/35) and p53 (Ser-15). In addition to linear duplex DNA, single-stranded oligonucleotides (ODNs), gapped DNA and flapped DNA also efficiently activated ATM kinase as evidenced by ATM autophosphorylation and phosphorylation of the various ATM kinase substrates. These in vitro results suggest that the chromatin structure is not obligatory for ATM activation, and altered DNA structures other than double-strand breaks can also efficiently activate ATM kinase.

A Naturally Occurring, Inducible, Constitutively Active Isoform of the Human Prolactin Receptor, ΔS2 SF1b, Reduces Proliferation and Migration in Human Prostate Cancer Cells

K. Huang, A. M. Walker; Division of Biomedical Sciences, University of California, Riverside, Riverside, CA

We previously showed that a molecular mimic of phosphorylated prolactin (PRL), S179D PRL, inhibited prostate tumor growth. In part this is through antagonism of a PRL autocrine growth loop, and in part this is through up-regulation of one of the short prolactin receptor (PRLR) isoforms, S1bF1, resulting in an increase in p21 and vitamin D receptor expression. In the current study, we identified a novel, naturally occurring form of PRLR, which lacks about half of the extracellular domain and is active in the absence of ligand. Stable prostate cancer cell lines expressing this constitutively active receptor, designated ΔS2 SF1b, were established. These cells grew more slowly than their control transfected counterparts. Overexpression of ΔS2 SF1b also inhibited cell migration as analyzed by wound healing and transwell assays. Semi-quantitative and real-time RT-PCR analysis revealed that ΔS2 SF1b expression up-regulated the prostate inhibitors TIMPs 1 & 2 and PANS 1 & 2, and down-regulated both the cognate proteases MMPs and uPA, and the growth factors bFGF and VEGF. Immunofluorescent staining of a cell junction component, E-cadherin, showed more cell-cell contacts in ΔS2 SF1b cells. Since S179D PRL upregulates intact SF1b and this is associated with decreased migration of endothelial cells, we investigated the effect of S179D PRL on prostate cancer cell migration and invasion. Treatment of LNCaP cells with S179D PRL inhibited cell migration in the transwell assays. Analysis of gene expression showed that S179D PRL upregulated both the intact and ΔS2 SF1b, extending the previous study to include the ΔS2 version. Also upregulated were the TIMPs and PADS. We conclude that overexpression of the constitutively active short PRLR isoform, ΔS2 SF1b, inhibits cell migration and likely reduces invasive properties. Similar results can be achieved by treatment with S179D PRL, which up-regulates the expression of this particular isoform. Supported by DK61005 and BC0501103 (DOD)

HYA-Synthase-1: A Potential Bladder Cancer Marker

R. Golshani,1 Y. Hirano,1,2 H. B. Klavse,3 K. Tanaka,1 S. Murata1,4; 1Laboratory of Frontier Science, Tokyo Metropolitan Institute of Medical Science, Tokyo, Japan, 2The Burnham Institute for Medical Research, La Jolla, CA, 3Laboratory of Molecular Biology, University of California, San Diego, La Jolla, CA, 4Sylvestor Comprehensive Cancer Center, University of Miami Miller School of Medicine, Miami, FL.

Objective: Hyaluronic acid (HA), a non-sulfated glycosaminoglycan, promotes bladder cancer growth and metastasis. Urinary HA test has ~90% accuracy in detecting bladder cancer, regardless of tumor grade and stage. HA is synthesized by a plasma membrane-associated enzyme, HYA-synthase (HYAS), present in three separate isoforms. We correlated HA-S1 expression in bladder cancer tissues and cell lines with HA levels and HA urine test results. Materials and Methods: 48 bladder specimens underwent HYAS1 real time PCR. Results were substantiated by HA tissue measurement and HA-S1 and HA-S2 immunoblot analyses. RT-PCR detected HYAS1 variants in bladder tissues and cell lines. Gel-filtration chromatography determined HA polymer size in bladder tissue. HYAS1 and HA were localized in 68 archival bladder tissues by immunohistochemistry. Urinary HA levels were measured and compared to immunohistochemistry results. Results: Real-time RT-PCR and northern blot analyses revealed HYAS1 transcript levels elevated 5-10-fold in bladder tumor (TBL) tissues relative to normal bladder (NBL) tissues. Measurement of HYAS1 transcript levels had ~80% accuracy in detecting bladder cancer. HA levels were elevated 2.5-fold in TBL tissues when compared to NBL tissues and correlated with elevated HYAS1 transcript levels. A HYAS1 splice variant, HYAS1-va, was expressed in bladder tissues but at 214 times lower than HYAS1 wild type transcript. The size and the level of HA present in TBL tissues and bladder cancer cell lines were consistent with HYAS1 protein expression. Immunohistochemistry of HYAS1 and HA in bladder tissues revealed that HYAS1 and HA expression has 79% and 88% sensitivity and 83.3% and 100% specificity, respectively, in detecting bladder cancer. The expression of both HYAS1 and HA in TBL tissues correlated with a positive HA urine test and with tumor recurrence and treatment (P < 0.001). Conclusion: Increased HYAS1 expression contributes to increased HA levels in tumor tissues and to a positive HA urine test.

Expression Patterns of Lectins in Cardiac Myxoma

P. Chu,3 S. Jung,2 A. Wu,3 Medicine, Chang Gung Memorial Hospital and University, Taipei, Taiwan, 2Pathology, Chang Gung Memorial Hospital and University, Taipei, Taiwan, 3Glyco-Immunology Research Laboratory, Chang Gung University, Taipei, Taiwan.

Objective: Cardiac myxoma, the most common primary tumor of the heart, has variable clinical presentations and variable immunohistochemical profiles. Lectins are simply defined as proteins which specifically bind (or crosslink) carbohydrates. The existence of glycoproteins in cardiac myxoma has not been demonstrated completely, except mucins genes, MUC1, MUC2, and MUC 5AC. The purpose of this investigation was to elucidate the expression patterns of lectins in cardiac myxomas. Methods: This study analysis of micro-tissue array comprising of 77 patients with cardiac myxomas that were surgically excised. The expression patterns of 21 glycoproteins in cardiac myxoma were elucidated by immunohistochemical analysis. Results: The patient population consisted of 46 (60%) women and 41 (40%) men with a mean age of 46 (range, 32-65) years. All cases of myxoma were sporadic myxomas rather than familial. Clinical presentations included: asymptomatic (25%), dyspnea (45%), stroke (10%), chest pain (9%), and fever (11%). All myxomas were located in the left atrium. Pathological scores for inflammation, necrosis, calcification, and location on the atrial septum varied, 10 lectins, including ricin, Bandeiraea (Griffonia) simplicifolia lectin-I, isolectin A4, wheat germ agglutinin, Bandeiraea (Griffonia) simplicifolia lectin-I, isolectin B4, Ricinus communis, Aleuria aurantia, Abrin-A, peanut agglutinin, Macheria pomifera and BRG5, were strongly (more than 50%); 7 lectins (Arctocarpus integrifolia, Lens culinaris, Prostate-specific antigen, Cysteine-rich antifungal protein 2B, BHG1, and BHG3) moderately (21-50%); and 4 (Abrus precatorius agglutinin, Vicia villosa B4), BH34, BHG4) weakly (less than 20%) were expressed in the membrane. Conclusion: In conclusion, the existence of lectins in cardiac myxoma may play an important role of the formation of tumors.

Molecular Mechanism of Assembly of Mammalian 20S Proteasomes

Y. Hirano,1 H. B. Klavs, K. Tanaka, S. Maruta1; 1Laboratory of Frontier Science, Tokyo Metropolitan Institute of Medical Science, Tokyo, Japan, 2The Burnham Institute for Medical Research, La Jolla, CA, 3Institute of Molecular Biology and Physiology, University of Copenhagen, Copenhagen, Denmark, 4PRESTO, Japan Science and Technology Agency, Kawaguchi, Saitama, Japan

The 26s proteasome is a central enzyme in the degradation of ubiquitin-conjugated proteins. The importance of the study of proteasomes is now growing from the standpoint of clinical medicine. A proteasome inhibitor called Bortezomib is in clinical use as an anticancer drug, and it has been proved that the proteasome is an attractive target for cancer therapy. The 20s proteasome, a catalytic core of the 26s proteasome, is composed of 28 subunits arranged in a cylindrical particle with four hexameric rings. The two outer rings are made up of seven kinds of β subunits, three of which are proteolytically active, whereas the outer rings are made of up seven kinds of σ subunits. However, the mechanism responsible for the assembly of such complex structure remains elusive. Recently we identified three novel chaperones involved in the maturation of mammalian 20S proteasomes, named Proteasome Assembling Chaperone (PAC) 1, PAC2 and PAC3. These three molecules associate with precursor 20S proteasomes. Their knockdown by siRNA causes insufficient α-ring formation and abnormally assembled proteasome precursors, resulting in poor 20S proteasome maturation. Our findings suggest cooperative system of multiple chaperones involved in the correct assembly of mammalian 20S proteasomes. In cancer proteasome biogenesis will provide useful information for effective cancer therapy.

pVHL And GSK3β Cooperatively Maintain the Primary Cilium

C. R. Thoma,1 J. I. Frew,1 M. Montani,1 H. Moch,2 W. Krek1; 1Biology, ETH Zurich, Zurich, Switzerland, 2Pathology, University Hospital Zurich, Zurich, Switzerland

Loss of normal cilia structure causes cystic pathology of the kidney. We show that pVHL, the product of the von Hippel-Lindau (VHL) tumor suppressor gene, when mutated gives rise to precancerous renal cysts and clear cell renal carcinoma, localizes to the primary cilium and functionally interacts with glycogen synthase kinase (GSK) 3β to maintain its structure. This function of
pVHL depends on its ability to stabilize the aneximal microtubules. Although pVHL is dispensable for cilia maintenance when GSK3β is active, it prevents cilia loss when GSK3β signaling is inhibited. Consistent with these findings, in VHL patients, GSK3β is subjected to inhibitory phosphorylation at serine 9 in renal cysts, but not in early VHL mutant lesions, and these cysts exhibit reduced frequencies of primary cilia. We propose that pVHL is part of a 'safeguard mechanism' that preserves the primary cilium and that disruption of this mechanism may contribute to cyst formation.

Silencing of Emmprin by RNA Interference Reduces the Tumorigenicity of the Pancreatic Cancer Cell Line MiaPaCa2

W. Schneiderhan, T. Gress, M. Buchholz, T. Seufferlein, J. Gschwend, M. Seck, G. Adler, M. G. Bachem; Clinical Chemistry, University Hospital, Ulm, Germany, 1Internal Medicine, University Hospital, Muenster, Germany, 2Internal Medicine, University Hospital, Ulm, Germany, 3Surgery, Klinikum, Aalen, Germany

Emmprin is a highly glycosylated membrane protein enriched on cancer cells of various malignancies. To study the role of EMMPRIN in cancer progression we generated from the pancreatic cancer cell line MiaPaCa2 clones stably expressing shRNA targeting EMMPRIN under the control of a tetracycline inducible H1 promoter. EMMPRIN expression was assessed by RTPCR, western-blotting, fluorescence-immunassay (DELFIA) and fluorescence-microscopy. The knock-out phenotype was characterized with respect to adhesion independent growth (soft-agar assay), DNA-synthesis (BrDU-incorporation), growth curves, tumorigenicity (xenograft model) and invasion through chorioallantoic membranes of chick embryos (CAM-assyay). Genes differentially regulated by Bsg were identified by a whole genome microarray followed by stringent analysis. RNAi reduced the expression of EMMPRIN up to 90% on protein- and mRNA level. In the presence of 10% fetal calf serum EMMPRIN silencing reduced adhesion dependent tumor cell proliferation whereas only a modest reduction of colony formation was observed. In addition DNA synthesis was reduced up to 30%. Moreover, EMMPRIN knock-out reduced motility and invasiveness of cancer-cells in a boyden chamber assay and in the CAM-Assay. Finally, EMMPRIN silencing reduced tumorigenicity of cancer cells in a Xenograft model in nude mice by almost 50%. We identified 913 genes differentially expressed after EMMPRIN silencing which were overrepresented in Gene Ontology groups linked to regulation of signal transduction, cell-growth and apoptosis. We demonstrate for the first time that EMMPRIN promotes progression of pancreatic cancer in in-vivo assays presumably by adhesion dependent mechanisms and identified a high number of differentially expressed genes upon phenotypic change. The high number of differentially expressed genes in EMMPRIN-knock out cells suggests an essential role for EMMPRIN in cancercell biology and help to further elucidate its molecular function. Finally the presented results imply the therapeutic potential of RNAi in the treatment of pancreatic cancer by targeting overexpressed genes like EMMPRIN.

Novel Signaling by Estrogen and Resveratrol to Modulate the Actin Cytoskeleton of Metastatic Breast Cancer Cells

N. G. Ariazi, L. A. Cologna, M. Cameron, S. F. Dharmawardhana; Anatomy and Cell Biology, Universidad Central del Caribe School of Medicine, San Juan, PR, 2Analytical Imaging Facility, Albert Einstein College of Medicine, Bronx, NY

Estrogen and structurally-related estrogen receptor modulators (SERM) play critical roles in breast cancer progression. Estrogen promotes breast cancer while resveratrol, an estrogen-like phytoestrogen from grapes, is considered to be a cancer preventative. Recent data have shown that in addition to signaling via nuclear receptors to promote gene transcription and cell proliferation, estrogen activates cell surface receptor networks that may impact cancer metastasis. However, not much is known about the role of estrogen and SERMs in cancer metastasis. Previously, we reported that in ER (+) breast cancer cell lines estrogen increased cell migration and lamellipodia formation while resveratrol (50 μM) decreased cell migration and induced a global and sustained filopodia response. The objective of this study was to elucidate the molecular mechanisms of estrogen and resveratrol signaling to the actin cytoskeleton. We demonstrate that in MDA-MB-231 breast cancer cells, filopodia formation by 50 μM resveratrol is time and concentration dependent and sustained up to 8 h. Resveratrol at 5 μM acts similar to estrogen by increasing lamellipodia, cell migration, and invasion. Since the Rho GTPases Cdc42 and Rac regulate actin reorganization, we investigated a role for Rac and Cdc42 in estrogen and resveratrol signaling in breast cancer cells. Resveratrol (50 μM) decreases Rac and Cdc42 activity while estrogen and 5 μM resveratrol increase Rac activity. MDA-MB-231 cells expressing dominant negative Cdc42 or dominant negative Rac retain the filopodia response to 50 μM resveratrol. Lamellipodia induced by 5 μM resveratrol or estrogen can be attenuated in cells expressing dominant negative Rac. We conclude that Rac regulates estrogen and resveratrol signaling to the actin cytoskeleton to modulate breast cancer cell migration/invasion and ultimately breast cancer metastasis. Moreover, this report contributes data to the suggestion that resveratrol has potential as a breast cancer metastasis treatment, but should be used with caution regarding concentration.

Novel Signaling by Estrogen and Resveratrol to Modulate the Actin Cytoskeleton of Metastatic Breast Cancer Cells

S. Ju, S. Park, J. An, S. Lee, T. Nguyen Quang, B. Kwon, S. Heo, B. Kim; Immunomodulation Research Center, University of Ulsan, Ulsan, Republic of Korea

Previously, we have reported that anti-4-1BB mAb treatment to melanoma-bearing mice enhances anti-tumor immunity due to CD8 T-cell expansion and increased IFN-γ production. In this study, we investigated the functional subpopulation of immune cells involved in 4-1BB-mediated anti-tumor activities. Pulmonary metastasis was established by intravenous injection of B16F10 melanoma cells to C57BL/6 mice. Anti-4-1BB mAb(3E1) were administered to mice on 2, 4 and 8 days post tumor injection. We found administration of 3E1 significantly increased the number of CD8+1CD11c- and NK1.1- cells with the suppression of metastatic colonies. Especially, we found marked expansion of CD11c+CD8+ cells by 3E1 treatment. Most of CD8+ T cells are IFN-γ+ and most of CD11c+ cells are CD11b+ cells. Most of CD11b+ cells are NK1.1+ cells.

Oxidative Stress-mediated Regulation of Ornithine Decarboxylase and Spermidine Spermine N-Acetyltransferase Expression in H-ras Transformed Fibroblasts

M. A. MacLean, R. A. R. Hurta; Biology, University of Prince Edward Island, Charlottetown, PE, Canada

Cellular growth regulation is multi-faceted. This present study demonstrates a unique link between oxidative stress-mediated cellular signaling and H-ras mediated cellular transformation and the expression of ornithine decarboxylase (ODC) and spermidine-spermine N-acetyltransferase (SSAT). ODC and SSAT are key rate limiting and regulatory enzymes involved in polyamine biosynthesis and catabolism, respectively. Altered polyamine metabolism in transformed cells is partly responsible for providing such cells with their increased rates of growth and division. This study examined the regulatory effects of hydrogen peroxide (H2O2)-induced oxidative stress on ODC and SSAT protein expression in NR3 cells, which are H-ras transformed, benign tumour-forming murine fibroblasts, and in the parental non-transformed 10T1/2 fibroblasts. Western blot analysis revealed that NR3 cells treated with H2O2 showed a dose and time dependent induction of both ODC and SSAT protein expression whereas ODC and SSAT protein expression levels were apparently unaffected by the same H2O2 treatment in 10T1/2 cells. The induction of ODC in NR3 cells appears to be mediated by both protein kinase C and mitogen-activated protein kinase mediated cellular signaling, whereas the H2O2-mediated induction of SSAT protein expression was mediated by phosphorylindinositol -3-kinase. This study further elucidates an aspect of the altered growth regulation and expression which occurs as a consequence of H-ras mediated cellular transformation. (NSERC funded)

Proteasome Inhibition Induces Nuclear IκBα Translocation, NFκB Inhibition, and Apoptosis in Prostate Cancer PC-3 Cells

H. T. Yu, C. Ghosh, S. Robinson, I. Vancurova; Biology, St. John's University, Queens, NY

Prostate cancer is the most common cancer in men. It proceeds from a localized, curable, androgen dependent disease to an invasive, metastatic, androgen-independent disease, for which there is no cure. The metastatic, androgen-independent prostate cancer is characterized by a constitutive activation of the transcription factor NFκB, which induces synthesis of pro-survival and pro-inflammatory genes that are associated with the prostate cancer. Thus, inhibition of NFκB activity represents an attractive anti-cancer approach. NFκB activity is regulated by a cytoplasmic inhibitor, IκBα. We have previously shown that NFκB activity can be inhibited by translocation of IκBα to the nucleus, and this is associated with an induction of apoptosis. We have searched for experimental treatment, or conditions, that would induce the nuclear translocation of IκBα in the metastatic prostate cancer PC-3 cells, thus inducing their apoptosis. Here we report for the first time that inhibitors of proteasome, known to induce apoptosis, induce the nuclear translocation of IκBα in prostate cancer PC-3 cells. This induced the accumulation of IκBα in time- and dose dependent, and is associated with the inhibition of NFκB activity, and increased apoptosis of PC-3 cells. A better understanding of the mechanisms by which IκBα translocates to the nucleus, in which the NFκB activity is inhibited, could lead to the development of novel anti-cancer therapies aimed at the selective inhibition of NFκB activity by the nuclear IκBα.
Polyphenolic Compounds Isolated from *Vaccinium macrocarpon* Affect Tumorigenesis in Breast and Colon Cell Lines

E. E. Correio,1 S. C. Rego,2 C. C. Neto,3 P. E. Hart;1 Medical Laboratory Science, UMass-Dartmouth, N. Dartmouth, MA;2 Biology, UMass-Dartmouth, N. Dartmouth, MA;3 Chemistry and Biochemistry, UMass-Dartmouth, N. Dartmouth, MA

The fruit of *Vaccinium macrocarpon*, cranberry, is very rich in polyphenolic compounds. These polyphenolic compounds have been suggested to have a variety of beneficial health effects. These studies explore the effect(s) of these polyphenolic compounds on the development of breast and colon tumor cell lines. Polyphenolic-rich extracts from cranberry fruit were isolated and fractionated by HPLC; total polyphenolic, proanthocyanidin-rich, flavanol-rich, anthocyanin-rich, and small polyphenolic-rich extracts as well as single compound fractions such as those containing ursoic acid were obtained. Bioassay incorporation assays indicate that breast (MCF-7) and colon (HCT-116 and HT-29) tumor cell lines treated with polyphenolics show decreased proliferation rates as compared to matched normal cell lines (MCF10A and FHIC) or untreated controls. A signifcant increase in apoptosis rates accompanies the decrease in proliferation rates in tumor cell lines as judged by a fluorescent TUNEL assay. Significant changes in apoptosis rates are not observed in normal cells or untreated controls. These studies indicate that polyphenolic compounds isolated from cranberry fruit have a tumor-cell-specific effect on apoptosis, and suggest that these compounds may have chemopreventive or chemotherapeutic potential.

Downregulation of Growth of Human Squamous Carcinoma Cells of the Head and Neck (SCCHN) by Overexpression of the Opioid Growth Factor Receptor (OGFr): In Vitro Studies

I. S. Zagon,1 M. F. Verderame,2 J. L. Hankins,1 P. J. McLaughlin;1 1Neural and Behavioral Sciences, Penn State University, Hershey, PA;2Medicine, Penn State University, Hershey, PA

The Opioid Growth Factor (OGF) is a constitutively expressed pentapeptide whose action as a negative growth regulator is mediated by the OGF receptor (OGFr). The OGF-OGFr axis tonically regulates growth of human squamous carcinoma cells of the head and neck (SCCHN) in vivo and in vitro. This study was designed to evaluate the repercussions on growth of amplification of OGFr signaling in SCCHN cell lines. Stable-transfected SCC-1 human SCCHN cell lines derived from a well-differentiated recurrent squamous cell carcinoma in the floor of the mouth were generated and characterized. OGFr binding assays revealed 2.4- to 8.4-fold increase in binding capacity compared to wild type (WT) and empty vector (EV) controls; binding affinity was comparable in all cell lines. OGFr protein expression assessed by immunohistochemistry and Western blotting was increased in clonal cell lines relative to controls. Under standard growth conditions, the cell number of OGFr clonal lines was reduced by 11% to 68% from the WT group, and doubling times were 7% to 67% longer. Addition of exogenous OGF further reduced (8% to 37%) cell growth of clonal lines. DNA synthesis of cells overexpressing OGFr was reduced from the WT group by 46% to 75%. Depletion of endogenous OGF with antibodies to this peptide increased growth 2-fold greater in clonal cells relative to increases of 32% and 34% for the WT and EV groups, respectively. These data show for the first time that molecular overexpression of the OGFr receptor decreases cell replication and DNA synthesis of SCCHN cells in tissue culture, indicating that OGFr is integral to cell replication. These results establish the fundamental principle that OGF and OGFr form an autocrine loop that regulates growth, and support treatment modalities using amplified OGF in order to decrease the growth of these neoplasias.

Overexpression of the Opioid Growth Factor Receptor (OGFr) Inhibits Growth of Human Squamous Cell Carcinoma of the Head and Neck (SCCHN) in Nude Mice

P. J. McLaughlin, S. M. Kreiner, C. R. Morgan, I. S. Zagon; Neural and Behavioral Sciences, Penn State University, Hershey, PA

The Opioid Growth Factor (OGF) is a constitutively expressed pentapeptide whose action as a negative growth regulator is mediated by the OGF receptor (OGFr). The OGF-OGFr axis tonically regulates growth of human squamous carcinoma cells of the head and neck (SCCHN) in vivo. Studies were designed to determine whether amplification of OGFr signaling in SCCHN may contribute to phenotypic changes, such as the loss of cell replication, which could be associated with malignant progression. Athymic mice were inoculated with 3 different cell lines amplified with OGFr (OGFr-9, OGFr-18, and OGFr-22). To evaluate a tumor burden response, each cell line, along with wildtype (WT) and empty vector (EV) was inoculated at 2 or 5 million cells/mouse. Tumor development and OGFr in tumors were monitored. Initial appearance of a measurable tumor was recorded when tumors were 62.5 mm3. WT and EV mice receiving 2 million cells had latency times of 10-11 days, while tumors generated from cells overexpressing OGFr appeared on days 13, 15, and 21 for the OGFr-9, OGFr-18, and OGFr-22 groups, respectively. WT and EV mice receiving 5 million cells had latency times of 8 days; latency to a measurable tumor was delayed up to 19 days (p<0.05) for the OGFr-9, OGFr-18, and OGFr-22 mice. Four weeks after cell inoculation tumors were collected and assessed for OGFr binding. Specific and saturable binding to radiolabeled OGF was detected, with significantly increased levels of OGFr in all clonal cell lines (2.5- to 3.7 fold greater) from WT and EV groups. Depletion of endogenous OGF with antibodies to this peptide increased growth 2-fold greater in clonal cells relative to increases of 32% and 34% for the WT and EV groups, respectively. These data show for the first time that molecular overexpression of the OGFr receptor decreases cell replication and DNA synthesis of SCCHN cells in tissue culture, indicating that OGFr is integral to cell replication. These results establish the fundamental principle that OGF and OGFr form an autocrine loop that regulates growth, and support treatment modalities using amplified OGF in order to decrease the growth of these neoplasias.

Overexpression of ARM Enhances Tumorigenesis in Malignant Melanoma

Y. Liao,1 S. Hsu,2 P. Huang1;1 Graduate Institute of Pathology, National Taiwan University, Taipei, Taiwan;2Department of Dermatology, National Taiwan University Hospital, Taipei, Taiwan

Tumorigenesis is often associated with reactivation of developmental programs. Transformed tumor cells may aberrantly re-express molecules that mediate proper embryonic development. ARM (ankyrin repeat-rich membrane spanning), also known as Kidins220 (kinase D-interacting substrate of 220kD), is a transmembrane protein expressed in the developing and adult neural tissues. Here, using immunohistochemical analysis, we report the significant expression of ARM in malignant melanoma (n=76), but not in benign nevi or other non-melanoma skin cancers such as basal cell carcinoma, and squamous cell carcinoma. The intensity of ARM immunoreactivity was positively correlated with Breslow tumor thickness (p<0.03). In contrast, compared with primary melanoma without metastasis, the expression level of ARM was significantly reduced in that with metastasis (P = 0.049). Two staining patterns of ARMs were revealed, the cytoplasmic granular pattern or membranous pattern, and the former was correlated with an increased hazard of poor prognosis (P = 0.06). To investigate the role of ARMs in the tumorigenesis of melanoma, stable B16-F0 cell clones with decreased expression of ARM were established by RNA interference. Knockdown of ARMs resulted in inhibition of cell proliferation, delayed anchorage-independent growth in soft agar, suppressed colony formation, and decreased tumor growth in SCID mice. Our study is the first to establish a link between overexpression of ARMs and melanoma metastasis.

Interactions of Tau with Alzheimer’s Disease Brain Microtubules and Other Neuronal Microtubules

S. C. Rego,1 C. C. Neto,2 P. E. Hart;1 1Medical Laboratory Science, UMass-Dartmouth, N. Dartmouth, MA;2Biology, UMass-Dartmouth, N. Dartmouth, MA

Tau is a microtubule-associated protein (MAP) expressed primarily in neurons. While it has been established that tau is expressed in other cell types, including prostate and breast carcinomas, its function in non-neuronal cells is unknown. We previously showed that tau interacts with the SH3 domain of Src family kinase members Fyn and Src, leading to tyrosine phosphorylation of tau, and it has also been demonstrated that tau binds to the prolyl isomerase Pin1. These interactions suggest that tau has functions independent of its microtubule-binding properties. Because prostate cancer cells are high in both Src and Pin1, and have been shown to contain tyrosine-phosphorylated tau, we set out to fully characterize the tau expressed in these cells. As detected by immunoblotting, tau expression is significantly higher in the cancerous prostate lines Du145, LNCaP, and PC3 than in non-cancerous prostate cells. It can be immunoprecipitated with anti-tau and is heat-stable like neuronal tau. All six alternatively spliced tau isoforms are transcribed in LNCaP cells, and RT-PCR results suggest that the 1N3R and 1N4R isoforms are the most prevalent. The less prevalent exons 4a and 6 are also present. LNCaP tau is phosphorylated at serine, threonine, and tyrosine sites, as detected by phospho-specific tau antibodies that also react with Alzheimer’s Disease brain. And while LNCaP tau is capable of binding microtubules, a significant proportion of it remains unbound, as detected by both confocal microscopy and microtubule binding assays with taxol-stabilized microtubules. In summary, tau from human prostate cancer cells has properties that are both similar and different from those of adult brain tau.

Overexpression of ARM Enhances Tumorigenesis in Malignant Melanoma

Y. Liao,1 S. Hsu,2 P. Huang1;1 Graduate Institute of Pathology, National Taiwan University, Taipei, Taiwan;2Department of Dermatology, National Taiwan University Hospital, Taipei, Taiwan

Tumorigenesis is often associated with reactivation of developmental programs. Transformed tumor cells may aberrantly re-express molecules that mediate proper embryonic development. ARM (ankyrin repeat-rich membrane spanning), also known as Kidins220 (kinase D-interacting substrate of 220kD), is a transmembrane protein expressed in the developing and adult neural tissues. Here, using immunohistochemical analysis, we report the significant expression of ARM in malignant melanoma (n=76), but not in benign nevi or other non-melanoma skin cancers such as basal cell carcinoma, and squamous cell carcinoma. Involvement of AMPK & P38 MAP Kinase in 8-CI-cAMP Induced Growth Inhibition

Y. Ahn, J. Han, K. Choi, J. Kim, S. Hong; Institute of Molecular Biology & Genetics, Seoul National University, Seoul, Republic of Korea.

8-CI-cAMP (8-chloro-cyclic AMP), which induces differentiation, growth inhibition and apoptosis in various cancer cells, has been investigated as a putative anti-cancer drug. Although we reported that 8-CI-cAMP induces growth inhibition via p38 MAP kinase (AMPK) and a metabolite of 8-CI-cAMP, 8-CI-adenosine mediates this process, the action mechanism of 8-CI-cAMP is still uncertain. Since 8-CI-cAMP is known to decrease the intracellular ATP pool, we tested if this ATP depletion could be related with the modulation of cellular growth. Intracellular ATP level decreased after the treatment with 8-CI-cAMP time-dependently, and excess addition of ATP could mitigate 8-CI-cAMP-induced growth inhibition. The reduction of ATP level resulted in the increase of AMP/ATP ratio, which could be the activating signal for AMP-activated protein kinase (AMPK). As expected, 8-CI-cAMP activated AMPK, which was also dependent on the metabolic degradation of 8-CI-cAMP. A potent agonist of AMPK, 5-aminoimidazole-4-carboxamide ribonucleoside (AICAR) could also induce growth inhibition and apoptosis.

Furthermore, AICAR was able to activate p38 MAPK and pre-treatment with AICAR inhibitor blocked this p38 MAPK activation. A p38 MAPK inhibitor attenuated 8-CI-cAMP- or AICAR-induced growth inhibition, but had no effect on AMPK activation. These results demonstrate that 8-CI-cAMP-induced growth inhibition is mediated by AMPK, and p38 MAPK works downstream of AMPK in this signaling pathway.

Activation of the ERK Signalling Pathway in Merlin-deficient Schwannoma

S. Amouei, C. O. Hanemann; Clinical Neurobiology, Peninsula Medical School, Plymouth, United Kingdom

Merlin is a tumour suppressor protein which belongs to the ERM (ezrin-moesin-radixin) protein family and acts as a membrane-cytoskeleton scaffolding protein. Merlin deficiency leads to the development of benign Schwann cell tumours, called schwannomas. Using our in vitro model of human primary Schwann and schwannoma cells, we have demonstrated a correlation between Merlin deficiency and specific tumour characteristics such as increased cell proliferation and decreased apoptosis. Moreover enhanced cell spreading and migration due to overexpression of integrins have been observed, suggesting a possible correlation between Merlin deficiency and integrin mediated downstream signalling. However, the molecular mechanism finally leading to schwannoma development has not yet between investigated. ERK activity has been shown to be involved in Schwann cell dedifferentiation and is known to play a role in tumour formation, thus we explored the ERK signalling pathway in more detail. Initially, our data demonstrate strong and long-lasting activation of MEK1/2 in schwannoma cells compared to normal Schwann cells. Moreover, MEK1/2, as well as Ras and B-Raf, both acting upstream of MEK1/2, was shown to be overexpressed in schwannoma cells. Additionally, preliminary investigations using inhibitors showed that MEK1/2 overexpression phenomena have suggested the involvement of MEK1/2 in schwannoma development.

Therefore we explored the ERK signalling pathway. Thus, we investigated the ERK signaling pathway in schwannoma model cells. However, our data showed strong and long-lasting activation of MEK1/2 in schwannoma cells compared to normal Schwann cells. Moreover, MEK1/2, as well as Ras and B-Raf, both acting upstream of MEK1/2, was shown to be overexpressed in schwannoma cells. Additionally, preliminary investigations using inhibitors showed that MEK1/2 overexpression phenomena have suggested the involvement of MEK1/2 in schwannoma development.

A Highly Invasive Variant of MDA-MB-231 Breast Carcinoma Cells Showed Increased Traction Forces and Higher Dynamics of Cytoskeletal Reorganization Compared to a Low Invasive Variant

C. T. Mierke, P. Kollmannsberger, D. Paramhao Zitterbart, C. Ranapach, W. H. Goldmann, B. Fabry; Medical Physics and Technology, University of Erlangen-Nuremberg, Erlangen, Germany

Cancer cells have different capacities to metastasize, thus it is important to understand the signaling pathways that govern these capacities. We tested the hypothesis that invasive tumor cells have nanomechanical properties that allow them to reorganize their shape, cytoskeleton and focal contacts more rapidly and to generate higher tractions than non-invasive cells. We isolated a highly invasive variant of MDA-MB-231 breast carcinoma cells (called BC-1) and a low-invasive variant (called BC-2). To measure the invasiveness of BC-1 and BC-2, we cultured them on a 3D collagen gel. The density of tumor cells that invaded after 3 days into the gel multiplied by their average invasion-depth was taken as an index of invasiveness. BC-1 cells were found to be more invasive (1.86±0.10 mm⁻¹) than BC-2 cells (3.59±0.15 mm⁻¹). The cytoskeletal dynamics were measured using magnetic tweezers and nanoscale particle tracking. For microrheology measurements, step forces from 1 - 10 nN were applied to fibronectin-coated beads bound to the cytoskeleton of adherent tumor cells. The bead displacement in response to the applied force followed a power-law, where the exponent is a measure of cytoskeletal dynamics, with low values corresponding to a solid-like, static behavior, and high values corresponding to a more liquid-like, dynamic behavior. BC-1 cells had a higher exponent (0.43±0.019) than BC-2 cells (0.33±0.002). The diffusion of fibronectin-coated beads bound to BC-1 and BC-2 was measured. Bead diffusion also followed a power-law, where BC-1 cells showed a higher superdiffusive behavior (b = 1.58) than BC-2 (b = 1.44). The 2D tractions measured during cell adhesion to collagen-coated polyacrylamide gel showed that BC-1 cells generate a higher 2D traction (0.46 pN) than BC-2 cells (0.06 pN). The cytoskeletal dynamics and traction generation both correlate with tumor cell invasiveness. Nanomechanical measurements do help in determining the invasion potential of tumor cells and also the potential of a tumor mass to metastasize.

Calcium Sensing Receptor Function in Human Colon Carcinoma

S. Chakrabarty, G. Liu, X. Hu, J. Varani; SimmonsCooper Cancer Institute, Southern Illinois University, Springfield, IL

Calcium is a versatile second messenger that has been implicated in cancer progression and metastasis. The calcium-sensing receptor (CaSR) is a G-protein coupled receptor that is expressed in various cell types, including cancer cells. The function of CaSR in cancer cells is still not well-understood. We investigated the role of CaSR in human colon carcinoma cells.

The CaSR is a G-protein coupled receptor that is expressed in various cell types, including cancer cells. The function of CaSR in cancer cells is still not well-understood. We investigated the role of CaSR in human colon carcinoma cells.

representing a previously undescribed genetic programme which likely contributes to mesangial cell dysfunction in DN. When HMCs were stimulated with CTGF and stained for tubulin and β-actin, widespread microtubular and actin rearrangement was apparent. This was accompanied by a polarized redistribution of myosin, suggesting activation of the machinery of cell migration. Redistribution of myosin was facilitated by phosphorylation of the myosin light chain in response to CTGF, which was inhibited by the addition of the myosin inhibitor 2.3 butanediolmonoxime. Increased levels of AR3P in response to treatment with CTGF were mediated via cdc42 dependent activation of PAK-1, which was inhibited by the addition of the RhodGTPase inhibitor, Toxin B. This data indicates that CTGF-mediated actin rearrangement may contribute to the pathophysiology of the glomerular mesangium in diabetic nephropathy.

673 Cholesterol Accumulation Impairs Endocytosis in Fibroblasts from Patients with Genetic Lysosomal Lipid Storage Disorders
C. Garracho,1 V. Muzikantov,2 E. Schuchman,2 S. Maro,2 1Institute for Environmental Medicine, University of Pennsylvania Medical School, Philadelphia, PA; 2Human Gentoics, Mount Sinai School of Medicine, New York, NY

The mechanisms by which accumulation of undegraded metabolites in genetic lysosomal storage disorders (LSDs) leads to cell dysfunction are incompletely understood. We evaluated the effects of intracellular lipid storage on endocytic pathways in skin fibroblasts from Fabry, Gaucher, type B and Niemann-Pick (NPB and NPC) patients, characterized by deficiency of α-galactosidase-A, glucocerebrosidase, acid sphingomyelinase, and NPC1 transporter. We monitored the rate of BODIPY-FITC-labeled LDL internalization by flow cytometry, the rate of LDL degradation by measuring free cholesterol content, and the rate of caveolae-mediated endocytosis by measuring the rate of cholera toxin binding sites. Cells from LSD patients had significantly decreased rates of endocytosis and LDL degradation compared to normal controls. These results suggest that LSDs may impair endocytosis and lipid metabolism, which may contribute to the pathogenesis of LSDs.

675 Chol Ergonic Acid Attenuates Adhesion Molecules Upregulation in IL-1β-Treated HUVECs
Y. Yu,1 C. Chen,2 W. Chang1; 1Nutrition, China Medical University, Taichung, Taiwan

Reactive oxygen species (ROS) are known to induce endothelial cell (EC) apoptosis and vascular smooth muscle cell (VSMC) proliferation. It has demonstrated that hyperlipidemia may impact vascular function through increased oxidative stress and synthesized ROS endogenously by inhibiting electron transport chain of mitochondria in vascular cell. Recent study has observed that exercise training may initiate adaptations to reduce oxidative sources or up regulate antioxidative enzymes. We subjected 4–6 month-old male Zucker rats to an 8-weeks chronic exercise training program on a motorized treadmill. A total of 12 obese rats were randomly divided into two groups, i.e sedentary group and exercise-trained group. All rats were sacrificed at 48 h after the end of their last training session to minimize acute exercise effects from the last training bout. Immunoblot analysis of harvested vessels showed that lower expression of caspase 3 and ERK1/2 in obese exercised group was found compared with obese sedentary group. However superoxide dismutase (SOD) and catalase were significantly expression in both obese and lean exercised group. The results of immunohistochemistry showed that caspase 3 and ERK1/2 were highly expressed on EC and VSMC in obese sedentary group. Similarly, this phenomenon could be reversed after exercise training. It was very interesting that Cu/ZnSOD and MnSOD mRNA level has no significant change from each group. The mRNA level of glutathione peroxidase was significantly elevated but catalase mRNA level was lowered instead. In conclusion, exercise training played a role in vascular protection by up regulating antioxidative protein expression and decreasing caspase 3 and ERK1/2 protein production in obese Zucker rats.

676 Cell-based Screening for Inhibitors of PYK2 Kinase Activity
A. P. Baumgart,1 T. C. Bonnett,1 D. T. Crawford,2 H. Li1; 1Wellcome Trust Sanger Institute, Hinxton, Cambridge, United Kingdom

Proline-rich tyrosine kinase 2 (PYK2), a member of the Focal Adhesion Kinase (FAK) family, is involved in many cellular processes including adhesion, cell spreading, migration, and apoptosis. PYK2 is activated in response to mechanical stimulation, calcium flux, integrin signaling and chemokines. In addition to having kinase activity, PYK2 forms complexes with other cytoskeletal proteins such as paxillin, cortactin, and src therefore may have both scaffolding and signaling functions. Since PYK2 knockout mice display increased bone compared with wild type littermates in vivo, PYK2 is a potential target for therapeutic intervention in diseases of bone metabolism. In vitro assays to monitor PYK2 activity have been developed, but monitoring the kinase activity in cells has been challenging because endogenous expression levels are generally low and no specific substrate has been identified. A phosphorylation event on tyrosine 402 of PYK2 is required for activation of this kinase and we chose to use this event to monitor the effect of inhibitors in cells. The work presented here describes a 384 well cell-based assay for Y402 phosphorylation that has been developed using L1-COR technology. PYK2 is indirectly overexpressed using the GeneSwitch system in NIH 3T3 cells, and after treatment with test compounds, the cells are fixed in situ and immunostained for PYK2 (phospho-Y402). A detection system using near-infrared (IR) dyes (800nm) affords stability, sensitivity, and elimination of interference from the autofluorescence typically found in many library compounds. A panel of compounds was tested and the IC50 data correlated with in vitro kinase activity. This medium-throughput assay is robust, reproducible, and has proven to be valuable in identifying cell active compounds that may warrant further investigation. This approach will not only assist in identifying cell-active inhibitors, but the principle should be applicable to a variety of kinase targets.

677 Developmental Expression of VPS33B Correlates with Human Phenotype of VPS33B Mutations
P. Gissin,1 D. Gleeson,2 A. Straatman-Iwanowska,1 D. Tannahill,2 E. Maher1; 1Section of Medical and Molecular Genetics, University of Birmingham, Birmingham, United Kingdom; 2The Wellcome Trust Sanger Institute, Hinxton, Cambridge, United Kingdom

Background: VPS33B is a human homologue of yeast Vps33p protein and is part of the homotypic fusion and protein sorting (HOPS) complex. HOPS complex proteins are involved in tethering of endosomes to the target membranes on late endosomes and lysosomes prior to SNARE-complex formation and membrane fusion but their mode of action is not clear. Previously we demonstrated that germline VPS33B mutations cause the Arthrogryposis, Renal Dysfunction and Cholestatosis (ARC) syndrome. To further elucidate the pathology of ARC syndrome we have investigated developmental expression of VPS33B. Methods We sequenced exons and exon-intron boundaries of VPS33B. Expression of VPS33B in developing mouse embryos was studied by in situ hybridization. Expression of VPS33B in human cells and fibroblasts was studied using rabbit polyclonal anti-VPS33B antibody. Results Germline VPS33B mutations were identified in 53 probands. In addition to the well characterised features of ARC syndrome, intracranial abnormalities were present in ~15% of cases. All patients exhibited severe degree of failure to thrive unexplained by liver or kidney disease. The expression pattern of the VPS33B in mouse embryonic tissues correlated well with the abnormalities in cerebral development and also renal tubular system. At E10.5 VPS33B expression can be detected weakly in neural tissue including the developing neural tube and the dorsal root ganglia. By E12.5, expression...
continues in these sites and expression in cranial ganglia and the gut becomes apparent. Expression in the kidney also becomes evident by E14.5. There was evidence of expression of VPS33B in human fibroblasts and also CaCo2 cells. Summary Embryonic expression of VPS33B in neural tissue correlates with the neurodevelopmental abnormalities found in ARC syndrome and is consistent with genetic origin for arthrogryposis. VPS33B deficiency causing gastrointestinal dysfunction may be associated with the severe failure to thrive seen in ARC syndrome.

678 Role of Protein 4.1R in Calcium Absorption in the Small Intestine: Defective Calcium Homeostasis in 4.1R-Null Mice
X. An, C. Liu, G. Debmah, N. Mohandas; Red Cell Physiology Laboratory, The New York Blood Center, New York, NY

Protein 4.1R (4.1R) was initially identified as a major component of erythrocyte membrane skeleton and plays a key role in maintaining erythrocyte morphology and membrane mechanical stability. 4.1R is abundantly expressed in various cells including epithelial cells, but the function of 4.1R in these cells is far from clear. In the present study, we used 4.1R null mice to explore the function of 4.1R in small intestine. We show that 4.1R is expressed at the apical domain of enterocytes. Importantly, small intestine of 4.1R null mice displayed morphological abnormalities. Importantly, in vivo calcium absorption assay demonstrated a significantly diminished calcium absorption in the small intestine of 4.1R null mice compared to that of wild type. In addition, 4.1R null mice displayed hyperplasia of parathyroid, increased parathyroid hormone levels, elevated serum 1, 25 (O H) 2 D levels, osteoporosis and decreased calcium content of bone. These findings imply that loss of 4.1R from enterocytes of small intestine impairs the calcium absorption which in turn leads to defective calcium homeostasis in 4.1R null mice.

679 The Mammalian Glucose Transporter Protein GLUT12 - Subcellular Localization in Response to Insulin and Glucose
S. D. Rogers, C. L. DelHaan; Medicine St Vincent's, The University of Melbourne, Melbourne, Australia

GLUT12 is expressed in insulin-sensitive tissues and possesses potential intracellular targeting motifs. We predicted that GLUT12, like GLUT4, translocates in response to insulin. In normal individuals, glucose homeostasis is maintained by insulin-stimulated transport of glucose into muscle and fat. In Type 2 diabetics, this homeostasis is compromised by the cellular loss of insulin-responsiveness, resulting in hyperglycemia. Glucose itself can also stimulate glucose transport. Although not well understood, this process is important in Type 2 diabetics where insulin action is impaired. We further hypothesized that GLUT12 responds to elevated glucose. We engineered fluorescent fusion proteins and exo-facially epitope-tagged constructs. GLUT12 trafficking was studied using retroviral expression, confocal microscopy and immunofluorescence. In glucose and insulin-starved CHO cells, GLUT12 was restricted to a perinuclear position. After exposure (ten minutes) to insulin (1mU) or high (25mM) glucose, GLUT12 translocated to the cell surface. GLUT12 co-localized in part with GLUT4. We initially identified GLUT12 in MCF7 breast cancer cells. Elevated glucose transport and metabolism are characteristics of cancer cells and we have demonstrated GLUT12 expression in human breast cancer but not in normal breast epithelial. In MCF7 cells, GLUT12 was localized to a perinuclear position. Translocation to the cell surface would be necessary for GLUT12 to contribute to cellular glucose uptake. Using confocal immunofluorescence, we have now demonstrated that in glucose and insulin-starved MCF7 cells, GLUT12 was localized to a perinuclear region and detected at the cell surface following exposure to insulin or high glucose. GLUT12 trafficking from intracellular compartments to the cell surface is important in the physiology or pathophysiology of glucose homeostasis and may also be important for glucose transport into and growth of tumor cells. Epidemiological data indicates increased cancer risk in Type 2 diabetics. Our results may provide a novel mechanistic link between diabetes and breast cancer.

680 Curcumin Attenuates Dystrophic Pathology in mdx Mice through Inhibiting NF-κB Activation
M. S. Zhu, C. Chen, Y. L. Hu, S. Chen; Model Animal Research Laboratory and State Key Lab of Pharmaceutical Biotechnology, Nanjing University, Nanjing, China, 2Center of Antibody Research, Nanjing ChuanBao Biotech Co., Ltd. Nanjing, Nanjing, China

The dystrophin-glycoprotein complex has emerged as a scaffold responsible for the membrane docking of signaling proteins. There is no definitive cure available currently. In dystrophin-deficient muscular dystrophy, abnormal activation of signal pathways may play important roles in dystrophic pathogenesis. In this report, we found a natural botanical gradient, curcumin, capable of attenuating dystrophic pathology significantly and the mechanism underlying was involved in NF-κB inhibition. After treating X-linked muscular dystrophy (mdx) mice with 1 to 10 mg of curcumin, the sarcomere integrity assessed by Evans blue staining and muscle strength determined both by grip strength test and traction test were improved significantly. Histological analysis demonstrated that curcumin reduced severity of myofibril necrosis and extent of regenerating fibers as well as the variability in size of fibers. Creatine kinase level and the expressions of tumor necrosis factor alpha, interleukin-1 beta and inducible nitric oxide synthase were decreased also after curcumin treatment. Consistently, elevated NF-κB activity in muscle fibers of mdx mice decreased after curcumin administration. Since curcumin is a non-toxic compound derived from C. longa, which was widely used in healthy food. The possible effect of curcumin may be worth studying in Duchenne muscular dystrophy therapy.

681 The Role of STAT1/IRF-1 on Hepatic Liver Injury Induced by LPS/D-galactosamine
H. Lee, Y. Oh, S. Lee, Y. Kwon, S. Park, W. Kim; 1Biomedical Sciences, Korea National Institutes of Health, Seoul, Republic of Korea, 2Gyn. Oncology, Hallym Sacred Heart Hospital, Seoul, Republic of Korea

We previously demonstrated that STAT1 play an essential role in a variety of liver injury models induced by administration of LPS/D-galactosamine (D-GaIN), however, the underlying mechanism involved is not clear. Here, we show that cotreatment with TNF-α and IFN-γ secreted by the administration of LPS/D-GaIN induced synergistically induced apoptosis in primary hepatocytes and HepG2 cells, associating with NO production and inducible nitric oxide synthase expression (NO/iNOS) and elevated ROS production, which are inhibited strongly by antioxidant NAC or L-NMMA, an iNOS/NO inhibitor. Although activation and expression of STAT1 did not change strongly in TNF-α/IFN-γ-treated cells compared with IFN-γ alone-treated cells, disruption of the STAT1 gene or IRF-1 gene via genetic knock-out strongly abrogated the synergism of TNF-α/IFN-γ on iNOS/NO induction, ROS production, loss of ∆Ψm, and apoptosis observed in STAT1+/+ and IRF-1+/+ mice. In contrast to wild type STAT1 overexpression, the synergistic effects of TNF-α/IFN-γ on iNOS/NO induction, ROS production, and apoptosis were significantly inhibited by overexpression of dominant negative STAT1. Furthermore, NF-κB activated by TNF-α/IFN-γ was attenuated in STAT1 deficient mice and strongly inhibited by NAC or L-NMMA, while a proteasome inhibitor MG132, which inhibited NF-κB activation, strongly inhibited iNOS/NO induction, ROS production, and loss of ∆Ψm by TNF-α/IFN-γ, results in the inhibition of apoptosis. Collectively, these findings demonstrated that TNF-α/IFN-γ synergistically potentiates iNOS/NO induction, ROS production and loss of ∆Ψm via STAT1 overexpression, playing an important role in promoting apoptosis and liver injury induced by LPS/D-GaIN.

682 Critical Roles of ATP3 on Streptozotocin-induced Diabetic Liver Injury in Mouse: ATP3 Mediates STAT1 Overexpression
S. Lee, H. Lee, Y. Oh, J. Mo, Y. Kwon, S. Park, W. Kim; 1Biomedical Sciences, Korea National Institutes of Health, Seoul, Republic of Korea, 2Gyn. Oncology, Hallym Sacred Heart Hospital, Seoul, Republic of Korea

It is well established that the administration of streptozotocin (STZ) accelerates liver injury as well as type 1 diabetes, however the underlying mechanisms is not fully understood. Here, we demonstrate that STZ causes severe liver damage as evidenced by a significant elevation of serum ALT levels, and massive necrosis, which is followed the increase of IFN-γ. Also, STAT1, which is implicated in hepatitis liver injury by virtue of its ability to promote hepatocytes apoptosis, rapidly activated and its stability is sustained for long times, correlated with the induction of ATP3, a stress-inducible gene, and several apoptotic-related proteins in STZ-injected mice. STAT1 overexpression is critically dependent upon ATP3 induced by STZ or IFN-γ treatment in primary hepatocytes because ATP3 depletion significantly decreased STAT1 overexpression, ROS production and hepatic apoptosis induced. Interestingly, ATP3 not only enhances the promoter activity of STAT1 but also interacts directly with STAT1, which is enhanced following IFN-γ treatment. Removal of the putative ATP3 binding site in STAT1 promoter inhibits the enhancement of ATP3 on transcription activity of these genes. Collectively, our results suggest that ATP3 functions as a potent regulator of STAT1 gene expression and it stability, which is highly induced the liver injury via promoting apoptosis.

683 N-Acetylaminothiosemicarbazone Treatment Rescues a Mouse Model of Hereditary Inclusion Body Myopathy
M. Huizing, R. Klootwijk, B. Galeano, I. Manoli, M. Sun, C. Ciccone, D. Darvish, D. Krasnewich, W. Gahl; 1NHGRI, NIH, Bethesda, MD, 2HIBM Research Group, Encino, CA
Hereditary Inclusion Body Myopathy (HIBM) is an adult onset recessive neuromuscular disorder of slowly progressive distal and proximal muscleatrophy and weakness. This myopathy is caused by deficiency of UDP-GlcNAc 2-epimerase/MannNac kinase (GNE), the rate-limiting, bifunctional enzyme catalyzing the first two committed steps of sialic acid biosynthesis. Decreased GNE activity impairs sialic acid production and interacts with syndromes of muscle glycoproteins such as α2-dystroglycan. Levels of polysialic acid on neural cell adhesion molecule (PSA-NCAM) may also be affected. To study the pathogenesis and treatment of HIBM, we created a GNE knock-in mouse mimicking the human M712T GNE mutation. Homozygous (+/-) mutant mice were born in a Mendelian distribution, but did not survive beyond postnatal day 3 (P3). GNE enzyme activity in skeletal muscle tissues of +/- mice at age P2 was 20% of normal. However, histological examination did not reveal any muscle pathology. Rather, the kidneys of +/- mice showed petechial hemorrhages, proteinsuria, and signs of glomerular disease. As a treatment option, we administered to pregnant females ManNac (1g/kg/d), an uncharged sugar intermediate located within the sialic acid pathway. Upon feeding +/- matings ManNac in their drinking water, 43% of the +/- pups survived beyond P3. At P2, +/- mice that received ManNac had less severe kidney hemorrhages, and their muscle GNE activities increased to 50% of normal mouse levels, suggesting that ManNac might stabilize the mutant enzyme. Surviving +/- mice were smaller than their littermates, but appeared healthy otherwise, even after weaning (P21), when they no longer received ManNac. It remains to be determined if the surviving +/- mice will develop a muscular pathology later in life. Taken together, survival of +/- mice, improved kidney pathology and increased GNE activity after ManNac administration strongly support consideration of a clinical trial of ManNac for the myopathy of HIBM.

684 Norrin Mediated TCF Signal Is Differentially Modulated by LRP5 and LRP5-G171V (HBM) Mutant in Response to Dkk1 and Kremen2
B. M. Bhat,1 H. Lam,1 V. Colebourn,1 P. Yavorsky,1 F. Bex,1 Women's Health and Musculoskeletal Biology, Wyeth Research, Collegeville, PA, 2Biological Technologies, Wyeth Research, Cambridge, MA
Mutations in Norrin lead to Norrie disease pseudoglioma (NDP) and X-linked Familial Exudative Vitreoretinopathy (FEVR), characterized by failure in retinal vascularization that results in blindness. FEVR can also be caused by mutations in either Frizzled4 (Fzd4) or its co-receptor LRP5/6, which are involved in Wnt β-catenin-TCF signaling. Recent reports indicate that Norrin is a ligand for LRP5-Fzd4 specific complex. Like Wnts, Norrin is a cysteine rich secreted protein, that remains associated at the cell surface and induces the β-catenin pathway. However, Norrin has no significant homology to Wnts. Mutations in the first β-propeller of LRP5 (e.g. LRP5-G171V) are associated with a high bone mass (HBM) phenotype. The HBM mutations attenuate inhibition of Wnt/β-catenin signal by the antagonist Dkk1 and its co-receptor Kremen2. To determine whether the signal induced by Norrin would, like Wnts, be affected by the HBM mutations and the functions of Dkk1 or Kremen2, we investigated their interaction in bone (U2OS) and non-bone (HEK293A) cells. Transfection of Norrin cDNA resulted in an enhanced β-catenin pathway TCF-signal in U2OS but not in HEK293A cells. However, co-transfection of Frizzled4 with Norrin into 293A cells activated the TCF signal indicating that endogenous functional Frizzled4 was lacking in HEK293 cells. This demonstrates how Norrin mediated TCF-signal can be regulated by cell type dependent Frizzled expression. Surviving +/- mice were smaller than their littermates, but appeared healthy otherwise, even after weaning (P21), when they no longer received ManNac. It remains to be determined if the surviving +/- mice will develop a muscular pathology later in life. Taken together, survival of +/- mice, improved kidney pathology and increased GNE activity after ManNac administration strongly support consideration of a clinical trial of ManNac for the myopathy of HIBM.

685 Mitotic Spindle Assembly and Function
R. Heald; Department of Molecular & Cell Biology, University of California, Berkeley, Berkeley, CA
A key event in mitosis is segregation of the duplicated chromosomes into two complete sets, one for each daughter cell. This task is performed by the mitotic spindle, a complex and dynamic machine consisting of microtubules and numerous other factors. Spindle formation relies on intricate spatial and temporal control of microtubule polymerization, and coordinated organization by motor proteins to generate a bipolar spindle array. While spindles are fundamentally the same in all eukaryotic cells, the mechanisms for assembling them may vary depending on the cell type. In most somatic cells microtubule organization is strongly influenced by centrosomes. The centrosome duplicates prior to the onset of mitosis, generating two foci that nucleate microtubules, which then interact with chromosomes through a ‘search and capture’ mechanism. Mitotic chromosomes play an active role in spindle assembly by forming attachments at their kinetochores that facilitate their metaphase alignment and subsequent segregation during anaphase. In addition, mitotic chromosomes generate biochemical signals to promote spindle assembly. This mechanism is most apparent and essential in systems such as female meiotic cells that lack focal centrosomes, but increasing evidence suggests that this is a conserved process operating in many cell types. Meiotic X. novius egg extracts provide a useful system to study this phenomenon, as chromatin itself, in the form of plasmid-DNA coated beads, is sufficient to induce spindle assembly in the absence of centrosomes and kinetochores. In this pathway microtubules are nucleated and stabilized around chromosomes, and subsequently ‘self-organize’ to form a mitotic spindle in the absence of paired microtubule nucleating sites. We are investigating the molecular components of centromere-driven spindle assembly pathways, and using fluorescence-based imaging techniques to visualize mitotic gradients in different cell types.

686 Mining the Genome for Mitotic Treasures
R. D. Yala,1 G. Goshima,2 E. Griffis,3 R. Wollman,4 J. Schol ey,5 N. Sturman; 1Department of Cellular and Molecular Pharmacology, HHMI, University of California, San Francisco, San Francisco, CA, 2Section of Molecular and Cellular Biology, University of California, Davis, Davis, CA
The formation of the microtubule-based mitotic spindle is essential for chromosome segregation in eukaryotes. Many of the molecules involved in forming the spindle and regulating the sequence of events in cell division are known. However, the inventory of proteins that participate in mitosis is undoubtedly incomplete. We have used whole genome RNAi screens to search for genes that play important roles in mitosis in Drosophila S2 cells. Using a high throughput microscope to collect images of mitotic spindles and a combination of manual and computational approaches to analyze these images, we have identified ~250 genes that play important roles in generating microtubules, localizing γ-tubulin, controlling spindle length or shape, aligning chromosomes at the metaphase plate, and regulating the spindle assembly checkpoint. To learn more about the functions of novel proteins identified by the screen, we have used GFP tagging to determine their localizations and dynamics and used RNAi strategies to examine the order of assembly of components at centrosomes and kinetochores. These studies provide a comprehensive view of the proteins that contribute to spindle architecture and function and suggest potential new targets for cancer chemotherapy.

687 Dynamics of Bacterial Chromosome Organization, Segregation, and Cytokinesis
L. Shapiro; Department of Developmental Biology, Stanford University School of Medicine, Stanford, CA
Many regular proteins and multiprotein complexes involved in the execution of the Caulobacter cell cycle, and chromosome replication and segregation must perform their functions at a specific place in the cell and at a specific time in the cell cycle. By fluorescently tagging 114 individual chromosomal loci and examining the position of each locus in the cell, we showed that in living cells prior to DNA replication, the loci are arranged in a linear order along the long axis of the cell, reflecting the order of genes on the circular chromosome. We further showed that upon initiation of DNA replication, one copy of the origin of replication is rapidly moved to the opposite pole of the cell and as each locus is replicated, in turn, its' copy moves to the new position in the incipient daughter half of the cell. Thus, replication and segregation are simultaneous processes independent of cell growth. We have identified a protein, MipZ, that functions to coordinate origin movement to the opposite cell pole with the placement of the tubulin FtsZ ring at the mid-cell. MipZ binds to ParB at the origin and moves with the duplicated origin to the opposite pole. A gradient of MipZ across the cell has its highest concentration at the cell poles and lowest at mid-cell. MipZ inhibits FtsZ polymerization; thus the cell division ring forms only at mid-cell, the cellular position of lowest MipZ concentration. Differential rate of growth of the two daughter cell compartments then leads to an asymmetrically placed division plane. Thus, bacterial ‘mitosis’ is an integral component cell cycle spatial and temporal regulation.

688 Bringing Research into the Undergraduate Curriculum
S. C. R. Elgin,1 C. Shaffer,2 W. Leung,3 J. Buhler,4 E. Mardis,3 D. Lopatto,4; 1Department of Biology, Washington University, St. Louis, MO, 2Department of Computer Science & Engineering, Washington University, St. Louis, MO, 3Department of Genetics, Washington University, St. Louis, MO, 4Department of Psychology, Grinnell College, Grinnell, IA
Undergraduate research experiences are a critical part of our biology curriculum, enabling students to understand how new knowledge is generated in their field. Undergraduate students often enter research through an individual apprenticeship during the summer. This has been found to generate a spectrum of intellectual and social gains, including greater understanding of the research process and the strategies and tools that scientists use to work on real problems (SURE survey data; D. Lopatto, 2004, Cell Biol. Educ. 3: 270). An alternative to summer research is a one semester, upper-level laboratory course built around a research problem. Bio 4342, Research Explorations in Genomics, is taught by collaborating faculty at Washington University from Biology, Computer Science, and the WU Genome Sequencing Center (see http://www.mlsc.wustl.edu/elgin/genomics). Students in Bio 4342 join a research team working on sequencing and
689 Epigenetic Regulation of X Chromosome Gene Expression in Germ Cells of C. elegans
S. Strome,1, L. B. Bender,1 C. R. Carroll,1 V. Reinke,2 J. Suh1, 1Department of Biology, Indiana University, Bloomington, IN, 2Department of Genetics, Yale University School of Medicine, New Haven, CT

Modulation of the way in which DNA is organized into chromatin has emerged as a key level of regulation of gene expression during development and in diseased states. One mechanism of chromatin modulation is condensation of histones. We are studying one example of such "epigenetic" regulation in the C. elegans germ line. Development of germ cells in worms requires that the X chromosomes be globally silenced; this is achieved at least in part by regulation of histone marks on the Xs. We have identified a system of "MES" protein regulators that dictate the different chromatin states of the autosomes vs. the X chromosomes and are required for germ cell viability. MES-2, MES-3, and MES-6 form a trimERIC complex (related to the ESC/EZJ complex in fruit flies and mammals) that participates in X silencing by concentrating a repressive histone modification, methylation of Lys27 on histone H3, on the Xs. MES-4 (related to NSD1 in mammals) also methylates histone H3 tails but at a different residue, Lys36. MES-6 and its methyl mark are dramatically concentrated on the 5 autosomes and are absent from most of the length of the X chromosome. Exclusion of MES-4 from the X requires MES-2/MES-3/MES-6 function. Intriguingly, the main effect on gene expression patterns of removing MES-4 function is desilencing of genes on the X. We hypothesize that MES-4 or H3 methylated on Lys36 repels a repressor from the autosomes, focusing its binding or action on the X. The MES system illustrates how chromatin modifiers can work in concert to achieve whole-chromosome regulation, and it focuses our attention on the distinction between the autosomes and X chromosomes.

690 Local Cell-Cell Interactions in Shoot Apical Meristems Yield Global Patterns of Development
M. Hesler, H. Jönsson, E. Mjönes, E. M. Meyenbauer, Division of Biology, California Institute of Technology, Pasadena, CA, Department of Theoretical Physics, University of Lund, Lund, Sweden, Department of Computer Science and Engineering, University of California, Irvine, Irvine, CA

The shoot apical meristems (SAMs) of a flowering plant are the sets of stem cells at the tip of each shoot, which ultimately provide the cells that make the stem, leaves, and flowers. A long-standing question in developmental biology is how permanent populations of stem cells are maintained, another question is how the cells, which are apparently unpatterned and undifferentiated, give patterns of differentiated offspring. One prominent example in plants is the pattern of phyllotaxis, the pattern (usually spiral) in which leaves and flowers appear around the shoot. We have developed a new set of live imaging methods for the Arabidopsis thaliana shoot apical meristem, and a set of reporters for gene expression domains, and protein localization within cells of the SAM. Using live imaging and the reporter constructs we and others have found that the SAM has a private and highly controlled circulatory system for the plant hormone auxin, which serves as the morphogen that induces new floral primordia. This circulatory system is based on movement within each SAM cell of a polar auxin transporter, and leads to successive peaks of auxin concentration in a precise pattern that is the spiral phyllotactic pattern. A private and active circulatory system for a morphogen may represent a new principle of development, and also raises a number of questions about the mechanism of control of the intracellular location of the transporter.

691 Wnt and Notch Cooperate to Maintain Proliferative Compartmental compartments in Crypts and Intestinal Neoplasia
H. Clevers, Hubrecht Laboratory, Netherlands Institute for Developmental Biology of the Royal Netherlands Academy of Arts and Sciences, Utrecht, The Netherlands

Mutations in the Wnt pathway components APC, beta-catenin and conductin all induce sustained complex formation of the co-activator beta-catenin with Wnt transcription factors. The resulting transactivation of Wnt target genes is believed to be the primary transforming event in colorectal cancer (CRC). Yet, the consequence of the presence of mutationally activated beta-catenin/Wnt in fully transformed CRC cells is unknown. We have constructed CRC cell lines carrying inducible dominant-negative Wnt constructs. Inhibition of beta-catenin/Wnt resulted in a rapid G1 arrest. DNA array analysis revealed the downregulation of a small set of transcripts. These genes were expressed in polyps, but also, physiologically, in the crypt progenitor compartments of the colon. By contrast, we observed the induction of multiple marker genes of intestinal differentiation upon inhibiting beta-catenin/Wnt in CRC cells. We conclude that beta-catenin/Wnt inhibits differentiation and imposes a crypt progenitor phenotype on CRC cells. Moreover, inhibition of beta-catenin/Wnt activity restores the differentiation program, despite the presence of multiple other mutations in CRC. Wnt target gene expression is always restricted to the crypt, but target genes can be sub-classified based on expression patterns within the crypt. We have tentatively identified at least three target genes which are expressed uniquely in the crypt stem cells. The Wnt cascade is not the only signaling pathway controlling cell fate along the crypt-villus axis. Upon conditional removal of the common Notch pathway transcription factor CSL/RBP-J2, we observe a rapid, massive conversion of proliferative crypt cells into post-mitotic goblet cells. A similar phenotype was obtained by blocking the Notch cascade using a gamma-secretase inhibitor. The inhibitor also induced goblet cell differentiation in intestinal undifferentiated, give patterns of differentiated offspring. One prominent example in plants is the pattern of phyllotaxis, the pattern (usually spiral) in which leaves and flowers appear around the shoot. We have developed a new set of live imaging methods for the Arabidopsis thaliana shoot apical meristem, and a set of reporters for gene expression domains, and protein localization within cells of the SAM. Using live imaging and the reporter constructs we and others have found that the SAM has a private and highly controlled circulatory system for the plant hormone auxin, which serves as the morphogen that induces new floral primordia. This circulatory system is based on movement within each SAM cell of a polar auxin transporter, and leads to successive peaks of auxin concentration in a precise pattern that is the spiral phyllotactic pattern. A private and active circulatory system for a morphogen may represent a new principle of development, and also raises a number of questions about the mechanism of control of the intracellular location of the transporter.

692 The Convergence of Embryonic and Tumorigenic Signaling Pathways Contribute to Tumor Cell Plasticity
L. Postovit,1 J. Topczewski,2 N. Margaryan,3 A. Sam,3 A. R. Hess,4 W. W. Wheaton,2 B. J. Nickoloff,2 J. Topczewski,2 M. J. C. Hendrix,1, Program in Cancer Biology and Epigenomics, Children's Memorial Research Center, Northwestern University Feinberg School of Medicine, Chicago, IL, Program in Developmental Biology, Children's Memorial Research Center, Northwestern University Feinberg School of Medicine, Chicago, IL, Department of Pathology, Loyola University Medical Center, Cardinal Bernardin Cancer Center, Maywood, IL

Bi-directional cellular communication is integral to both cancer progression and embryological development. Furthermore, aggressive tumor cells are phenotypically plastic, sharing many properties with embryonic cells. To study these possible similarities we utilized the developing zebrafish as a biosensor for tumor derived signals. The data demonstrate that aggressive melanoma cells, but not poorly aggressive cells, can direct the fate of pluripotent zebrafish stem cells. Specifically, the aggressive tumor cells were able to orchestrate the formation of ectopic embryonic axes by secreting Nodal, a potent embryonic morphogen. Highlighting the potential role of this molecule in melanoma dissemination, Nodal protein expression was positively correlated with melanoma metastasis and inhibition of Nodal signaling reduced melanoma cell invasiveness. Moreover, depletion of Nodal signaling in aggressive melanoma cells caused the reversion of these cells toward a more melanocytic phenotype, and resulted in the abrogation of tumor progression in Smad2-independent and dependent mechanisms, respectively. We further determined that aggressive breast cancer cells similarly produce Nodal. From these data, we uncovered a key role for Nodal signaling in tumor cell plasticity and tumorigenicity, thereby providing a novel molecular target for regulating tumor progression.

693 Synergy between Notch and Kras Signaling in Pancreatic Tumorigenesis
J. De La O, L. Murtaugh, Human Genetics, University of Utah, Salt Lake City, UT

Differeentiation of stem and progenitor cells limits their capacity for tumorigenesis, and signals that prevent differentiation may indirectly promote cancer. Notch signaling inhibits differentiation in the developing pancreas, and it appears to be re-activated in pancreatic tumors and their initiating lesions (PanINs). To investigate the role of Notch in tumorigenesis, we have used two conditional mouse models: Kras<sup>12D</sup>, generated by Tuveson and colleagues, in which Cre recombinase induces expression of an endogenous activated Kras allele similar to that found in human tumors; and Rosa26<sup>Cre<sub>Lys<sub>36</sub></sub></sup>, developed by us, in which Cre induces expression of an activated Notch receptor. These alleles can be induced alone or together, throughout the pancreas or in specific pancreatic cell type. Widespread activation of Kras alone causes a small subset of cells to form PanINs lesions; Notch activation, by contrast, blocks differentiation in all cells but does not affect PanIN formation. Our hypothesis is that the blockade to differentiation imposed by Notch sensitizes cells to transformation by Kras, is strongly supported by experiments in which the two pathways are activated simultaneously. Not only does Notch activation dramatically sensitize cells to Kras-induced PanIN formation, it expands the range of cell types susceptible to activated Kras. In particular, we find that co-activation of Notch and Kras in adult acinar cells leads to their rapid dedifferentiation and dysplasia; this is the first demonstration that a specific adult cell type can serve as a site of tumor initiation in the pancreas. Endogenous Notch activation occurs in response to acute injury of the adult pancreas, and chronic injury of the organ is a
Aneuploidy Acts Both Oncogenically and as a Tumor Suppressor

B. A. A. Weaver, 1 A. D. Silk, 2 C. Montagna, 3 P. Verdier-Pinard, 4 D. W. Cleveland, 1 Ludwig Institute for Cancer Research, University of California, San Diego, La Jolla, CA, 2Pathology and Molecular Genetics, Albert Einstein College of Medicine, Bronx, NY, 3Department of Structural Biology, Sloan Kettering Institute, New York, NY, 4Institute of Biotechnology, Korea University, Seoul, Republic of Korea, 5School of Medicine, Kyung Hee University, Seoul, Republic of Korea, 6School of Medicine, Kyung Hee University, Seoul, Republic of Korea, 7Department of Structural Biology, Sloan Kettering Institute, New York, NY, 8Gerontology and OB/GYN & Women's Health, Albert Einstein College of Medicine, Bronx, NY, 9Department of Medicine, Radiology and Biomedical Engineering, Columbia University, New York, NY, 10Institute of Biotechnology, Korea University, Seoul, Republic of Korea

An abnormal chromosome number, a condition known as aneuploidy, is a common characteristic of tumor cells. Recognizing this correlation, Boveri proposed nearly 100 years ago that aneuploidy causes tumorigenesis. This has remained untested due to the difficulty of selectively generating aneuploidy in the absence of other defects. We now show that cells and mice that have reduced levels of the mitosis-specific, centromere-linked motor protein CENP-E develop aneuploidy and chromosomal instability in vitro and in vivo despite an intact DNA damage response and normal levels of p53. Chromosome painting demonstrates that aneuploidy is from loss or gain of whole chromosomes. In vivo, splenocytes, peripheral blood lymphocytes and colonic crypt cells exhibit significantly increased levels of near-diploid aneuploidy in CENP-E heterozygous mice. Near-diploid aneuploidy increases with age, with higher rates found for chromosome loss than gain. An increased rate of aneuploidy is demonstrated to contribute to transformation in vitro, as scored by loss of contact inhibition, anchorage independent growth, and tumor formation in immunocompromised mice. Aneuploidy from reduced levels of CENP-E is also shown to drive an elevated level of spontaneous lymphomas and lung tumors in aged animals. Reduced CENP-E function, in examples of chemically or genetically-induced tumor formation (loss of the tumor suppressor p19ARF), an increased rate of aneuploidy is a more effective inhibitor than initiator of tumorigenesis. These findings both confirm Boveri’s hypothesis and also reveal a previously unsuspected role of aneuploidy and chromosomal instability in preventing tumorigenesis.

Tissue Stiffness Promotes Mammary Tumorigenesis through Enhanced PI3 Kinase Activation

K. R. Johnson, 1 L. Kass, 2 N. Zahir, 1 P. Mrass, 3 W. Weninger, 3 D. Gasser, 4 S. S. Margulies, 1 P. A. Janmey, 1 V. M. Weaver; 1 Biomechanics, University of Pennsylvania, Philadelphia, PA, 2Pathology and Laboratory Medicine, University of Pennsylvania, Philadelphia, PA, 3Immunology, Wistar Institute, Philadelphia, PA, 4Genetics, University of Pennsylvania, Philadelphia, PA

Altered epithelial-mesenchymal interactions associated with profound changes in the tissue microenvironment, and although inducing a reactive stroma in tissue can enhance malignant transformation, the mechanism is poorly understood. We are using MMTV-Her2/neu mice and organotypic mammary epithelial cell (MEC) three-dimensional tissue models to study how alterations in the physical properties of the extracellular matrix (ECM) could modulate mammary tumorigenesis. Using compression and shear analysis, we show that malignant transformation is preceded by and associated with a progressive stiffening of the tissue. Biochemical, immunological, and polarization microscopy analysis indicate that gland stiffness, altered tissue morphology, and tumor invasiveness are functionally linked to increased collagen deposition, bundling, and crosslinking. We examined the relevance and molecular mechanisms whereby ECM stiffness might influence normal breast epithelia and breast tumor behavior. Studies combining MECs expressing an inducible homodimerizing ErbB2 construct (p75BB) with ribose-induced crosslinked collagen gels demonstrated that ECM stiffness can cooperate with oncogene activation to drive MEC transformation and invasion. Results indicate that ECM stiffness perturbs tissue morphogenesis by altering polarity, disrupting cell-cell interactions, and increasing growth and proliferation. Moreover, we show that matrix stiffness enhances epidermal growth factor (EGF) receptor-dependent PI3 kinase activation and PI3K-activated mTOR pathway activation in mammary epithelial cell lines and mouse mammary tissue sections. We are currently investigating whether matrix stiffness promotes tumor progression by altering EGF signaling through PI3 kinase and if so how. Nuclear Import, Architecture, and Tumor Suppression

L. C. Trotman, 1,2 A. Alimonti, 1,2 X. Wang, 1 Z. Chen, 1,2 P. P. Scaglioni, 1,4 J. Teruya-Feldstein, 3 S. Chi, 1 H. Kim, 1 H. Yang, 1 N. P. Pavletich, 3 B. S. Carver, 10 M. A. Keaton, D. J. Lew; Duke University, Durham, NC

The proto-oncogene AKT (PKB) is activated in many human cancers, mostly due to loss of the tumor-suppressor, a membrane lipid phosphatase, which ranks among the most frequently mutated genes in human cancer. In such tumors, AKT, which normally is both nuclear and cytoplasmic, becomes strongly enriched at cell membranes where it is activated by phosphorylation. Yet, although many targets of phospho-AKT are nuclear, it has remained unclear how relevant nuclear phospho-AKT (pAKT) function is for tumorigenesis. Here we show that the structural protein HDAC6 signaling and activation of β-catenin, all characteristic of breast tumor cells, contribute to increased transcription and translation of angiogenic factors. However, each of these pathways is attenuated in polarized and organized normal breast cells or can be reduced if tumor cells are forced to adopt a polarized, organized acinar structure. Thus, we hypothesized that correct polarity and 3-D tissue architecture, independent of changes in proliferation, was sufficient to regulate the angiogenic switch. Restoring expression of a key morphoregulatory transcriptional mediator, HoxD10 which is lost in aggressive tumors, reverted tumor cells to an polarized phenotype. This normalized phenotype was accompanied by a reduction in VEGF expression and a concomitant increase in ANG-1, a vascular stabilizing gene. Co-cultures of reverted polarized breast epithelial cells had a significantly reduced ability to induce endothelial cell migration as compared to disorganized tumor cells. We also observed that attenuation of the angiogenic switch by HoxD10 requires interactions with a three-dimensional laminin rich basement membrane. Introduction of signaling defective S48 integrin mutants impaired the ability of HoxD10 to induce polarity, and attenuate the angiogenic switch and consequently enhanced endothelial cell branching and migration.

Bromage, 11 P. Tempst, 11 C. Cordon-Cardo, 2 T. Misteli, 12 X. Jiang, 3 P. P. The progression from pre-malignant to invasive breast cancers is dependent upon generating a new vascular supply. A variety of changes in the breast tumor environment have been linked to increased production/release of angiogenic factors with the tumor cells themselves playing a central role in generation of these mediators including VEGF. Increased MAPK, PI3K, altered integrin α6β4 signaling and activation of β-catenin, all characteristic of breast tumor cells, contribute to increased transcription and translation of angiogenic factors. However, each of these pathways is attenuated in polarized and organized normal breast cells or can be reduced if tumor cells are forced to adopt a polarized, organized acinar structure. Thus, we hypothesized that correct polarity and 3-D tissue architecture, independent of changes in proliferation, was sufficient to regulate the angiogenic switch. Restoring expression of a key morphoregulatory transcriptional mediator, HoxD10 which is lost in aggressive tumors, reverted tumor cells to an polarized phenotype. This normalized phenotype was accompanied by a reduction in VEGF expression and a concomitant increase in ANG-1, a vascular stabilizing gene. Blocking Inhibitory Phosphorylation of Cdk1 Prolongs the Reversibility of Mitotic Exit in Vertebrate Cells

T. A. Potapova, J. R. Daum, G. J. Gorbsky; Molecular, Cell and Developmental Biology, OMRF, Oklahoma City, OK

Cyclin B proteolysis is hypothesized to ensure one-way directionality of mitotic exit. In support of this hypothesis, we previously demonstrated that mitotic exit induced by Cdk1 inhibitors can be reversed if the proteolysis cyclin B is abrogated by blocking proteasome activity or by expressing non-degradable cyclin B (Potapova et al., Nature 2006 Apr 13;440(7086):954-8). However, the ability of cells to return to mitosis decreased as they were maintained in G1 for long periods of time. This result suggested that an additional mechanism was preventing reactivation of Cdk1 during later G1. This second block was not dependent on protein synthesis hence was not due to production of small protein inhibitors. Using phospho-specific antibodies, we found that Cdk1 activity was inhibited by inhibitory phosphorylation on T14 and Y15. Interfering with these phosphorylations prolonged reversibility for hours after cells entered G1. As with the reversals of early G1 cells, cells reverses from later G1 re-condensed their chromosomes, disassembled the nuclear envelopes, formed mitotic spindles and re-aligned chromosomes at metaphase plates. Reversal of late G1 cells often led to the appearance of additional spindle poles. In some cases, cells failed to reverse cytokinesis, and daughter cells often built a complete bipolar spindle with chromosomes aligned in the middle, forming what we termed “minicells”. When cyclin B was preserved by proteasome inhibition, cells reverse even after 3 hours in G1. Cells expressing non-degradable cyclin B1 also showed an extended period of reversibility (up to 90 min) in the absence of inhibitory Cdk1 phosphorylation. At longer times (2 hours or more), such cells briefly re-entered mitosis but then exhibited morphological changes consistent with apoptosis. We hypothesize that apoptosis is a cellular response to reactivation of Cdk1 in the absence of other mitotic regulators that were degraded during the M phase to G1 transition.

Examining How Polo-like Kinases Regulate Metaphase Spindle Assembly and Maintenance Using Cell-permeable Chemical Inhibitors

U. Peters, J. H. Ken, J. Cherian, B. H. Kwok, T. M. Kapoor; Laboratory of Chemistry and Cell Biology, Rockefeller University, New York, NY

The stable propagation of genomes requires proper cell division, a very dynamic process that takes minutes, with several individual steps taking seconds. Cell permeable small molecules that target tubulin and can act on fast time-scales have been powerful tools to examine the functions of this cytoskeletal protein during cell division. Many proteins, including kinases, are now known that regulate spatial and temporal aspects of tubulin polymerization. To find small molecule probes for these proteins we carried out a phenotype-based screen with a small collection of 100 diaminoquinolines (DQs). We identified compounds that induce changes in spindle geometry, chromosome polemitotic index. Monopolar mitotic spindles were induced by 4 inhibitors including one, named DAP-81, that targets Polo-like kinases (Plks), evolutionarily conserved serine/threonine kinases, in vitro. Inhibition of Plks in DAP-81 treated cells was confirmed by comparing PI3K-RNAi phenotypes and by measuring the levels of Cdc25c-phosphorylation (S198), a known Plk inhibitor, BTO-1. High-resolution multi-mode live-cell microscopy of mammalian cells revealed that Polo-like kinases are required for the assembly and maintenance of bipolar mitotic spindles. Polo-like kinase inhibition can destabilize chromosome-associated microtubules while stabilizing and bundling astral microtubules, leading to monopolar mitotic spindles. Measurements of the tension across kinetochores in collapsing bipolar spindles further indicate that spindle pulling forces are still present despite the observed changes in microtubule dynamics. These data provide insight into the spatially-specific regulation of microtubule dynamics by Polo-like kinases during cell division.

Bub1 Is Essential for Assembly of the Inner Centromere

Y. Boyarchuk, A. Salic, M. Dasso, A. Arnautov; SCCR/PRCM, NICHD/NIH, Bethesda, MD, 2Department of Cell Biology, Harvard Medical School, Boston, MA

During mitosis the inner centromere region recruits protein complexes that regulate sister chromatids cohesion, monitor tension and modulate microtubules attachment. Biochemical pathways that govern formation of the inner centromere remain elusive. The kinetochore protein Bub1 was shown to promote assembly of the outer kinetochore components such as BubR1, Mad2, CENP-F and CENP-E on centromeres. Here we show that Bub1 is also essential for formation of a functional inner centromere. Depletion of Bub1 from Xenopus egg extract or from HeLa cells resulted in displacement of chromosome passenger complex and MCAK from the inner centromere region. Moreover, Bub1 controls the binding of Shugoshin to chromatin, while the chromosome passenger complex directs loading of Shugoshin specifically onto centromere. We further show that Bub1 kinase activity is pivotal for recruitment of all of these components. Taken together, our findings demonstrate that Bub1 acts at multiple points to assure the correct kinetochore formation.

Cell Cycle Regulation by Cyclin-Cdkks and Proteolysis

We are investigating the role of ubiquitin-mediated proteolysis in mitotic entry and exit, and in coordinating mitosis with DNA replication. In particular we are trying to understand how cells degrade the right protein at the right time to ensure that their two daughter cells receive an identical copy the genome in mitosis. This is clearly essential to genomic stability and defects in the checkpoints controlling chromosome segregation may contribute to tumorigenesis. Key to the control of chromosome segregation is the regulation of the Anaphase Promoting Complex/Cyclosome (APC/C) ubiquitin ligation by the spindle assembly checkpoint. We have developed a live cell assay to monitor APC/C activity and its inhibition by the spindle checkpoint. This has revealed that the checkpoint is intrinsic to the timing of mitosis and underlies the difference in the timing of cyclin A, cyclin B and securin degradation. We have found that the APC/C is recruited to unattached kinetochores by the checkpoint proteins that may explain the tight temporal control on the APC/C by the checkpoint. We are testing the idea that this temporal control requires that the checkpoint and ubiquitination machinaries interact at the spindle. Using our time-lapse fluorescence microscopy as a real time assay for proteolysis we are trying to elucidate how different proteins are selected for destruction at different times in throughout mitosis.

Aurora B Kinase Is Activated by Microtubules and TD-60

S. E. Rosasco, P. Stukenberg; Biochemistry and Molecular Genetics, University of Virginia, Charlottesville, VA

Aurora B kinase regulates microtubule-based processes of mitosis including the attachment of kinetochores to microtubules, and the positioning of the cytoskeletal furrow. Aurora B activity requires interaction with the chromosome passenger INCENP, and phosphorylation of Ser850 on INCENP further stimulates kinase activity. Aurora B and INCENP also interact with Survivin and Borealin/Dasa, which are important for centromere cohesion in prometaphase and metaphase and midzone localization during anaphase. TD-60 is putative guanine nucleotide exchange factor that regulates the localization of chromosome passenger complexes to the centromere (Mollinari et al., 2003). A select population of TD-60 interacts with the Aurora B complex. Chromosome passengers fail to localize to centromeres after addition of anti-TD-60 antibodies to Xenopus extracts, which recapitulates the siRNA phenotype (Mollinari et al., 2003). Partial depletion of Xenopus extracts separates two functions of TD-60: INCENP and Aurora B localize to centromeres, but INCENP is not phosphorylated on Ser850. Thus TD-60 regulates both the localization and activity of chromosome passengers in vivo. This regulation is critical because extracts partially depleted of TD-60 are unable to congress chromosomes to the metaphase plate. In vitro, microtubules stimulate purified chromosome passenger kinase activity 3-5 fold, while microtubules and TD60 stimulate over 100 fold. These data suggest that TD-60 localizes passenger proteins to the centromere and then coordinates with INCENP to regulate Aurora B kinase activity. Reference List Mollinari,C., Reynaud,C., Martineau-Thuilier,S., Monier,S., Kieffer,S., Garin,J., Andreassent,F.R., Boulet,A., Goad,B., Kleinman,J.P., Margolis,R.L. (2003). The mammalian passenger protein TD-60 is an RCC1 family member with an essential role in prometaphase to metaphase progression. Dev.Cell 5, 295-307.
Fibronectin Regulates Mammary Epithelial Cell Growth during Acinar Morphogenesis

C. M. Williams, J. E. Schwarzbrauer; Department of Molecular Biology, Princeton University, Princeton, NJ

The mammary gland consists of a series of branching ducts, ending in hollow, sphere-like acini surrounded by a basement membrane. Breast cancer is accompanied by loss of this tissue organization and dynamic changes in the extracellular matrix, including the appearance of fibronectin in the tumor stroma. The correlation between a fibronectin-rich stroma and aberrant proliferation may indicate a role for fibronectin signaling in breast oncogenesis. Culture of MCF-10A mammary epithelial cells (MECs) on a Matrigel basement membrane recapitulates in vivo acinar morphology. We have found that fibronectin in this culture system either promotes or impedes the differentiation of acini depending upon protein levels. Endogenous expression of fibronectin is crucial for MCF-10A cells to execute the differentiation program. Knock-down of endogenous fibronectin using small interfering-RNAs resulted in smaller acini containing fewer polarized cells and delayed lumina formation compared to acini formed by mock-treated MECs. Long-term culture of MECs in the presence of excess exogenous fibronectin also yielded aberrant acini as characterized by larger size, continued cell proliferation, reduced cell polarity, and lack of a hollow lumen. These data indicate that a certain basal level of fibronectin is required for optimal cell growth and differentiation during acinar development in vitro. When acini were allowed to complete the differentiation program before exposure to excess exogenous fibronectin, the addition of fibronectin was sufficient to reverse the established growth arrest and stimulate re-entry into the cell cycle. Thus, a fibronectin-rich stroma provides extracellular signals that are important for cell growth and contact differentiation from the basement membrane resulting in defective acinar morphologies. These findings suggest that increased fibronectin, as in the stroma of breast tumors, may cause loss of acinar organization by stimulating MEC proliferation.

Rac1, Matrix Force, and Tissue Architecture: The Oxidative Effect

M. Nuth, J. C. Friedland, J. N. Lakin, J. Chenrot, A. R. Kennedy, V. M. Weaver; 1School of Medicine, University of Pennsylvania, Philadelphia, PA, 2Fox Chase Cancer Center, Philadelphia, PA, 3Radiation Oncology, University of Pennsylvania, Philadelphia, PA

Tissue differentiation and homeostasis are associated with tissue organization that is regulated by cell-integrin-extracellular matrix (ECM)-dependent Rac activation. Malignant transformation is characterized by perturbations in tissue architecture and is associated with acquisition of cell motility, invasion, increased growth and survival, and aberrant cell-ECM interactions and Rac activity. We showed that transformed tissue is significantly stiffer than normal tissue, and that force disrupts tissue morphogenesis and increases cell growth and invasion (Paszek et al., Cancer Cell 2005). Here we report that matrix stiffness significantly modifies the localization and basal activity of Rac and alters Rac localization to permit Rac-dependent cell growth and invasion through NADPH oxidase-dependent induction of reactive oxygen species (ROS). We found that mammary epithelial cells (MECs) interacting with a compliant reconstituted basement membrane (rBM) assemble polarized, growth arrested tissue-like structures with high specific activity of Rac and Pak that co-localize and are spatially-restricted to the basal domain of the acini. In contrast, MECs interacting with a stiff rBM form highly disorganized, disoriented structures that fail to growth-arrest or polarize and display randomly distributed total and active Rac. Intriguingly, polarized acini expressing a V12Rac adenovirus lose polarity and begin to grow and invade once their surrounding ECM is stiffened appreciably, yet they are able to retain their differentiated, polarized phenotype if they are simultaneously treated with the NADPH oxidase inhibitor diphenyleneiodonium or infected with a Rac mutant that is incapable of activating ROS via NADPH oxidase. Accordingly, we are now employing an inducible GST-wild type and V12Rac and proteins to explore the possibility that matrix tension promotes expression of the malignant epithelial tissue phenotype in part by permitting Rac-dependent activation of NADPH oxidase. In addition, we are assessing the relevance of elevated force-dependent ROS on tissue and cell behavior.

Endocytic Components Are Coupled to Adhesion Signaling

D. P. LaLonde, J. Pignatelli, M. Grubinger, C. E. Turner; Department of Cell/Developmental Biology, SUNY Upstate Medical University, Syracuse, NY

Integrin ligation with an extracellular matrix (ECM) regulates cell spreading, motility and focal adhesion dynamics. Perturbation of these signaling pathways contributes to abnormal growth and tumor metastasis. Recent reports have elucidated a role for caveola-dependent endocytosis in integrin signaling, while a role for clathrin-dependent endocytosis has been implied but is not well tested. Herein, we show that β2-adaptin, a component of clathrin coated pits, is enriched in focal adhesions during cell spreading on an ECM. Depletion of β2-adaptin or clathrin heavy chain using RNAi knockdown results in increased cell spreading, enhanced membrane ruffling and the generation of new adhesion structures resembling podosomes or invadopodia that are hallmarks of Src-transformed and invasive tumor cells. These structures are functional, as they actively degrade the underlying matrix and result from upregulated Src activity. Our results suggest a previously unappreciated role for endocytic proteins in tumor cell metastasis via regulation of adhesion signaling. Supported by NIH GM57407 & HL070244

Another β1 Tail-binding Factor Cooperates with the PTB-like Domain of Talin to Activate β1 Integrins

M. Bouaouina, Y. Lai, D. A. Calderwood, Department of Pharmacology, Yale University School of Medicine, New Haven, CT

The activation of integrin adhesion receptors from low to high affinity in response to intracellular cues controls cell adhesion, migration and signaling. Binding of the cytoskeletal protein talin via its PTB-like domain to the β3 integrin cytoplasmic tail is necessary and sufficient for β3 activation. The talin-binding motif is conserved between integrin β tails, talin binds most integrin β subunits, and talin is required for β1 integrin activation. It has therefore been assumed that talin activates β1 and β3 integrins in a similar fashion. Here we report that, while the conserved talin PTB domain-integrin interaction is required for β1 activation, over-expressed integrin-binding fragments of talin do not activate β1 integrins. Furthermore, while over-expressed free β1 tails trans-dominantly inhibit β3 integrins by sequestering talin, free β1 tails defective in talin-binding can still suppress β1 integrin activation. These data point to an additional β1-binding factor that cooperates with talin during β1 activation. Mutagenesis of the β1 tail has identified residues that lie outside the talin-binding site which are required for β1 activation, and are likely to be involved in the binding of this second β1-specific activating factor. Free β1 tails mutated at this site and also defective in talin binding are unable to trans-dominantly suppress β1 integrin activation. We propose that the requirement for a second β1-specific activating factor provides a mechanism to selectively regulate β1 integrins.

FAK Modulates Cell Adhesion Strengthening via Two Distinct Mechanisms: Integrin Activation and Vinculin Recruitment

K. E. Michael, S. K. Hanks, A. J. Garcia; 1Petit Institute for Bioengineering and Bioscience, Georgia Institute of Technology, Atlanta, GA, 2Department of Cell and Developmental Biology, Vanderbilt University School of Medicine, Nashville, TN

Integrin-mediated cell adhesion to extracellular matrices (ECM) plays critical roles in tissue development/repair as well as pathological conditions. Matrix-bound integrins associate with the cytoskeleton and cluster to form focal adhesions (FA), which link the cytoskeleton to ECM. Integrin-ECM bonds provide the underlying structure for adhesion strength, and FA assembly further enhances adhesion strength by distributing forces among cytoskeletal elements. Focal adhesion kinase (FAK) is an essential non-receptor tyrosine kinase that regulates FA turnover and migration and is commonly overexpressed in tumors. Using FAK−/− cells engineered to re-express FAK under a tetracycline-inducible promoter and a hydrodynamic adhesion strength assay, we show FAK-dependent differences in adhesion strengthening, both in strengthening rate and steady-state strength. Compared to FAK−/− cells, FAK re-expression significantly increased strengthening rate (3 fold). The binding rate of alpha5beta1 integrin to fibronectin was also elevated (3 fold) in the presence of FAK; however, no differences in steady-state integrin binding levels were detected. Differences in strengthening rate were dependent on alpha5beta1 binding to fibronectin, as demonstrated by antibody blocking. Although FAK−/− and FAK re-expressing cells displayed equal surface densities of alpha5beta1, FAK re-expressing cells exhibited higher levels of activated integrins, as indicated by activation-specific antibodies. In contrast, steady-state adhesion strength was reduced in the presence of FAK (30%). Steady-state differences in adhesion strength were associated with differences in recruitment of vinculin, but not talin, to the adhesion area. Immunostaining showed less FA containing area occupied by vinculin (25%) for cells expressing FAK. These results indicate that FAK modulates cell adhesion strengthening via two distinct mechanisms: strengthening rate is regulated via integrin activation and binding, while vinculin recruitment modulates steady-state strength. This analysis provides insights into the regulatory role of FAK in adhesion interactions

Integrin of Functions as a Type I PKA Specific A-kinase Anchoring Protein

C. J. Lim, J. H. Nam, N. Youn, Y. Ma, P. S. Amieux, G. S. McKnight, S. S. Taylor, M. H. Ginsberg; 1Medicine, University of California San Diego, La Jolla, CA, 2Chemistry and Biochemistry, University of California San Diego, La Jolla, CA, 3Pharmacology, University of Washington, Seattle, WA

Localized activation of CAM-dependent protein kinase (PKA) at the leading edge of migrating cells phosphorylates protein substrates including the α4 integrin cytoplasmic domain. Phosphorylation of α4 (phospho-α4) prevents association with the signaling adaptor, paxillin, facilitating Rac activation and pseudopodium formation. The subcellular localization and substrate
specificity of PKA, a tetramer of two regulatory (R) and two catalytic (C) subunits, is governed by R subunit binding to A-kinase Anchoring Proteins (AKAPs). To investigate the mechanism by which spatial localization of α4 phosphorylation is achieved, we sought to identify the PKA isoforms and AKAPs involved. α4 and PKA-C were found in a complex. Using matrix immobilized α4 cytoplasmic tail protein in pull down assays, we identified PKA-R1, but not PKA-R2, in this protein complex. In vitro, PKA-α4 association was abrogated in PKA-R1-null mouse embryonic fibroblasts (MEF). To assess the possibility that α4 may function as an AKAP, direct binding between α4 cytoplasmic tail with purified PKA was assessed. α4 bound directly to Type I PKA holoenzyme, but not to the constituent PKA-R1 or PKA-C subunits. Furthermore, the α4-Type I PKA interaction was insensitive to AKAP-derived amphiphatic peptide disruptors, suggesting α4 as a novel and non-canonical form of AKAP for Type I PKA. In vivo, PKA-R1 co-localized with α4 at the prostatic membranes of cells undergoing polarized migration. Agonist stimulation of α4 phosphorylation was abolished in PKA-R1-null MEFs, suggesting tethering of Type I PKA to α4 is required for spatial restriction of PKA activity and α4 phosphorylation. Consistent with this idea, leading edge phospho-α4 in migrating cells was diminished when only Type I PKA is mislocalized by expression of mitochondrially targeted A-kinase binding peptides. Mistargeting of Type I PKA also resulted in significant inhibition of the velocity and directional persistence of α4-dependent cell migration. Thus, the α4 cytoplasmic domain is a novel, non-canonical, Type I specific AKAP.

The Role of Two GT Pases in Co-translational Protein Targeting
S. Chandrasekar,1 P. Walter,2 S. Shan1; 1Division of Chemical Engineering and Chemical Engineering, California Institute of Technology, Pasadena, CA; 2Department of Biochemistry and Biophysics, University of California, San Francisco, San Francisco, CA

The signal recognition particle (SRP) and its receptor (SR) constitute the major cellular machinery that delivers nascent proteins to the eukaryotic ER membrane, or the bacterial plasma membrane. During this process, two GT Pases in SR and SR form a unique complex in which they reciprocally activate each other’s GTP hydrolysis activity. We have isolated different classes of mutant GT Pases that block the SRP-SR interaction at specific stages, indicating that the SRP-SR binding and activation involve a series of conformational changes. To assess the contribution of these steps to the protein targeting reaction, we tested the effect of various GTPase Pases in a co-translational targeting assay. A class of mutants that allows the assembly of a stable SRP-SR complex but specifically blocks the reciprocal activation of GTP hydrolysis severely blocks translocation, in contrast to previous results using GTP analogues that suggested that GTP hydrolysis is not required. Instead, our results suggest that although the hydrolysis reaction per se is not crucial, the molecular rearrangements that lead to reciprocal GT Pase activation provides essential drive force for protein targeting. The co-translational targeting assay also allowed us to probe the fidelity of protein targeting. Surprisingly, the translocation defect of preproteins with mutant signal sequences can be effectively rescued by reducing the rate of translation elongation. We propose that ongoing translation provides kinetic competition with the targeting process that can improve the fidelity of protein targeting. These results also raise the possibility that the spectrum of proteins delivered by the SRP could be quite dynamic and subject to regulation by changes in cellular environment.

Regulation of ER-Golgi Trafficking and Golgi Biogenesis by Rab GTPase-activating Proteins
A. K. Haas, R. Kopajtic, E. Fuchs, S. Yoshimura, F. A. Barr; Max Planck Institute of Biochemistry, Martinsried, Germany

Rab GT Pases control vesicle movement and tethering membrane events at discrete membrane trafficking steps. A key determinant of Rab function is the lifetime of the activated GTP-state, and this is under the control of a family of GT Pase activating proteins (GAPs). Here we show that a subset of the 38 human Rab GAPs are important for controlling Rab function at the Golgi apparatus. To do this we have screened all predicted human Rab GAPs for the ability to change Golgi morphology and block trafficking from the ER to the Golgi. From this screen we were able to identify a novel Rab GAP domain-containing regulator of trafficking between the ER and Golgi. Overexpression of this protein but not a catalytically inactive mutant causes a complete dispersal and apparent loss of the Golgi apparatus. Structural proteins of the cis- and medial Golgi redistributed in a hazy throughout the cytoplasm, whereas Golgi localized enzymes accumulated in the ER. Surprisingly, this does not block the formation of COPII vesicles. Under these conditions COPII vesicles undergo a non-productive cycle of formation and recruitment of the Golgi matrix protein GM130, then collapse back into the ER. Finally, a biochemical analysis showed that this protein is the GAP for Rab1 and Rab2. Together, these findings highlight the importance of Rab GAPs as specific regulators of membrane trafficking. They also suggest that Rab1 and Rab2-mediated tethering of COPII vesicles is coupled to the recruitment of Golgi matrix proteins, and that this is required for the maintenance of a stable Golgi structure.

712
The Coiled-coil Domain of Sec2p Activates the Rab GTPase Sec4p
G. Dong, M. Medkova, P. Novick, K. M. Reinesch; Department of Cell Biology, Yale University School of Medicine, New Haven, CT

The Rab GT Pases, with regulatory roles in multiple stages of intracellular transport, are the largest subgroup in the Ras-like GT Pase superfamily. Like all small GT Pases, the Rab proteins interact with signaling partners in their GTP bound form but not in their GDP bound form. The two forms differ in the switch regions, I and II, which surround the nucleotide binding site. GT Pases are activated by guanine exchange factors (GEFs) that catalyze the exchange of GDP for GTP. GEFs are classified into different families, which act on different groups of GT Pases. GEFs for all almost all subfamilies of the Ras-like GT Pases have been studied extensively, except for the GEFs that act on the Rab GT Pases. Here we present the crystal structure of the GEF domain of Sec2p in complex with its GT Pase partner Sec4p, a key regulator in polarized exocytosis in yeast. As a 220 Å long coiled-coil, the Sec2p GEF domain represents a new class of GEF and also a novel use of the coiled-coil motif as a GEF. Sec2p facilitates exchange by inducing extensive structural reorganizations in the Sec4p switch regions and the phosphate-binding loop (P-loop) that are incompatible with nucleotide binding. GDP exchange assays demonstrate that Sec2p has nucleotide exchange activity for Sec4p but not for other Rab GT Pases, including Rab1a, Rab2, Rab4, Rab6, Ypt1p, and Ypt32p. The structure suggests that the determinants for Sec2p specificity reside in the switch regions and the P-loop. We have confirmed the importance of switch I by constructing Sec4p and Ypt1p chimeras in which the switch I regions were interchanged. Switch II and the P-loop are nearly identical for the two proteins. Only Ypt1p with a Sec4p switch I was activated by Sec2p.

713
Phosphorylation of RhoGDI by Src Regulates Rho GT Pase Binding and Cytosol-Membrane Cycling
C. DerMardirianoss, G. Rocklin, J. Seo, G. Bokoch; Immunology, The Scripps Research Institute, La Jolla, CA

Rho GT Pases (Rac, Rho, and Cdc42) play important roles in regulating cell function through their ability to coordinate the actin cytoskeleton, modulate the formation of signaling reactive oxygen species, and to control gene transcription. Activation of Rho GT Pase signaling pathways requires the regulated release of Rho GT Pases from RhoGDI complexes, followed by their reuptake after membrane cycling. We show here that Src kinase and phosphatases promote RhoGDI both in vitro and in vivo at Tyr156. Analysis of Rho GT Pase-RhoGDI complexes using in vitro assays of complexation and in vivo by co-immunoprecipitation analysis indicates that Src-mediated phosphorylation of Tyr156 causes a dramatic decrease in the ability of RhoGDI to form a complex with RhoA, Rac1, or Cdc42. Phosphomimetic mutation of Tyr156–Glu results in the constitutive association of RhoGDIY156E with the plasma membrane and/or associated cortical actin. Substantial cortical localization of tyrosine-phosphorylated RhoGDI is also observed in fibroblasts expressing active Src, where it is most evident in podosomes and regions of membrane ruffling. Expression of membrane-localized RhoGDIY156E mutant is associated with enhanced cell spreading and membrane ruffling. These results suggest that Src-mediated RhoGDI phosphorylation is a novel physiological mechanism for regulating Rho GT Pase cytosol-membrane cycling and activity.

714
A Septin GT Pase Required for Spatial Control of Microtubule Organization and Efficient Vesicle Transport
E. T. Spilotis,1 S. J. Hunt,2 M. Kinoshita,3 W. J. Nelson; 1Biological Sciences, Stanford University, Stanford, CA; 2Biochemistry and Cell Biology, HMRO, Kyoto University, Kyoto, Japan

Septins are conserved GT Pases that form filamentous structures that associate with cellular membranes and the cytoskeleton. Yeast septins are required for polarized membrane growth, but the function of mammalian septins counterparts is unknown. Here, we show that in non-polarized Madin-Darby canine kidney (MDCK) cells, Septin 2 (SEPT2) filaments are found at sites of vesicle export from the trans-Golgi network. At these sites SEPT2 associates with a distinct subset of microtubule tracks which are recognized by a monoclonal antibody (B3) to polyglutamylated motifs of α-tubulin. Lack of SEPT2 colocalization with acetylated microtubules revealed that SEPT2 is spatially restricted to the polyglutamylated subset of stable microtubules. In quantitative membrane trafficking assays, microinjection of SEPT2 antibodies resulted in the down-regulation of Golgi-to-plasma membrane vesicle transport of apical (p75-GFP) and basal-lateral (VSVG-GFP) marker proteins. Similarly, in polarizing MDCK cells, SEPT2 knock-down by RNAi resulted in the intracellular accumulation of p75-GFP and VSVG-GFP. This phenotype was accompanied by failure of the microtubule cytoskeleton to reorganize along the apico-basal axis of polarity. In non-polarized MDCK cells, disruption of SEPT2 association with microtubules by SEPT2-depletion or by overexpression of MAP4-GFP, a cytosolic binding partner of microtubule-free SEPT2, resulted in the loss of polyglutamylated microtubules. Significantly, MAP4-GFP overexpression phenocopied SEPT2 in the down-regulation of Golgi-to-plasma membrane vesicle transport. This effect was quantitatively dependent on the levels of MAP4-GFP.
expression and accompanied by loss of the microtubule-bound SEPT2 filaments. These data suggest that microtubule-bound SEPT2 acts as a scaffold for the polyglutamylation of microtubule tracks, which in turn, as previously suggested by others, may negatively modulate the binding of microtubule-associated proteins (“speed bumps”), while favoring the accumulation of kinesin motor proteins. In conclusion, our data establish septin GTPases as spatial landmarks for the organization of distinct microtubule tracks and reveal a novel requirement for the efficiency of intracellular membrane transport.

715 Spatial And Kinetic Regulation of the Exocyst for Polarized Exocytosis: A Tale of Two Rh0 GTPases
X. Zhang, B. He, J. Zhang, A. Zajac, W. Guo, Biology Department, University of Pennsylvania, Philadelphia, PA

The exocyst is an octameric protein complex composed of Sec3, Sec5, Sec6, Sec8, Sec10, Sec15, Exo70 and Exo84. The exocyst is localized to specific domains of the plasma membrane, where it tethers the post-Golgi secretory vesicles preceding membrane fusion. How the exocyst is targeted to sites of secretion and how it functions in polarized exocytosis are unclear. We have found that the GTP-bound Cdc42 directly interacts with the N-terminals of Sec3 and further identified key residues on Sec3 that mediate this interaction. In addition, we have identified a region adjacent to the Rho-binding domain (RBD) in Sec3 that interacts with phospholipids and is responsible for Sec3 targeting to the plasma membrane. Besides Sec3, the exocyst component Exo70 interacts with another Rho protein, Rho3, in its GTP-bound form. Sec3 and Exo70 function in parallel for vesicle tethering to specific domains of the plasma membrane. We have designed a genetic assay, in which the functional implications of Rho-binding to either Sec3 or Exo70 can be assessed. Using this assay, we found that disruption of Sec3-Cdc42 interaction not only blocked exocytosis, but also caused severe cell polarity defects. On the other hand, disruption of Exo70-Rho3 interaction did not cause any polarity defect but kinetically affected secretion. Our studies not only shed light on the molecular basis of vesicle targeting to the plasma membrane, but also revealed the important but different roles Rh0 GTPases play in exocytosis and cell polarity.

716 Yeast Kinesin-8 Is a Highly Processive Motor That Depolymerizes Microtubules in a Length-dependent Manner
V. Varga, J. Helenius, K. Tanaka, A. A. Hyman, T. U. Tanaka, J. Howard, Max Planck Institute of Molecular Cell Biology and Genetics, Dresden, Germany, School of Life Science, University of Dundee, Wellcome Trust Biocentre, Dundee, United Kingdom

In eukaryotic cells, the dynamics of microtubules are tightly regulated. Numerous in vivo studies indicate that one of the factors responsible for destabilization of microtubules are motor proteins from the kinesin-8 family. Here we demonstrate for the first time that Saccharomyces cerevisiae kinesin-8, Kip3p, indeed acts like a depolymerase in vitro. Furthermore, our TIRF based microscopy assay revealed that Kip3p has several novel properties that clearly distinguish it from other microtubule destabilizing kinesins, such as MCAK from the kinesin-13 family. First, Kip3p disassembles microtubules exclusively at the plus end, unlike MCAK, which depolymerizes microtubules from both ends. Second, Kip3p targets the plus end by directed ATP-dependent movement, unlike MCAK, which transiently diffuses along the microtubule lattice. And third, Kip3p is extremely processive, indeed it is the most processive cytoskeletal motor characterized to date. As a consequence of this high processivity, the rate of depolymerization of microtubules by Kip3p is length-dependent. This length-dependent depolymerization provides a new mechanism for controlling the length of subcellular structures that can account for effects of Kip3p mutations on microtubule and spindle length seen in yeast and metazoan cells.

717 Structural Features of the Microtubule Important for MCAK Activity
K. M. Hertz, C. E. Walczak; Medical Sciences Program, Indiana University, Bloomington, Bloomington, IN

MCAK is a Kinesin-13 member that depolymerizes microtubules (MTs) and regulates MT dynamics. Previous studies showed that MCAK binds specifically to the MT end to induce depolymerization, but it is unknown what structural features of the MT are necessary for end specific recognition by MCAK. We used subtilisin treated MTs (MTs that are lacking the C-termini of α- and β-tubulin) as well as a variety of alternative tubulin substrates to study which structural features of the MT are required by MCAK to bind to and depolymerize MTs. We found that the removal of only the β-tubulin C-terminus led to a 2-fold decrease in depolymerization efficiency, whereas the removal of both α- and β-tubulin C-termini decreased depolymerization efficiency by 3-fold. However, removal of the C-terminus of either β-tubulin alone or of both α- and β-tubulin did not significantly affect the ability of MCAK to bind to the MT, nor did C-terminal removal alter MCAK localization to the ends of the MT. Our results show that the ability of MCAK to depolymerize subtilisin MTs (SMTs) is reduced, but not totally inhibited. We also employed alternative tubulin substrates to study how MCAK recognizes the end of the MT. We found that MCAK bound to a variety of curved tubulin substrates, but does not appear to depolymerize these polymers. In addition, curved tubulin substrates competed with the ability of MCAK to bind to the lattice and ends of unaltered MTs. Finally, we also found that the presence of tubulin polymers with increased lateral edges or curved tubulin substrates negatively affected the ability of MCAK to depolymerize unaltered MTs, indicating that lateral edges as well as curvature of the MT end may play important roles in MCAK induced depolymerization of MTs.

718 Nucleotide-induced Head Movement in Flagellar Dynae Revealed by Cryo-Electron Microscopy
T. Oda, N. Hirokawa, M. Kikka; Department of Cell Biology, University of Texas Southwestern Medical Center, Dallas, TX, Department of Cell Biology and Anatomy, Graduate School of Medicine, University of Tokyo, Tokyo, Japan

Outer dynein arms (ODAs) of the flagellar axoneme generate forces needed for flagellar beating. Our understanding of the force generating mechanism of ODA is limited by the absence of detailed structural information. Here, we have established a new method to reconstruct the three-dimensional structure of the in vitro reconstituted ODA-microtubule complex from cryo-electron microscopy images. Significant conformational changes of ODA were revealed from the ODA structures in two functionally critical states; the rigor (ATP-depleted) state and the relaxed (ATP-vanadate) state. From the rigor state to the relaxed state, the head domain of the β-heavy chain is displaced by 3.7 nm toward the B-tubule and inclined 44 degree inwards. These structural changes suggest a power "pull" model.

719 Huntington Participates in Dynactin/Dynactin-mediated Vesicle Trafficking
J. P. Caviston, J. L. Ross, S. M. Antony, M. K. Tokito, E. L. F. Holzbaur; Department of Physiology, University of Pennsylvania, Philadelphia, PA

Huntingtin (Ht) and dynactin are both present on vesicles purified from mouse brain and inhibitory antibodies to Ht cause these vesicles to dissociate from microtubules, suggesting that Ht facilitates dynein-mediated vesicle motility. Knockdown of Ht by RNAi in cultured cells results in Golgi disruption, similar to the effects of compromising dynactin/dynactin function. RNAi of dynactin results in a significant redistribution of Ht to the outer periphery of cells, suggesting that dynactin transports Ht-associated vesicles towards the cell center. Together, these findings indicate that Ht binds to dynactin and may act in a complex with dynactin/dynactin and HAP-1 to modulate vesicle association with microtubules and facilitate vesicular transport.

720 Eg5 and Dynein Act Antagonistically during Spindle Assembly in Mammalian Cells
N. P. Ference, P. Wadsworth, Biology, University of Massachusetts, Amherst, MA

During prophase, Eg5 has been functionally assigned to spindle pole separation, although its role in microtubule biogenesis at this stage has not been directly addressed. To do so, we used an LLC-PK1 cell line expressing photoactivatable GFP-tubulin. In control prophase cells, photoactivated marks move across a wide distribution of rates (0.5μm/min - 4.9μm/min) both toward (P)
and away from (AP) spindle poles. ~61% of all motion is P and ~39% is AP. In the presence of the Eg5 inhibitor monastrol, the distribution of rates is identical to controls, but there is a significant shift in directionality: ~14% of all motion is P and ~86% is AP. Although an actual decrease in P motion could create an artificial increase in AP motion (and vice versa), this does not appear to be the case as 20 control cells produced 62 P marks and 39 AP marks while 10 monastrol-treated cells produced 6 P marks and 36 AP marks, indicating a true shift in both P and AP motion in the absence of functional Eg5. Because our recent work has shown that ~1/3 of all control AP motion is dynen-dependent (specifically, the population moving between 2.25 m/min and 4.49 m/min) and because this particular motion is increased following Eg5 inhibition (13 control cells and 13 marks in 10 monastrol-treated cells), we postulated an antagonistic interplay between Eg5 and dynein. Such an interplay allows one to consider the hallmark of Eg5 inhibition (spindle collapse) not as a direct consequence of impaired Eg5 function, but as a shift in the balance of forces. To test this, we injected monastrol-treated monopolar spindles with p150-CC1 (a dynein inhibitor). In 50% of such cells, monopolar spindles bipolarize into normal, metaphase-looking spindles (n = 3 cells), within 30 min of injection, supporting our initial postulation.

271

In Vivo Measurement of Molecular Motor Forces
G. T. Slabuha, S. P. Gross; Developmental and Cell Biology, University of California, Irvine, Irvine, CA

Molecular motor proteins actively transport organelles and other cell constituents along microtubules. In vitro studies have determined many of the motors’ basic functional properties. However, less is known about motor function and regulation inside living cells, in particular the number of motors moving a cargo, and how these motors work together. Recent work suggests that multiple motors move cargoes, but to date there has been limited direct evidence supporting this hypothesis. In addition, the magnitude and impact of cytosolic (viscous) drag on motor function is also controversial, with some studies proposing that cytosolic drag applies tremendous load on motor-driven cargoes. Because applied load decreases motor processivity, viscous drag could then play a crucial role in ending runs in a given direction. Here, we present direct measurements addressing these issues. We constructed a specialized optical trap, and measured the force that motors can exert while hauling lipid droplets along microtubules in Drosophila embryos. We report direct in vivo measurement of the forces that molecular motors exert in hauling individual endogenous cargoes, and provide direct evidence that multiple motors cooperate to move a cargo. We find that the number of motors moving the cargoes was relatively small (typically less than 3) and that the number of active motors did not depend on the size of the cargo. Moreover, because cargoes moved at velocities comparable to unloaded in vitro (up to 1 μm/s), and did not exhibit a significant correlation between stalling force and velocity, we conclude that the effect of cytosolic viscous drag is much smaller than 2.5 pN - the typical force driving lipid droplets.

272

Coronin 1B Coordinates Arp2/3 and Cofilin Activity at the Leading Edge
J. E. Bear, 1 L. Cai, 2 T. W. Marshall, 1 A. C. Uetrecht, 1 D. A. Schafer; 1 Cell & Developmental Biology, UNC-Chapel Hill, Chapel Hill, NC, 2 Biology, University of Virginia, Charlottesville, VA

Arp2/3-dependent actin filament nucleation and Cofilin-driven filament turnover are two major factors that control the dynamics of lamellipodia in motile cells, but the coordination of these activities is poorly understood. Coronin 1B is highly conserved F-actin binding, WD repeat proteins that have been implicated in cell motility in model organisms. Yeast Coronin inhibits Arp2/3 complex in vitro, but the function of Coronins in mammalian cells is not known. We report that human Coronin 1B inhibits actin nucleation by the Arp2/3 complex and that this inhibition is regulated by the Slingshot-1L (SSH1L) phosphatase via the dephosphorylation of Serine 2 on Coronin 1B. Furthermore, we find that SSH1L, Coronin 1B and Arp2/3 exist in a ternary complex in vivo that is bridged by Coronin 1B. Functional studies of lamellipodial dynamics indicate that depletion of Coronin 1B alters lamellipodial protrusion and that Coronin 1B is required for enhanced ruffling at the cell periphery induced by expression of SSH1L. In addition to being a substrate for SSH1L, Coronin 1B is required for proper targeting of SSH1L to lamellipodia where it likely regulates filament turnover by activating Cofilin. Consistent with this idea, depletion of Coronin 1B increased cellular levels of phospho-Cofilin and expression of an activated Cofilin mutant partially suppressed the effects of Coronin 1B knockdown on lamellipodia dynamics. Together, our data suggest that Coronin 1B coordinates Arp2/3 and Cofilin activity at the leading edge.

273

WHAMM is an Arp2/3-activating Protein That Interacts with Dynamic Endomembrane Compartments and Microtubules
K. G. Campellone, N. J. Webb, E. A. Znameroski, M. D. Welch; Molecular and Cell Biology, UC Berkeley, Berkeley, CA

The Arp2/3 complex, a critical actin nucleator that functions in a variety of essential cellular processes, is regulated by a family of proteins called nucleation-promoting factors (NPFs). Mammalian cells express several well-characterized NPFs including the WASPs (WASP and N-WASP) and the WAVEs (Scar/WAVE1-3), which control actin nucleation during distinct cellular functions including endocytosis and lamellipodial protrusion. Given the important roles of NPFs in modulating actin dynamics, we sought to identify additional family members, and have uncovered a novel class of mammalian NPFs comprised of two proteins: JMY and WHAMM (WHAMM Homologue associated with Actin Membranes and Microtubules). Each contains a C-terminal WCA segment conserved among other NPFs, a central region predicted to form coiled-coils, and an N-terminal domain of unknown function. Both full-length WHAMM and its isolated WCA region stimulate Arp2/3-mediated actin assembly in vitro, confirming it possesses NPF activity. In cultured fibroblasts, WHAMM localizes primarily to a perinuclear Golgi-related membrane compartment, and to peripheral tubulo-vesicular structures that can reside along microtubules, patterns not observed for other NPFs. Consistent with a role in membrane trafficking, cellular expression of GFP-WHAMM revealed that WHAMM-associated structures are highly dynamic and that WHAMM induces actin assembly in proximity to internal membranes. Moreover, cellular expression at high levels of GFP-WHAMM exhibit a dramatic disruption of their Golgi networks. Pharmacological agents that perturb membrane transport, microtubule dynamics, or actin polymerisation interfere with WHAMM localisation and/or movement of WHAMM-associated membranes, indicating that crosstalk between both cytoskeletal components and internal membranes is related to WHAMM function. Cellular expression of truncated WHAMM derivatives indicates that its C-terminal WCA segment is required for actin assembly, its N-terminal domain associates with perinuclear membranes, and its central coiled-coil region bundles microtubules. In summary, our studies suggest a role for WHAMM in coordinating membrane dynamics with actin- and tubulin-based cytoskeletal elements.

274

P. K. Mattila, A. Pykäläinen, J. Saarikangas, V. O. Pasilainen, P. Lappalainen; University of Helsinki, Institute of Biotechnology, Helsinki, Finland

Regulators of actin dynamics, Missing-in-Metastasis (MIM) and IRSp53, share a similar domain structure to each other. Expression of full-length MIM/IRSp53 or their dimeric C-terminal IM/IRSp53/MIM-domain promotes filopodia/microspike formation in cultured mammalian cells. Filopodia formation was proposed to result from IM-domain’s F-actin bundling activity and its interactions with Rho family GTases. Here, we provide evidence that neither actin bundling nor GTase binding contributes to filopodia formation by MIM. Instead, our data shows that IM-domains bind P(4,5)P2 and cross-link P(4,5)P2-rich membranes. Consistently, IM-domain localizes to the interface between plasma membrane and F-actin bundles in filopodia. IM-domain of MIM is also capable of drastically deforming P(4,5)P2-rich membranes. Systematic metausgenesis analysis revealed that MIM’s IM-domain interacts with lipids through a similar mechanism to the structurally related BAR (Bin-Amphiphysin-Rvs) domains, and that its actin-binding sites are composed of large basic patches near the distal ends of the dimeric domain. Together, these data show that IM-domain is a distant, functional member of lipid-binding BAR domain family and may promote filopodia formation through a novel mechanism involving F-actin cross-linking to the plasma membrane.

Rho Kinase Differentially Regulates Phosphorylation of Nonmuscle Myosin II Isotypes A and B during Cell Rounding and Migration
J. C. Sandquist, K. I. Swenson, K. A. DeMali, A. R. Means; 1 Department of Pharmacology and Cancer Biology, Duke University, Durham, NC, 2 Department of Cell and Developmental Biology and Lineberger Comprehensive Cancer Center, University of North Carolina, Chapel Hill, NC

The actin-myosin cytoskeleton is generally accepted to produce the contractile forces necessary for cellular processes such as cell rounding and migration. All vertebrates examined to date are known to express at least two isoforms of non-muscle myosin II, referred to as myosin IIA and myosin IIB. Studies of myosin IIA and IIB in cultured cells and null mice suggest that these isoforms perform distinct functions. However, each myosin II isotype contributes individually to all the cellular functions attributed to “myosin II” has yet to be fully characterized. Using isoform specific small-interfering RNAs we found that depletion of either isoform resulted in opposing migration phenotypes, with myosin IIA- and IIB-depleted cells exhibiting higher and lower wound healing migration rates, respectively. In addition, myosin IIA-depleted cells demonstrated impaired thrombin-induced cell rounding and undertook a more motile morphology, exhibiting decreased stress fibers and focal adhesions, with concomitant increases in cellular protrusions. Cells depleted of myosin IIIB, however, were efficient in thrombin-induced cell rounding, displayed a more retractive phenotype and maintained focal adhesions, but only in the periphery. Lastly, we present evidence that Rho kinase preferentially regulates

134
phosphorylation of the regulatory light chain associated with myosin IIA. Our data suggest that the myosin IIA and IIB isoforms are regulated by different signaling pathways to perform distinct cellular activities, and that myosin IIA is preferentially required for Rho-mediated contractile functions. J.C.S. is a Howard Hughes Medical Institute Predoctoral Fellow. K.A.D Present address: Department of Biochemistry, University of Iowa, Iowa City, IA 52242; USA.

731 The Eukaryotic mRNA Cycle: Movement of Yeast mRNAs between Polysomes and P-bodies and Its Role in the Control of Translation and Degradation R. Parker; Department of Molecular and Cellular Biology, HHMI/University of Arizona, Tucson, AZ

Translational control is an important aspect of the regulation of gene expression in eukaryotic cells. In addition to the translating pool of mRNA associated with polysomes, recent experiments have defined cytoplasmic foci, referred to as P-bodies, wherein untranslated mRNAs accumulate and where mRNA decapping and decay can occur. Several lines of evidence indicate that yeast mRNAs within P-bodies can also return to translation. For example, reporter mRNAs exit translation and concentrate in P-bodies when translation initiation is blocked, and resume translation...
and exit P-bodies when translation is restored. These results define a cycle of mRNA movement wherein mRNAs travel from polysomes to P-bodies and then back to the translating pool. This mRNA cycle has several important properties and identifies three critical decision points in controlling the function of mRNAs: 1) the mechanism of targeting transcripts to P-bodies, 2) deciding the fate of transcripts within P-bodies, and 3) the mechanism by which transcripts return to translation. Importantly, proteins required for the accumulation of mRNAs in P-bodies also function in global translation repression in yeast, mRNA repression in metazoa, and in the regulation of translation in neurexins. This suggests that translation repression by sequestration into P-bodies is competitively balanced with translation in many biological contexts.

732 Analyzing the Function of Microtubule Localized RNAs during Mitosis
M. D. Blower,1 R. H. Head1; K. West2; M. M. Pettersen,2 1Molecular Biology, Massachusetts General Hospital, Boston, MA, 2Molecular and Cell Biology, University of California, Berkeley, Berkeley, CA

Accurate segregation of chromosomes during mitosis and meiosis is required for organismal development and viability, and depends on the assembly and function of a dynamic mitotic spindle that orchestrates chromosome movements. Previous work has demonstrated that several proteins involved in RNA metabolism (Rae1, Maskin, and CPEB) are localized to the mitotic spindle and contribute to spindle assembly. Furthermore, we have shown that RNA is localized to mitotic microtubules in Xenopus egg extracts, and contributes to spindle assembly in a translation independent manner that may reflect a structural role. We have found that several different types of microtubule-associated RNA are present on the spindle including ribosomal RNA and messenger RNA (mt-mRNA). We have used Affymetrix gene chip microarrays to determine which mRNAs are specifically enriched on the mitotic spindle in both Xenopus and human cell extracts. We have found that a conserved set of mRNAs are localized to the microtubules during mitosis and that a subset of these mRNAs are actively translated on microtubules. Another set of mt-mRNAs appears to be present in inactive storage granules, and these mRNAs appear likely to regulate various aspects of development. While translation of RNA is not required for spindle assembly in egg extracts, our preliminary results suggest that local, mitotic translation of mt-mRNAs is likely to regulate various aspects of mitosis and cell cycle progression. We will present the results of experiments investigating how mt-mRNAs are targeted to the spindle, and the functional importance of spindle-localized protein translation. These experiments should provide insight into the role of mt-mRNAs during mitosis and development.

733 Dissecting the Links between Genes, Nuclear Periphery, and Post-transcriptional mRNP
J. Chekanova,1 K. Abruzzi,1 M. M. Rosbash,2 D. Belostotsky2,1 Biological Sciences, State University of New York at Albany, Albany, NY, 2School of Biological Sciences, University of Missouri—Kansas City, Kansas City, MO

Nuclear surveillance pathways ensure that eukaryotic mRNPs is properly processed and assembled into export-competent mRNPs prior to export to the cytoplasm. As a consequence, mRNA processing defects in mutant strains frequently lead to RNA retention within nuclei. Moreover, this often occurs in discrete nuclear foci detectable by FISH, i.e., mRNA-containing nuclear dots. Here we study this phenomenon in a wild-type strain background, using an integrated GAL reporter gene containing a cis-acting mutation that impairs 3′ end processing. We find that nuclear dots contain non-nascent mRNA that are tethered to, yet distinct from the site of their synthesis. Remarkably, the dot-genome tether is not strictly dependent on ongoing transcription.1 Furthermore, the dot-gene tether is related to another tether that links transcriptionally active GAL loci with the nuclear periphery. Surprisingly, this second tether is also independent of ongoing transcription. Additional experiments suggest that the dot and its post-transcriptional mRNP contribute to the tether that links the gene to the nuclear periphery. Finally, a genetic screen has identified candidate factors that collaborate with the dot mRNP and contribute to the gene-dot as well as the dot-pore tether.1 EMBO J., in press.

734 Promotion of Postsynaptic Differentiation by Neurexin Isoforms
Y. Kang,1 T. X. Zhang,1 F. A. Dobie,1 H. Wu,1 A. Craig2;1 Brain Research Centre, University of British Columbia, Vancouver, BC, Canada, 2Anatomy & Neurobiology, Washington University, St. Louis, MO

Development of synaptic connections between nerve cells is precisely regulated to control the number and location of different synapse types. The two main synapse types in the mammalian brain are excitatory glutamate and inhibitory GABA synapses. Neurexins and neurelinos are cell adhesion molecules found at both glutamate and GABA synapses. Both partners have synaptogenic activity: neurelinos presented to axons induce presynaptic vesicle clustering, while neurexins presented to dendrites induce clustering of neurotransmitter receptors and postsynaptic scaffolding molecules. There are multiple isoforms of both neurexins and neurelinos generated from multiple genes and by alternative splicing. α-neurexins contain multiple LNS domains whereas β-neurexins generated from a downstream promoter contain a single LNS domain. Here we report on the expression patterns, neurelin binding, and synaptogenic activity of different neurexin isoforms. Synaptogenic activity was measured as the ability of each neurexin isoform expressed on COS cells to induce clusters of postsynaptic proteins in contacting dendrites of cocultured hippocampal neurons. β-neurexins promoted clustering of both glutamate and GABA postsynaptic proteins. Insertion of alternatively spliced residues at splice site 4 of β-neurexins, in the LNS domain, selectively reduced its ability to cluster glutamate postsynaptic proteins. Insertion at site 4 also reduced binding to neurelin-1, which normally localizes to glutamate synapses, but not to neurelin-2, which normally localizes to GABA synapses. RT-PCR from hippocampal culture and developing rat brain showed a developmental increase in the fraction of neurexins lacking the S4 insert. Surprisingly, preliminary results in the coculture assay revealed even greater selectivity of α-neurexins for inducing clustering of GABA but not glutamate postsynaptic proteins. These results indicate selective roles for different neurexin isoforms at glutamate versus GABA synapses. Together with data from other labs, our results suggest that the neurexin-neurelin-synaptic complex may be as or more important for development of GABA synapses compared with glutamate synapses.

735 The "Filopodial Scaffolding" Hypothesis: Synaptogenesis in Drosophila Embryo Requires Corroboration of Both Filopodial Clustering and Postsynaptic Scaffolding Protein Dlg, F. Carrero-Martinez,1 M. Farrer,1 E. Suzuki,1 A. Chiba1;2 Department of Biology, University of Puerto Rico, Mayaguez, PR, 2Department of Cell and Developmental Biology, University of Illinois at Urbana-Champaign, Urbana, IL, 3National Institute of Genetics, Mishima, Shizuoka, Japan

Targeting cytosolic molecules to membrane is an extremely effective means to enhance (“activate”) their functions. Previously, due to limited access in embryos, the mechanisms that initiate a new synapse have rarely been analyzed in vivo. Here we dissect the process using uniquely identified synapses in Drosophila and offer a model that integrates both cellular and molecular components. Using GFP-labeling, we show that every neuromuscular synaptogenesis in live embryos is preceded by a transient stabilization/clustering of presynaptic and postsynaptic filopodia from matched partners upon their initial contact. Filopodial interactions between non-partner cells, though extensive and essential for proper axon guidance, do not lead to such a filopodial behavior. Overexpression of a dominant-negative Ezrin in targets eliminates this filopodial clustering and, thereby, blocks synaptogenesis. Immuno-SEM that separately labels presynaptic filopodia vs. postsynaptic filopodia reveals their extensive mutual interdigitiation as well as a narrow (50 nm) membrane-wrapped cytoplasmic space in individual filopodia. One of the first presynaptic cytosolic molecules that enter this filopodial cytoplasm is Dlg, a member of PSD-95 family scaffolding proteins. The special subcellular environment at the filopodial cluster makes Dlg practically “targeted” to the membrane where transmembrane adhesion/signaling molecules appose their counterparts on the presynaptic side, amplifying the probability of their molecular signaling and complexing. Previous work indicates a strong maternal effect that masks Dlg knockout phenotypes in embryos. By using a temperature-sensitive allele and a dominant-negative Dlg, we uncover the role of postsynaptically expressed Dlg during synaptogenesis. Although not essential for the formation of the filopodial cluster, Dlg is required to maintain the contact between the axon and target while nascent synapse progressively attains its functionality. We propose that synaptogenesis is a predictable outcome which follows from the filopodial interdigitation between a pair of synaptic partners that activates scaffolding proteins: the “filopodial scaffolding” hypothesis of synaptogenesis.

The Polarity Proteins PAR-6 and aPKC Are Required for Dendritic Spine Morphogenesis
H. Zhang, I. G. Macara; Center for Cell Signaling, University of Virginia, Charlottesville, VA

Dendritic spines are small protrusions that serve as primary sites of excitatory synaptic transmission in the CNS. Despite their importance in integrating information flow in the brain, the molecular mechanisms regulating spine morphogenesis are not well understood. Since spines are highly polarized structures, we hypothesize that proteins required for global cell polarity are also necessary for spine formation. We previously showed that the polarity protein PAR-3 regulates spine formation through spatially restricting the Rac guanine nucleotide exchange factor Tiam1. Interestingly, this process functions independently of PAR-3’s binding partners PAR-6 and aPKC Homologous Ras Protein Kinase C (aPKC). Here we show that PAR-6 and aPKC are also essential for spine morphogenesis, but their actions are distinct from those of PAR-3. Endogenous PAR-6 localizes to dendritic spines and redistributes away from spines upon synaptic activation. Overexpression of PAR-6 promotes the formation of mature spines, whereas knockdown of endogenous PAR-6 inhibits their formation. The effects of PAR-6 are dependent on its PDZ and aPKC binding domains but not on its ability to bind Cdc42. Furthermore, overexpression of PKCζ produces a phenotype reminiscent of PAR-6 overexpression, whereas knockdown of PKCζ inhibits spine formation. Taken together, these results suggest an essential role for PAR-6 in regulating spine formation that is mediated by aPKC.
Post-synaptic Signaling of New Players at the Synapse

N. Y. Ip; Department of Biochemistry, Hong Kong University of Science and Technology, Kowloon, Hong Kong, China

Neurons communicate with each other at synapses. During the past decade, enormous progress has been made in identifying and characterizing the molecular players at the post-synaptic side of synapses. Several receptor tyrosine kinases (RTKs), such as ErbB, MusSK, Ephs and Trks, have been demonstrated to play pivotal roles in synaptic development and functions. At the neuromuscular synapse, for example, activation of MusSK by agrin leads to the clustering of acetylcholine receptors while TrkB activation is involved in the stabilization of these receptors. Recent evidence suggests that Ephs, the largest family of receptor tyrosine kinases, and their ligands, ephrins, are important in the formation and maintenance of excitory synapses in the central nervous system. While EphBs are important for promoting dendritic spine morphogenesis, EphA signaling mediates spine retraction. Activation of EphB by ephrinBs transduces signals that elicit local changes in small GTPase activity leading to actin rearrangement and in turn induces spine protrusions. While activation of EphA4 has been reported to result in dendritic spine retraction in hippocampal slices, the underlying mechanisms are not well understood. We recently demonstrate that cyclin-dependent kinase 5 (Cdk5), a member of the Cdk family, mediates the downstream signaling of EphA4 activation at hippocampal synapses. Importantly, activation of EphA4 enhances Cdk5 activity which in turn stimulates RhoA GTPase and contributes to spine morphogenesis. Thus, while early studies on EphA4 and Cdk5 focused on the roles in axon guidance, our findings reveal an important role of Cdk5 in the regulation of EphA4-dependent regulation of synaptic structure and functions. This work was supported in part by the Research Grants Council of Hong Kong (HKUST 6131/02M, 6119/04M, 6421/05M and 3/03C) and the Area of Excellence Scheme of the University Grants Committee (AoE/B-15/01).

Visualization of Synaptic Protein Synthesis and Accumulation Using a Novel Chemically Controllable Reporter of Protein Age

M. Z. Lin, R. Y. Tsien; UCSD, La Jolla, CA

Spatial regulation of synaptic protein turnover, including local protein synthesis and degradation, is believed to play a crucial role in the structural plasticity of synapses and in the maintenance of long-term potentiation. Recently, studies of local protein turnover in cell culture have been facilitated by optical reporters of protein translation and methods for pulse-chase protein labelling. However, existing methods either do not recapitulate regulation of protein localization or other aspects posttranslational control, or are difficult to adapt to living animals. We have developed TimeSTAMP, a drug-controlled method for the Time-Specific Tagging and Age Measurement of Proteins with spatial specificity. This method has a high signal-to-noise ratio, can be used to tag proteins while preserving mechanisms of posttranslational regulation, and is compatible with slice preparations or freely behaving animals. We are currently applying the TimeSTAMP method to visualize the turnover of synaptic components at synapses under various stimulation conditions, and to perform retrospective analyses of the spatial distribution of synaptic growth events in intact neuronal networks.

Neural F-box Protein Scraper Regulates Synaptic Vesicle Release

I. Yao,1 H. Ageta,1 H. Takagi,1 T. Kihara,1 K. Inokuchi,1 M. Setou1,2; 1Mitsubishi Kagaku Institute of Life Sciences, Tokyo, Japan, 2National Institute for Physiological Sciences, Okazaki, Japan

The ubiquitin-proteasome system (UPS) has important functions in various cellular events. Recently, UPS has emerged as a key regulator of synaptic development and function. However, the relationships between the synaptic plasticity and UPS are not fully understood. Here, we report an ubiquitin-ligase Scraper which regulates the short term synaptic plasticity and protein turnover in the brain. The Scraper knockout mice have decreased paired pulse facilitation (PPF), accompanied with increased frequency of miniature excitatory postsynaptic currents (mEPSC), fast synaptic vesicle depletion, a smaller readily releasable pool (RRP) of synaptic vesicles. Scraper ubiquitinates the synaptic vesicle priming factor RIM1 for proteasomal degradation both in vitro and in vivo. Our results demonstrate the essential roles of Scraper dependent UPS in the short term synaptic plasticity, via the regulation of synaptic vesicle release.

Localized Sphingoid Base Generation Helps Recruit and Activate the Ypk1/2 Signaling Cascade

J. L. Brace,1 E. L. Weiss,1 C. M. Rudin;1 Biochemistry, Molecular Biology and Cell Biology, Northwestern University, Evanston, IL, 2Sidney Kimmel Comprehensive Cancer Center, Johns Hopkins, Baltimore, MD

Signal transduction pathways allow cells to respond efficiently to environmental cues and promote cellular adaptation to environmental changes. Sphingoid bases activate a signaling cascade initiated by the kinases Pkh1 and Pkh2. These kinases, which are related to mammalian PDK1, activate the AGC family of kinases, including Ypk1/2, Pkc1 and Sch9, which in turn regulate growth-controlled pathways. This function of Svf1 has an interesting parallel in the JNK cascade initiated by the kinases Pkh1 and Pkh2. These kinases, which are related to mammalian PDK1, activate the AGC family of kinases, including Ypk1/2, Pkc1 and Sch9, which in turn regulate growth-controlled pathways. Our results indicate that PP2B play a functional role in the regulation of c-Jun-induced cell transformation. This work was supported in part by the Research Grants Council of Hong Kong (HKUST 6131/02M, 6119/04M, 6421/05M and 3/03C) and the Area of Excellence Scheme of the University Grants Committee (AoE/B-15/01).

Regulation of c-Jun N-terminal Kinase (JNK) and p38 upon Contact Inhibition

D. Hutter, J. Saksa, M. Slasz, E. Rothenberger; Biology, Monmouth University, West Long Branch, NJ

The c-Jun N-terminal kinase (JNK) and p38 pathways are mitogen-activated protein (MAP) kinase pathways known to have roles in growth control and apoptosis in normal mammalian cells. However, little is known about the role of negative regulation of these pathways by MAP Kinase Phosphatases (MKPs). To investigate the role of MKPs in the regulation of JNK and p38 during the transition to a contact inhibited state, cultures of normal fibroblast cells (BJ) and fibrosarcoma cells (HT-1080) were grown to different stages of confluency. The levels of MKP-1 expression and the amount of active MAP kinase proteins in the fibroblast cultures were assessed through western blot analysis and compared to those of the fibrosarcoma cultures. In normal fibroblasts, the level of MKP-1 protein is increased upon contact inhibition. Concurrently, the amount of total JNK is higher in subconfluent cells than in confluent cells, while density-dependent regulation of JNK or MKP-1 is not seen in fibrosarcoma cultures. Preliminary data indicate that the total level of p38 protein is not altered upon contact inhibition in normal fibroblasts. Further experimentation will delineate if the activation of JNK or p38 is influenced by contact inhibition and the causal relationship between MKP activity and growth control.

PP2B-mediated c-Jun C-terminus Dephosphorylation is Required for c-Jun-induced Cell Transformation

C. Huang; The Institute of Basic Medical Sciences, College of Medicine, National Cheng Kung University, Tainan, Taiwan

The proto-oncogene c-Jun is one of the components of AP1 that mediates cell proliferation, survival and death. The protein stability and the DNA binding affinity of c-Jun is regulated by C-terminal phosphorylation and the amount of active MAP kinase proteins in the fibroblast cultures were assessed through western blot analysis and compared to those of the fibrosarcoma cultures. In normal fibroblasts, the level of MKP-1 protein is increased upon contact inhibition. Concurrently, the amount of total JNK is higher in subconfluent cells than in confluent cells, while density-dependent regulation of JNK or MKP-1 is not seen in fibrosarcoma cultures. Preliminary data indicate that the total level of p38 protein is not altered upon contact inhibition in normal fibroblasts. Further experimentation will delineate if the activation of JNK or p38 is influenced by contact inhibition and the causal relationship between MKP activity and growth control.

PP2B-mediated c-Jun C-terminus Dephosphorylation is Required for c-Jun-induced Cell Transformation

E. Kiyokawa, T. Nishioka, K. Hikake, H. Yoshizaki, M. Matsuda; Department of Pathology, Kyoto University, Kyoto, Japan

Phosphoinositides (PIs) are a family of phospholipids containing myo-inositol as their head group. Despite a relatively low abundance in biological membranes, PIs have been reported to regulate a myriad of cellular process owing to their metabolic turnover. Phosphatidylinositol PtdIns (4,5) biphosphate [PI(4,5)P₂] is a major PIP, derivative from Pts, and is mainly located in the inner leaflet of the plasma membrane. Upon growth factor stimulation, intracellular second messengers, such as inositol 1,4,5-triphosphate (IP₃), diacylglycerol (DGIDA) and diacylglycerol (DGIDA), are generated from PI(4,5)P₂. Localization of these second messengers has been assessed by the expression of GFP-tagged proteins which are able to interact to them. When they are over-expressed, however, these probes tend to accumulate in membrane structures such as ruffles. To understand the accurate spatio-temporal regulation of PI (4,5)P₂ and DG, we developed probes for PI(4,5)P₂, [PipP,4(5)P₂] and [PipP,4(5)P₂] and diacylglycerol (DIIDAs) based on the principle of fluorescent energy transfer (FRET). PipP-PI(4,5)P₂ and DGIDA consist of the PH domain from PLCg and the C1 domain from PKCδII, respectively, sandwiched between GFP and YFP. To localize these probes to the plasma membrane, the C-terminal sequence from K-Ras was utilized. FRET efficiency of PipP-PI(4,5)P₂ and DGIDA decreased within 5 minutes after platelet-derived growth factor (PDGF) stimulation. The time course of FRET alteration showed inverted correlation to the amount of PI(4,5)P₂ production and PLCg phosphorylation. On the other hand, FRET efficiency of PipP-PI(4,5)P₂ was observed on the plasma membrane of the entire cell, while that of DAG was limited to the nascent lamellipodia. These data suggest that lipid second messengers are regulated by spatially different mechanisms.

Ectopic Expression of COX-2 Induces Dedifferentiation in Rabbit Articular Chondrocytes

H. Tokuda,1 A. Iida, 2 H. Nishino 1; 1Molecular Biochemistry, Kyoto Prefectural University of Medicine, Kyoto, Japan, 2Pharmacology, Takasaki University of Health and Welfare, Takasaki, Japan

Many researchers have been studying the mechanism of growth factor and cytokine in hypertrophied muscle by exercise; however, the communication mechanism between the growth factor and cytokine of the cells in the control muscle tissues remains unknown. In this study, we carried out an experiment to study the cell communication mechanisms by the observation of Notch and Delta Notch activity was increased in hypertrophied soleus muscle by tenotomy. Notch was localized on the plasma membrane of small fibers and small cells but not found in large fibers of hypertrophied muscle or in the control muscle tissues. Delta activity was increased in hypertrophied soleus muscle. Delta was localized on the plasma membrane of small fibers and small cells in the hypertrophied muscle, and it was also slightly observed in the control muscular tissues. Based on the above result, we conclude that Notch and Delta appear not only in stem cells and satellite cells, but also in thin muscle fibers of hypertrophied muscle tissues, and moreover, they seem to take the roles of communication between the cells for induction of muscle hypertrophy.

Growth Inhibitory Effects of Brazilian Herbal Medicine Against Human Breast and Lung Cancer Cells

M. L. Petreaca, M. Yao, M. Martins-Green; Cell Biology and Neuroscience, University of California, Riverside, Riverside, CA

The angiogenic chemokine Interleukin-8 (IL-8/CXCL8) promotes endothelial cell de-adhesion and contraction during early stages of angiogenesis, thereby increasing endothelial permeability. This chemokine can transactivate Vascular Endothelial Growth Factor Receptor-2 (VEGFR2/FK/RK/KDR) in human microvascular endothelial cells, and this transactivation is critical for IL-8-induced permeability. However, in this study, we show that IL-8 stimulates phosphorylation in a dose-dependent manner, and this phosphorylation occurs by receptor transactivation because it is blocked by an inhibitor of VEGFR2 tyrosine kinase activity but not by an inhibitor of the VEGF-receptor binding site. We therefore investigated possible mechanisms involved in IL-8-mediated VEGFR2 transactivation and found, using co-immunoprecipitation assays, that VEGFR2 forms complexes with the IL-8 receptors CXCR1 and CXCR2 after IL-8 treatment with a time course compatible to that of VEGFR2 phosphorylation. Furthermore, because previous studies have identified the Src family of kinases as having key roles in various transactivation events, we also elucidated the importance of these kinases in IL-8-induced VEGFR2 transactivation and receptor complex formation. We found that an inhibitor of Src kinases prevents IL-8-induced permeability, VEGFR2 phosphorylation, and receptor complex formation, showing that Src activity is essential in these events. We then investigated the mechanism(s) whereby VEGFR2 mediates IL-8-induced permeability, focusing upon RhoA; RhoA is critical in stimulation of permeability, and we have shown previously that IL-8 stimulates RhoA activation. We performed GST-TRBD pull-down assays, which isolate active RhoA, in combination with a VEGFR inhibitor and found that the observed IL-8-induced RhoA activation is dependent upon VEGFR2. Because IL-8 and VEGF function in pathological permeability events in vivo, inhibition of specific signaling pathways downstream of VEGFR2 may serve as effective treatments for excessive permeability caused by either or both factors.

Growth Inhibitory Effects of Brazilian Herbal Medicine Against Human Breast and Lung Cancer Cells

H. Tokuda, A. Iida, H. Nishino; 1Molecular Biochemistry, Kyoto Prefectural University of Medicine, Kyoto, Japan, 2Pharmacology, Takasaki University of Health and Welfare, Takasaki, Japan

Tabebuia avellanedae (Bignoniaceae) (TA), which is native in South America from Brazil to northern Argentina, is well known in traditional folk medicine used for the treatment of various disease including breast cancer. In this study, we investigated the growth inhibitory activity of TA against breast and lung cancer cells. We performed MTT assay and thereby acted as a chemopreventive agents against carcinogenic compounds. In this study, we report the growth inhibitory activity of TA against breast and lung cancer cell lines.

Ectopic Expression of COX-2 Induces Dedifferentiation in Rabbit Articular Chondrocytes

L. Won Kil, Y. Seon Mi, Y. Eun Kyung, L. Ji Hye, O. Su Kil, K. Song Ja; Kongju National University, Gongju, Republic of Korea

Arthritic joints produce large amounts of PIs (which are involved in cartilage inflammation). The rate-limiting step of PG production is the initial conversion of arachidonic acid to PGJ₂ by cyclooxygenases (COX). Therefore, we have investigated the role of COX-2 protein on differentiation in rabbit articular chondrocyte. A previous study from our lab identified that IL-1β increased expression of COX-2 and induced dedifferentiation. Ectopic expression of COX-2 was sufficient to cause dedifferentiation in articular chondrocytes as determined by the expression of type II collagen via Aicn transfection and Western blot. Also, COX-2 overexpression caused suppression of SOX-9 expression, a major transcription factor that regulates type II collagen expression, as identified by the Western blot and RT-PCR. And then, we were identified that COX-2 overexpression inhibited type II collagen expression in articular chondrocytes by immunohistochemistry. However, Inhibition of COX-2 activating PDBT(NF-κB inhibitor) causes dedifferentiation as demonstrated by the enhancement type II collagen and SOX-9 expression by the Western blot. Our results collectively suggest that COX-2 overexpression causes dedifferentiation in articular chondrocytes through NF-κB pathway. To determine whether overexpression of COX-2 also caused similar dedifferentiation in zebrafish embryo, COX-2 cDNA was transiently transfected in zebrafish.

ERK-1/2 Regulate That 15-Deoxy-delta12,14-Prostaglandin J2-induced Cyclooxygenase-2 Expression and Dedifferentiation in Rabbit Articular Chondrocyte via NFκB Independent Pathway

J. Lee, S. Y. Wu, W. Lee, E. Yoon, C. Shin, S. Kim; Kongju National University, Gongju, Republic of Korea

 Peroxisome proliferators-activated receptors (PPARs) is a protein which belong to ligand-activated nuclear receptor family. It activate transription by means of various ligands that exist endogenous and exogenous. Nevertheless, physiological function of PPARα is not clear. Therefore, we investigated effect of PPARα in dedifferentiation in articular chondrocyte with 15d-PGJ2 and 15d-PGJ2. We found that 15d-PGJ2 induced COX-2 expression and dedifferentiation in chondrocyte with time/dose-dependent manner. Also, 15d-PGJ2 increased peroxisome proliferators response element (PPRE) luciferase activity and BADGE (Bisphenol A diglycidyl ether), the antagonist of PPARα, abolished it. These result indicates that effect of 15d-PGJ2 depend on PPARα activation. We found that 15d-PGJ2 activate ERK-1/2 rapidly. Treatment of PD98059, inhibitor for ERK-1/2, prevented from 15d-PGJ2 induced dedifferentiation and inflammation. Our findings demonstrate that 15d-PGJ2 regulate dedifferentiation and COX-2 expression regulated via ERK-1/2.
pathway. But these regulation caused by 15d-PGJ2 seems to be independent from NFXb pathway, well known as important COX-2 regulation signal. Thus, these study exhibit that adjustment of PPARγ signaling pathway may offer novel approach for therapeutic inhibition of degradation on articular chondrocyte.

749 Regulation Mechanism of Phospholipase C(PLC)-η in Neuronal Cells

N. Oh, K. Heo, P. Suh, S. Ryu; Life Science, POSTECH, Pohang, Republic of Korea

PLC (Phospholipase C) catalyzes the hydrolysis of phosphatidylinositol 4,5-bisphosphate (PIP2), generating inositol 1,4,5-triphosphate (IP3) and diacylglycerol (DAG) which play key roles in cell signaling. To date, many studies have shown how various PLC isoforms are activated and regulated in distinct ways. However, regulation mechanism of PLC-η, a novel PLC isoform, has yet to be known. In the present study, we tried to find the binding proteins of PLC-η and elucidate how they are regulated. As a result, we identified novel proteins which interact with PLC-η. Also, PLC-η was phosphorylated by serotonin, and intracellular Ca2+ level increased in PLC-η-overexpressing cells. Then we observed that Akt and Erk were activated in PLC-η-overexpressing stable cell line when several extracellular signalling molecules were added. Finally, several G protein coupled receptor (GPCR) ligands effectively activated PLC-η. Taken together, PLC-η may be activated through GPCR pathway, and its activity is regulated by phosphorylation.

750 Phosphatase of Regenerating Liver (PRL)-3 Regulates IGF-1 Signaling in 293T Cells

D. C. Besette, C. J. Pallien; 1Pathology and Laboratory Medicine, University of British Columbia, Vancouver, BC, Canada, 2Paediatrics, University of British Columbia, Vancouver, BC, Canada

Protein of regeneration liver (PRL-3) is a member of a novel subfamily of protein tyrosine phosphatases (PTPs) that possess a C-terminal CAAX box motif involved in prenylation-dependent membrane targeting of these proteins. PRL-3 is consistently upregulated in a panel of liver metastases derived from colon carcinomas while exhibiting low expression in primary tumors and little to no expression in normal colon epithelia. Furthermore, overexpression of PRL-3 promotes cell migration and invasion abilities, and permits formation of metastases in vivo. However, little is known of PRL-3-mediated cellular signaling pathways. Because of the role of insulin-like growth factor (IGF) signaling in cancer, we investigated the role of PRL-3 in mediating IGF-1 signaling. IGF-1 signaling can activate either MAPK signaling or Akt signaling depending on the molecules that interact with the IGF-1 receptor (IGF-1R). Phosphorylation of Akt on Ser473 and Thr380 is required for activation and is unchanged by the presence of PRL-3, suggesting PRL-3 does not affect Akt activation. In contrast, Erk phosphorylation induced by IGF-1 stimulation is decreased by approximately 40% in the presence of exogeneous PRL-3. A catalytic inactive PRL-3 mutant does not change Erk phosphorylation compared to parental cells, suggesting PRL-3 catalytic ability is responsible for its signaling effects. This effect is specific for Erk as neither the JNK nor p38 MAPKs are affected by PRL-3 expression. Upstream signaling events leading to Erk activation are being investigated to further elucidate the role of PRL-3 in IGF signaling. Determining the molecular action of PRL-3 in regulating cellular activities will provide important insight into its role in metastasis and cancer, and, possibly, identify new targets for therapeutic interventions in advanced disease.

753 Stat1 Is Required for Oxysterol-induced Apoptosis in Macrophages

S. Agrawal, T. Choudhuri, G. Stark, G. Chisolm; 1Cell Biology, Cleveland Clinic, Cleveland, OH, 2University of Cincinnati College of Medicine, Cincinnati, OH, 3Molecular Genetics, Cleveland Clinic, Cleveland, OH

Atherosclerosis is an inflammatory disease of major arteries that lead to coronary occlusion. The disease is characterized by accumulation of oxidized lipoprotein and monocyte-derived macrophages in early stages and later, the development of a necrotic core. Apoptotic and necrotic macrophages and macrophage-derived foam cells can be readily detected in lesions. 7-ketocholesterol (7KC) is a major oxysterol formed on oxidized low-density lipoprotein (oxLDL) and it accumulates in atherosclerotic lesions. 7KC induces apoptosis in a variety of cells, including macrophages, in vitro. 7KC induces apoptosis in similarity-concentrated dependent manner in human THP-1 monocyte/macrophage-like cells whether unidentified, differentiated or after oxLDL treatment to form foam cells. Using a specific DNA decoy to block DNA binding to the transcription factor Stat1 in human THP-1 cells or comparing macrophages from wild type and Stat1-/- mice, we found that inhibition of Stat1 significantly blunted 7KC-induced apoptosis. ApoE-/- and Stat1-/- mice were lethally irradiated and transplanted with bone marrow from either apoE-/- or apoE-/-Stat1-/- mice. After feeding an atherogenic diet for 14 wk, cells in aortic root atherosclerotic lesions from apoE-/-Stat1-/- bone marrow recipient mice showed less apoptosis (by TUNEL) and caspase3-activation than those from apoE-/- recipients. Thus, Stat1 is an important pro-apoptotic signaling molecule in macrophages in vitro and in atherosclerotic lesions in vivo. Identification of the essential signaling events of apoptosis that pertain in vivo could suggest targets for therapeutic intervention. This project is supported by National Institute of Health Grant NIH HL29582.

754 Overexpression of the Type I Phosphatidylinositol 4-phosphate 5-kinase Alpha Produces a Defect in Store-operated Calcium Entry in RBL-2H3 Mast Cells

L. Vasudevan,1 A. Wiesner,2 A. Jeromin,2 B. Baird,2 D. Holowka; 1Molecular Biology and Genetics, Cornell University, Ithaca, NY, 2Chemistry and Chemical Biology, Cornell University, Ithaca, NY, 3Center for Learning and Memory, University of Texas, Austin, TX

Allergic reactions are triggered when multivalent antigens crosslink IgE-FcεRI complexes in mast cells. The hydrolysis of phosphatidylinositol 4,5-bisphosphate (PIP2) and mobilization of calcium are important in this signaling pathway to activate release of inflammatory mediators, synthesis of cytokines, and to produce morphological changes such as ruffling. To examine the roles of PIP2, in these processes, we stably overexpressed HA-tagged WT type I phosphatidylinositol 4-phosphate 5-kinase alpha (PIPS-5-kinase Iα) and a catalytically inactive mutant kinase in RBL-2H3 mast cells. Expression was confirmed in two mutant clones and three WT clones by immunocytochemistry and western blotting. Our studies demonstrate that cells overexpressing the WT PIP5-kinase Iα (WT cells) show hyper-tyrosine phosphorylation of FcεRI, whereas those expressing the mutant kinase show hypophosphorylation. Despite this enhanced receptor phosphorylation in the WT cells, the calcium response to stimulation by antigen is reduced by 40%. Furthermore, the calcium response to store depletion by thapsigargin is similarly reduced, indicating a defect in calcium influx via store-operated calcium entry channels. We also find that cells overexpressing the mutant kinase show substantially reduced antigen-stimulated ruffling compared to untransfected control cells and WT cells, indicating a role for PIPS-5-kinase Iα in stimulated ruffling. In conclusion, our studies reveal that the pool of PIP2, synthesized by PIPS-5-kinase Iα plays diverse roles in regulating IgE-receptor signaling: it positively regulates receptor phosphorylation and stimulated cell ruffling and negatively regulates the calcium response at the level of store-operated calcium entry. Ongoing studies are focused on understanding the mechanisms by which PIPS-5-kinase Iα participates in these activation processes.

755 Extracellular Metalloproteinase from Vibrio vulnificus Induces Production of Inflammatory Mediators in Macrophage Raw 264.7 Cells

J. E. Park, A. K. Chang, N. H. Lee, J. S. Lee; Chosun University, Gwangju, Republic of Korea

Vibrio vulnificus is an aero- and water-pathogen in human. It secretes a broad-specificity metalloproteinase (vEP) that has many biological activities and is associated with skin lesions and serious hemorrhagic complications. Inflammatory mediators produced by cells such as monocyte and macrophage play an important role during the process of inflammation. Among the matrix metalloproteinases (MMP), macrophage elastase (MMP-12) is able to degrade extracellular matrix component (ECM) such as elastin and initiate the process of inflammation. As vEP is capable of degrading a number of different ECM proteins such as collagen and elastin, we wanted to know whether it has any effect on the production of inflammatory mediators. Using MTS-assay we showed that vEP caused no apparent toxicity to the macrophage Raw 264.7 cells at concentrations ranging from 1 to 10 μg/ml. At 1 μg/ml vEP, the expression of mRNA for tumor necrosis factor-α (TNF-α) and interleukin 6 (IL-6) were significantly upregulated as measured with real-time PCR. In addition, the level of IkB-α expression was also down regulated. Western blot of cell lysate revealed an increase in the level of TNF-α and a reduction in the level of IL-6, suggesting that a direct interaction between vEP and these cytokines. As the C-terminal domain of vEP is thought to facilitate its binding to insoluble proteins such as those that are present in the ECM, the effect of various vEP mutants with C-terminal deletion on the production of inflammatory mediators was also investigated using TNF-α as a representative molecule. Overall, the results suggest that vEP might play a direct role in the triggering of an inflammatory response following Vibrio infection.

756 Regulation of Melanosome Transport by cAMP-dependent Protein Kinase Does Not Require Its Catalytic Activity

M. Park, V. I. Gelland; Cell and Molecular Biology, Northwestern University, Chicago, IL
Transport of pigment organelles (melanosomes) in *Xenopus laevis* melanophores is tightly regulated by cAMP. Melanosome dispersion or aggregation is triggered by the increase or decrease of cAMP concentration in the cytoplasm, respectively. These effects of cAMP are mediated by cAMP-dependent protein kinase (PKA). Using overexpression studies, we showed that melanosome transport is regulated by Cj catalytic subunit of Xenopus PKA, while an isoform Cx subunit has no effect on transport. Surprisingly, catalytically inactive mutants of Cj were able to regulate melanosome transport like the wild type PKA Cj. Mutational studies confirm that this phenomenon is not due to the activation of endogenous PKA. Furthermore, subcellular fractionation and fluorescence microscopy showed that PKA pool is associated with melanosomes. Our results indicate that PKA Cj is a distinct catalytic subunit that is recruited to melanosomes and regulates melanosome transport by a novel mechanism.

ERK1c Regulates Golgi Fragmentation during Mitosis
Y. D. Shaul, R. Seger; Biological Regulation, Weizmann Institute of Science, Rehovot, Israel
Extracellular signal-regulated kinases (ERK) are signaling molecules that regulate a wide array of cellular processes. Recently we cloned an alternatively spliced isoform of ERK1, named ERK1c, and demonstrated that it is regulated differently from other ERKs upon various stimulations. In addition, we showed that this isoform could be found in the Golgi apparatus under various conditions. Preliminary data from our working hypothesis states that ERK1c participates in the regulation of mitotic Golgi fragmentation, which is known to be mediated by MEK1 without the involvement of ERK1/2. Therefore, the Objective of the work was to study the function and regulation of ERK1c in the Golgi during mitosis. Using FACS analysis, SiRNA, and immunofluorescence technique, our results show that during late G2 phase and mitosis, ERK1c expression and activation, were increased. Additionally, at these phases ERK1c translocate to the Golgi complex. ERK1c knockdown resulted in significant attenuation of the Golgi fragmentation and consequently also mitotic progression, whereas the overexpression of ERK1c facilitated these processes. Similar to ERK1c, changes in MEKs activity during mitosis affected Golgi fragmentation, while changes in ERK1/2 expression level did not affect this process, suggesting that at least one of the MEKs facilitates the Golgi fragmentation specifically by ERK1c. Interestingly, the MEK isoform that regulates this process seems to be the alternatively spliced MEK1b, which phosphorylates specifically ERK1c but not ERK1 or ERK2. We concluded that ERK1c is a unique MEK effector that extends the specificity of the ERK signaling cascade to regulate Golgi fragmentation. Therefore, alternatively spliced isoforms are another mean for determining the specificity of the ERK cascade that regulates different and even opposing cellular processes.

Signaling Pathways of Light Induced Macrophage Migration and Vascular Smooth Muscle Cell Proliferation
W. Lin, C. Wei, Y. Chou; Pharmacology, National Taiwan University, Taipei, Taiwan
The biological actions of LIGHT, a member of the tumor necrosis factor superfamily, are mediated by the interaction with lymphotixin-β receptor (LTβR) and/or herpes virus entry mediator (HVEM). Previous studies had suggested a key role of LIGHT and HVEM receptors in atherosclerotic vascular disease. To elucidate the role of LIGHT in the function of macrophages and vascular smooth muscle cells (VSMC) in relation to atherosclerosis, we determined the effects of LIGHT on macrophage migration and VSMC proliferation. We found LIGHT through HVEM activation can induce both events. LIGHT-induced macrophage migration was associated with activation of signaling kinases, including MAPKs, PI3K/Akt, and NF-κB. LIGHT-induced VSMC proliferation was also shown to be associated with the activation of MAPKs, PI3K/Akt, and NF-κB, which consequently led to altered expression of cell cycle regulatory molecules. Down-regulation of p21, p27 and p53, and inversely up-regulation of cyclin D and RB hyper-phosphorylation were demonstrated. In conclusion, LIGHT acts as a novel mediator for macrophage migration and VSMC proliferation, suggesting its involvement in the atherogenesis.

βPix Regulates Golgi Fragmentation During Mitosis
A. Chahidi, A. Sorokin; Medicine, Medical College of Wisconsin, Milwaukee, WI
Recently, we described a novel technology for site-specific covalent tethering of synthetic ligands to a novel reporting protein (RP) in living cells, in vitro and on a solid support (Luo et al, 2005). Here we are using this technology in combination with live cell imaging and conventional protein analysis techniques to study dynamics of nuclear transcription factor κB (NF-κB) signaling in cultured mammalian cells. We demonstrated that activation of TNF-α receptor leads to nuclear translocation of the p65-RP fusion in transiently stably expressing cells. The kinetic parameters of translocation are within physiological limits. Pretreatment of cells with SN50 (an inhibitor of nuclear import) prevents nuclear translocation of protein fusion. Incubation of the cells with Leptomycin B (specific inhibitor of the nuclear export factor CRM1) leads to accumulation of p65-RP in the nucleus. Activation of TNF-α receptor leads to a degradation of intrinsic IκB, as well as fluorescently labeled IκB-RP. This degradation is efficiently blocked by Lactacystin, a potent 26S proteosome inhibitor. To study the effect of different levels of p65-RP on NF-κB signaling we utilized three systems for inducible protein production, Coumarmycin-Nobobyocin based; CRE (cAMP responsive element) based; and NFAT (nuclear factor of activated T-cells) based. The level of p65-RP in transiently transfected uninduced cells was negligible. Upon application of the appropriate inducer, the level of the p65-RP is significantly increased. The fluorescently labeled p65-RP is properly localized in the cytosol in all three systems. However, upon application of TNF-activated T-cells (based), the level of p65-RP in transiently transfected uninduced cells was negligible. Upon application of the appropriate inducer, the level of the p65-RP is significantly increased. The fluorescently labeled p65-RP is properly localized in the cytosol in all three systems. However, upon application of TNF-activated T-cells (based) and/or herpes virus entry mediator (HVEM) and/or herpes virus entry mediator (HVEM), our results show that during late G2 phase and mitosis, ERK1c expression and activation, were increased. Additionally, at these phases ERK1c translocate to the Golgi complex. ERK1c knockdown resulted in significant attenuation of the Golgi fragmentation and consequently also mitotic progression, whereas the overexpression of ERK1c facilitated these processes. Similar to ERK1c, changes in MEKs activity during mitosis affected Golgi fragmentation, while changes in ERK1/2 expression level did not affect this process, suggesting that at least one of the MEKs facilitates the Golgi fragmentation specifically by ERK1c. Interestingly, the MEK isoform that regulates this process seems to be the alternatively spliced MEK1b, which phosphorylates specifically ERK1c but not ERK1 or ERK2. We concluded that ERK1c is a unique MEK effector that extends the specificity of the ERK signaling cascade to regulate Golgi fragmentation. Therefore, alternatively spliced isoforms are another mean for determining the specificity of the ERK cascade that regulates different and even opposing cellular processes.

βPix/ p66Shc/Foxo3a Signaling Complex Regulates Cell Proliferation through p27kip1 Down-regulation
A. Chahidi, A. Sorokin; Medicine, Medical College of Wisconsin, Milwaukee, WI
The Rac1/Cdc42 guanine nucleotide exchange factor, βPix, is a multidomain protein that regulates cytokesin organization through interaction with focal adhesion proteins. In this study, we identify the amino acid sequence, E140LRQDINW146, located at the C-terminus region of βPix that binds both the adaptor protein p66Shc and the forkhead transcription factor Foxo3a. βPix induces serine-36 phosphorylation of p66Shc through ERK and ERK1c activation. The depletion of p66Shc by RNA interference inhibits βPix-mediated Foxo3a phosphorylation. Furthermore, we show that βPix over-expression results in down-regulation of the cytosolic-catalytic kinase inhibitor p27kip1 independently of Akt. βPix-mediated p27kip1 down-regulation induces cell cycle and cell proliferation into S phase of the cell cycle. Interestingly, the expression of βPix mutant, βPixΔ(603-608), that is unable to form a complex with p66Shc and Foxo3a blocks p27kip1 down-regulation, cell proliferation and cell progression into S phase. Our results demonstrate for the first time a direct role of βPix in cell proliferation, and extend the network of proteins that interact with βPix to include p66Shc and Foxo3a.

Probing Dynamics of NF-κB Signaling Using Novel Protein Labeling Technology
N. Karassina, C. Zimprich, R. Learish, G. Los; R&D, Promega Corp, Madison, WI
Extracellular signal-regulated kinases (ERK) are signaling molecules that regulate a wide array of cellular processes. Recently we cloned an alternatively spliced isoform of ERK1, named ERK1c, and demonstrated that it is regulated differently from other ERKs upon various stimulations. In addition, we showed that this isoform could be found in the Golgi apparatus under various conditions. Molecular Mechanism of EGF-enhanced Aurora-A Gene Expression in Tumor Cells
L. Hung; Department of Pharmacology, National Cheng Kung University, Tainan, Taiwan
Human Aurora-A is a potential oncoprotein which is highly expressed in many malignant tumors and cancer cell lines. The increased level of Aurora-A is through the DNA amplification, protein stabilization and transcriptional up-regulation. The detailed mechanism of transcriptional regulation of Aurora-A in tumors is still unclear. The epidermal growth factor receptor (EGFR) is a transmembrane receptor tyrosine kinase and it is also highly expressed in many tumors and cancer cell lines. In recent years, the nuclear localization of EGFR has been demonstrated by many groups. The nuclear localization of EGFR is strongly correlated with highly proliferating activity and where it functions as a transcription activator. The nuclear EGFR recognizes the AT-rich

Inherent Uncertainty in Protein Cycle and Nature’s Dance of Life: Expanding Paul Silverman’s Final Vision for Cell Biology Fundamentals
A. Goodman; Center for Statistical Consulting, University of California, Irvine, CA

Paul Silverman’s vision for uncertainty was first to explicitly advocate exploring for uncertainty beyond protein cycle’s determined behavior. Author and others proposed uncertainty as appropriate complement to the unrealistic certainty of determinism. This was underscored by Science’s 125th Anniversary four “What Don’t We Know?” concerning biology. Uncertainty within complexity is most realistic cellular model is: Cell Behavior = Certain Determined Part + Unknown Determinable Part + Uncertain Diversity. Too many biological, chemical and physical processes must “succeed” for cell behavior to be determined. Uncertainty is due to complexity and is generated by cascading effects of intricate processes compounded by interactions. A combination of determined and uncertain processes is uncertain. Cellular variables are likely random, probability is likely fundamental, and cellular mathematics is likely statistics. Uncertainty beyond what is known is not as plausible to believe in an essential uncertain world with growing areas of known certainty, as it is to believe in an essential certain world with shrinking areas of unexpected unknowable uncertainty. Physics “theory of everything” will probably include uncertainty. Uncertainty fills void beyond knowledge. Last major bastions of determinism since cell biology is surrounded in almost all respects by equally complex disciplines, why is it that cell biology and perhaps dark energy/matter physics appear to be the last major bastions of unrealistic determinism? Quantum physics, cell chemistry, evolutionary biology, medicine, social science, commerce and industry have all accepted and even managed uncertainty. What gets us into far more trouble than what we do not know is what we do know that is not true (Mark Twain).

Two Populations of p27 Use Differential Kinetics to Phosphorylate Ser10 and Thr187 in Response to FGF-2 Stimulation

J. Lee, T. Oh, E. Kay1,2, Doherty Eye Institute, Los Angeles, CA, 1Department of Ophthalmology, Keck School of Medicine of University of Southern California, Los Angeles, CA

The cyclin-dependent kinase inhibitor p27 regulates cell cycle progression; its activity is controlled by its concentration and subcellular localization. We investigated whether FGF-2 facilitates phosphorylation of p27 at the serine 10 (Ser10) and threonine 187 (Thr187) sites by PI 3-kinase and whether these two phosphorylation sites were differentially regulated. FGF-2 stimulation dramatically increased the phosphorylation of p27 at Ser10 and Thr187 using differential kinetics: the maximum phosphorylation at Ser10 and Thr187 were observed 6 and 16 h after FGF-2 stimulation, respectively. FGF-2-induced p27 phosphorylation at both sites was completely blocked by LY294002. We determined the physical and biochemical interaction of p27 with Cdk2/Cyclin E complex in response to FGF-2 stimulation; maximum binding of p27 to Cdk2/Cyclin E complex occurred at 12 h; maximum level of phosphorylation of p27 at Thr187 in the ternary complex was observed at 16 h; ubiquitination of the Thr187-phosphorylated p27 (pp27Thr187) was observed starting at 12 h and continuing for up to 24 h. However, the phosphorylation of p27 at Ser10 occurred in the nucleus with a maximum level of phosphorylation stimulation of p27 (pp27Ser10) was ubiquitinated and was simultaneously exported to cytoplasm at a maximum rate 8 h after FGF-2 treatment. We further investigated which of the two phosphorylated p27 (pp27Thr187 and pp27Ser10) was involved in G1/S progression. When LY294002 was used, the inhibitor blocked 64% of cell proliferation stimulated by FGF-2; the blocking of nuclear export of pp27Ser10 by leptomycin B greatly decreased the FGF-2 stimulated cell proliferation (44%), suggesting that p27 phosphorylation of p27 at Ser10 is the major mechanism for G1/S transition. Our results suggest that different kinetics are observed in phosphorylation of p27 at Ser10 and Thr187 in response to FGF-2 stimulation and that pp27Thr187 and pp27Ser10 may represent two separate populations of p27 observed during G1/S transition.

Stages of Medial Nuclear Division Arrest in S. cerevisiae

T. Hattier, F. Najm, N. Mallhora, J. Drážka, A. M. Tartakoff, Pathology, Case Western Reserve University, Cleveland, OH

Several yeast cell mutants arrest after DNA replication but before cleavage homologs, with the nucleus spanning the bud neck - a situation known as "medial nuclear division arrest" (MND). This terminal phenotype is characteristic of mutants which simultaneously DNA damage by exposing the single-stranded extents of chromosomess (cck13-1), in strains which cannot activate the anaphase promoting complex (due to depletion of Cdc20p) or by induction of the kinase, Mps1p, which triggers the spindle checkpoint. These mutants are cause chomatic to oscillate along the long axis of the nucleus. Upon arrest, we nevertheless observe that each condition leaves the nucleus anchored at the maternal extremity of the nucleus, emphasizing the strength of the linkage between the nucleus and the periphery of the nucleoplasm. To learn whether each form of MND arrest is coincident, we have constructed a corresponding triple mutant (MAT a). In this strain each arrest is reversible and each can be imposed for as long as ten hours. We therefore have systematically performed order-of-function experiments in which each arrest is followed by reincubation under conditions which activate a second cause of arrest, with addition of alpha factor to allow easy evaluation of cell cycle progression. These epistasis experiments imply that the arrest due to cdc13-1 precedes the others, and that the Cdc20p-dependent step is coincident with the Mps1p-dependent step. The DNA damage checkpoint defined by cdc13-1 therefore precedes the spindle checkpoint. The relative order of the DNA damage and spindle checkpoints will be compared with those which operate in the mammalian cell cycle. Supported by NIH Training Grant T32 HD007104-30.

Stimulatory Translational Components of Heat-stressed Cells of Sacccharomyces cerevisiae Transiently Accumulate in Cytoplasmic Aggregates

F. Janda,1 P. Vasicova,1 J. Vojtova,1 J. Frydlova,1 P. Ivanov,2 J. Hasek,3 Cellular and Molecular Microbiology, Institute of Microbiology AS CR, Prague, Czech Republic, 1A. Belozersky Institute of Physico-Chemical Biology, Moscow, Russian Federation

In higher eukaryotic cells exposed to various environmental stresses translation initiation factors accumulate in cytoplasmic aggregates, called stress granules. The stress granules were identified in heat-stressed yeast by RNA polymerization but until now their formation has not been referred to budding yeast Saccharomyces cerevisiae. We constructed various S. cerevisiae strains expressing fusion proteins intragenously tagged with GFP and/or mRFP from their chromosomal sites and analyzed redistribution of translational factors after heat shock. The heat shock resulted in accumulation of 80S ribosome (determined by polysome profile) and protein aggregation. In the aggregates, we identified translation initiation factors eIF3 and eIF4G, mRNA binding protein Pab1 and elongation factor Yef3p. In contrast, translation initiation factor eIF2b/Su2p and ribosomal proteins Rps2 and Rps7B (40S) and Rpl5, Rpl10 and Rpl25 (60S) as well as glycosyl enzymes Pgp1 and Pkp1 (negative control), were not present in the aggregates. Further, formation of aggregates was transient. It was prevented by the cyclobeximide pretreatment and was independent of the phosphorylation of eIF2alpha by Gcn2 kinase. In the aggregates, heat shock proteins (Hsp104p, Hsp70 family) were also identified and Hsp104p appeared to affect their dissolution. Together, our data indicate that the aggregates represent dynamic structures composed of some translational components and that these structures resemble but are not identical with stress granules described in higher eukaryotic cells. This work was financed by grants CSF 204/05/0383, LC545 and ICAV0250200510.

A Role for Cytoplasmic Poladenylation Element Binding Protein in Cell Cycle Control in Astrocytes

W. Oh, J. Choi, K. Ko, K. Jones, S. Banerjee, C. Shin, D. G. Wells, 1Pharmacology, Seoul National University, Seoul, Republic of Korea, 2Molecular, Cellular and Developmental Biology, Yale University, New Haven, CT, 3Pharmacology, Gorkok University, Chungia, Republic of Korea

Cytoplasmic poladenylation regulates specific mRNA translation in developing oocytes and mature neurons. Cytoplasmic poladenylation element binding protein (CPEB) is an mRNA-binding protein that regulates this process. When bound, CPEB holds the mRNA in a translationally dormant state; upon phosphorylation by Aurora A kinase, the bound RNA is poladenylated leading to translational activation. We now describe CPEB expression in rat astrocytes. Here, CPEB and Aurora kinase are localized to the centrosome of dividing astrocytes suggesting a role for CPEB in cell cycle regulation. When growth-arrested primary astrocytes were induced to proliferate by the addition of serum to the media, a rapid phosphorylation of CPEB and polyadenylation of a CPEB target mRNA encoding cyclin B1 was detected. The increase in the polyadenylation of cyclin B1 mRNA resulted in an increase in cyclin B1 protein synthesis that could be detected in the presence of a transfection inhibitor, indicating it was the result of mRNA translational activation. To determine the consequences of altering CPEB protein levels on cell proliferation we used both FACs analysis and a biochemical marker for dividing cells, phospho-histone H3. Over-expression of unphosphorylated CPEB inhibited cell cycle progression while expressing RNA sequences containing the binding site for CPEB, thus sequestering the endogenous CPEB protein from its target mRNAs, resulted in an increase in cell division. Similarly, siRNA knockdown of CPEB expression in astrocytes promoted cell cycle progression. These results suggest that CPEB-dependent mRNA translation plays an important role in cell cycle regulation in astrocytes, possibly mediated in part through the regulation of cyclin B1.

Activation of H3 Histamine (H3R) Receptors Induces Inhibition of Growth of Several Cholangiocarcinoma Cell Lines by PLC/IP3/Ca2+-dependent Inhibition of ERK1/2 Phosphorylation

H. Francis, J. Venter, S. Vaculin, S. DeMorrow, S. Glaser, B. Vaculin, S. Arnold, B. Green, R. Summers, G. Alpini; 1R&E, Scott & White Hospital, Temple, TX, 2Medicine, The Texas A&M University System HSC, Temple, TX, 3Medicine, Scott & White Hospital and Texas A&M University System HSC, Temple, TX, 4Medicine, Central Texas Veterans HCS and The Texas A&M University System HSC COM, Temple, TX

We have previously shown that the H3R agonist, RAMH, inhibits the growth of the cholangiocarcinoma cell line, Mz-Cha-1, but there remains limited understanding of the mechanisms of action by which H3R regulation the growth of biliary tumors. The IP3/Ca2+-PKC/MAPK pathway modulates cholangiocarcinoma growth. Gastrin inhibits cholangiocarcinoma growth via Ca2+-dependent PKCalpha activation, whereas the D2 dopaminergic receptor, quinelorane, inhibits cholangiocarcinoma growth by activation of the Ca2+-dependent PKCgamma. The AIMS of this study were to determine: (i) if the intra- and extra-hepatic cholangiocarcinoma cell lines express the H3R (ii) if RAMH inhibits cell growth of other cholangiocarcinoma cell lines (iii) if concomitant RAMH and Ca2+ inhibition of cell growth is also observed. In this study we found by RT-PCR that all the cell lines expressed the H3R. Treatment with Ca2+ and RAMH resulted in a significant decrease in proliferation of HuH-7 and HuH-28 cell lines by 44% and 37%, respectively, and inhibition of cell cycle progression with accumulation in G0/G1 phase. In contrast, treatment with Ca2+ and RAMH had no effect on the proliferation of CCLP-1 cell line. In conclusion, our results suggest that the activation of the H3R may be a potential therapeutic target for the treatment of cholangiocarcinoma.
IP3, levels by RIA and the phosphorylation of PKCα, beta-I, beta-II and gamma and the MAPK kinases, ERK1/2 and JNK by immunoblotting. RESULTS: All cholangiocarcinoma cells lines and H69 cells express H3R. RAMH decreased growth at 10, 25 and 50 micromolar for 48 hours in all cholangiocarcinoma cell lines but not H69. The following blocked the inhibitory effect of RAMH on cholangiocarcinoma growth: (i) the Ca2+ chelator, BAPTA/AM (5 micromolar) (ii) the PKCα inhibitor, Go6976 (1 micromolar) and (iii) the phospholipase C inhibitor (U-73122, 1 micromolar). In Mz-ChA-1 cells, RAMH increased IP3 levels and PKCα phosphorylation but decreased the phosphorylation of ERK1/2 but not JNK. CONCLUSIONS: RAMH inhibits the growth of several cholangiocarcinoma cell lines via PLC/PKCα/PKCα-dependent dephosphorylation of ERK1/2. The activation of H3R may be important in the management of cholangiocarcinoma.

773 Mitotic Checkpoint Slippage in Vertebrates in the Presence of Microtubule Poisons

D. A. Brito, L. C. Rieder; Wadsworth Center—NYS Dept. of Health, Albany, NY

In the presence of unattached/weakly attached microtubules, the spindle assembly checkpoint (SAC) delays exit from mitosis by preventing the anaphase promoting complex (APC)-mediated proteolysis of cyclin B, a regulatory subunit of cyclin-dependent kinase 1 (Cdk1). The SAC does not arrest cells permanently, even when it cannot be satisfied (e.g., in the presence of microtubule (MT) poisons), and escape from mitosis in the presence of an unsatisfied SAC requires that cyclin B/Cdk1 activity be somehow inhibited. We have recently shown that in vertebrates, exit from mitosis in the presence of nocodazole occurs through the continuous and proteosome-dependent degradation of cyclin B that ultimately drives cells out of mitosis in the presence of an active SAC (D.A. Brito and L.C. Rieder, 2006, Curr. Biol. 16:1194-1200). During this study we also observed that the rate of “leakage” through the SAC was positively correlated with the number of MTs remaining in the nocodazole-treated cell. To further explore this latter finding we are studying how mitotic RPE1 cells behave in the presence of taxol, a drug that, unlike nocodazole, stabilizes and/or promotes MT polymerization. We find that RPE1 cells incubated with 5 nM or 5 μM taxol are delayed in mitosis for the same duration (208±121 min, n=4 versus 203±85 min, n=141, respectively). Surprisingly, however, cells incubated in 500 nM are delayed for 698±356 min (n=77), similar to that of nocodazole-treated cells lacking MTs. Since cells treated with 5 μM taxol show an increased MT mass, relative to the other drug concentrations, and exit mitosis substantially faster than those treated with 500 nM taxol, the mere presence of MTs does not enhance mitotic exit rate. Our preliminary data also suggests that BAB1, Mad1 and Mad2 are present in reconstituted nuclei of cells incubated with the higher taxol concentrations.

774 Regulation of E2F Function through Prohibitin-RNF2 Interaction: New Mechanism of E2F1 in Cell Cycle

D. Choi, Y. Bae, H. Choi, S. Kang; Graduate School of Life Sciences and Biotechnology, Korea University, Seoul, Democratic People's Republic of Korea

Prohibitin, the tumor suppressor protein, has an important role in transcriptional regulation of various genes involved in cell cycle control and proliferation. Recent studies reported that the growth-suppressive property of the prohibitin protein is exhibited by repressing the transcriptional activity of E2F family proteins. In this study, we show that RNF2, a member of Pcg (polycromb-group) proteins, regulates the prohibitin-mediated E2F1 transcriptional activity through the p16-Cdk4/cyclin D-Rb pathway. We found by co-immunoprecipitation experiments that prohibitin interacts with RNF2. Interestingly, the expressed amounts of prohibitin were affected interdependently at a post-transcriptional level. Furthermore, knock-down of either RNF2 or prohibitin by the RNAi technique increased the amount of p16, whereas overexpression of either RNF2 or prohibitin did not affect the expression of the p16 protein. Cell proliferation also was regulated by the prohibitin-RNF2 interaction. Based on these results, we will discuss a novel pathway of E2F1 activity regulation.

775 Conditioned Media of Lung Carcinoma Cell Line Induce the Morphological Change and the Inactivation of Myofibroblast, MRC-5 Cells

S. Hayakawa, T. Nakatani, E. Hondo, Y. Yano, S. Kumazawa, H. Munakata; 1Dept. of Biochemistry, Kinki University School of Medicine, Osaka, Japan, 2Dept. of Gastroenterology and Hepatology, Kinki University School of Medicine, Osaka, Japan, 3Life Science Research Institute, Kinki University, Osaka, Japan, *School of Food and Nutritional Sciences, University of Shizuoka, Shizuoka, Japan

A critical feature of fibrotic disease involving the pulmonary fibrosis is the appearance of fibroblast-like cells expressing α-smooth muscle actin (α-SMA) within the areas of active fibrosis. The expression of α-SMA suggests that the fibroblast have acquired characteristics of contractile cells. Such cells are termed myofibroblast. Several substances, such as PGE2, are known to cause the inactivation of myofibroblasts, but the mechanism of inactivation has not been fully understood yet. We found that the conditioned media of a human lung carcinoma cell line, A549, caused the inactivation of myofibroblast cell line, MRC-5. In the present study, we investigated the effect of the conditioned media of A549 on the inactivation of MRC-5 cell. The shape of the MRC-5 cells changed to stellate form after the treatment with the A549 conditioned media, along with the decrease inactivation of myofibroblasts, but the mechanism of inactivation has not been fully understood yet. We found that the conditioned media of a human lung carcinoma cell line, A549, caused the inactivation of myofibroblast. The substance was partially purified by HPLC. The identification of this substance by NMR is in progress. Our results may provide useful information on the kinase inhibitors were increased after 2 days by conditioned media treatment. FACS analysis showed that cell cycle arrest was induced at early stage of morphological change. We found that the cell cycle arrest by A549 conditioned media was induced at GO/G1 phase. Our interest has been then focused on the identification of substance that causes the inactivation of myofibroblast. The substance was partially purified by HPLC. The identification of this substance by NMR is in progress. Our results may provide useful information on the differentiation of myofibroblasts.

776 Covert Genetic Selections Identify Genes Which Regulate Yeast Growth

D. Wu, E. Townsley, A. M. Tartakoff; Pathology, Case Western Reserve University, Cleveland, OH

Genetic complementation strategies are well-suited to analyze cellular phenotypes of monogenic origin. We here show that related selections can identify single genes which contribute either positively or negatively to phenotypes which are not of monogenic origin. To implement this search procedure, we have developed mSPI (~“Microarray-Based Single Promoters-Inhibitors”). It is based on cDNA enrichment (‘covert selection”) rather than overt correction of cellular phenotype. It therefore can access relations and optimization strategies which are inaccessible via classical selections. We exemplify this use of mSPI by identifying a spectrum of ectopic cDNAs which favor (or oppose) growth of S. cerevisiae. For this purpose, we grow a pool of thousands of transformants which carry single plasmids from a yeast cDNA library. cDNAs which are present at the beginning of the experiment and those which persist are quantitated on microarrays. The resulting hierarchy of differential cDNA enrichment or depletion has a large dynamic range, due to the amplification of distinct cell subpopulations during culture. These data therefore make corresponding predictions as to which cDNAs stimulate or inhibit growth. Validation experiments confirm most of these predictions. mSPI thus provides a powerful, streamlined and unprejudiced genome-wide selection for cDNAs which can improve (or impair) cell performance. mSPI should be applicable to all cell types for which satisfactory libraries and microarrays are available. Identification of such genes is critical for orienting therapeutic interventions. Supported by the National Science Foundation (MCB-0431496) and by a Presidential Research Initiative Grant from Case Western Reserve University.

777 Role of Emi1 in the Regulation of the APC/C

B. Di Fiore, J. Pines; Wellcome Trust/Cancer Research UK, Gudron Institute, University of Cambridge, Cambridge, United Kingdom

Ubiquitin-mediated proteolysis is critical for the key regulatory steps in mitosis, and the Anaphase Promoting Complex/Cyclosome (APC/C) ubiquitin ligase plays a fundamental role in this regulation. APC/C is regulated at several levels, and is only active when complexed with Cdc20 or Cdh1, which contribute to the timing of APC/C activity. APC/C activity can be inhibited by Emi1, which is reported to bind Cdc20 and Cdh1. Thus, the destruction of Emi1 has been proposed to regulate the activation of APC/C at mitosis, and Emi1 synthesis to inactivate the APC/C for cells to initiate S phase. We are investigating the regulation and the role of Emi1 in mammalian cells, to understand better how APC/C activity is regulated in vivo. By time-lapse microscopy we observed that in living cells Emi1 degradation starts in prophase. However, in vivo, the timing of cyclin degradation in mitosis is not affected by Emi1, indicating that Emi1 does not inhibit mitotic APC/C activity. Moreover, we found that Emi1 is involved in the regulation of APC/C activity in interphase.
Genome-wide Analysis of Polyplody in Yeast: Scaling Effects and Genome Stability

Z. Storchova, A. Breneman, J. Cande, J. Dunn, K. Burkhank; E. O'Toole, D. Pellman; Dana-Farber Cancer Institute, Boston, MA, Harvard University, Cambridge, MA, University of Colorado, Boulder, CO, SUPRASYS, Bulgaria

Polyplody occurs during development, cellular stress, disease, and evolution. Despite its prevalence, little is known about the physiological alterations that accompany polyplody. We previously described "polyoid-specific lethality", where a gene deletion that is not lethal in haploid or diploid budding yeast causes lethality in triploids or tetraploids. Here, we report a genome-wide screen to identify ploidy-specific lethal functions. Only 39 in 3740 mutations screened exhibited ploidy-specific lethality. Almost all of these mutations affect genomic stability by impairing homologous recombination, sister chromatid cohesion, or mitotic spindle function. Because detailed analysis of genetic instability in wild-type tetraploids uncovered a dramatic increase in chromosome loss rates, we focused on chromosome segregation and mitotic spindle function in these cells. We show that wild-type tetraploids have a high incidence of syntenic/monopolar kinetochore attachments to the spindle pole. Although tetraploids had a highly increased requirement for Ipl1/Aurora B, Aurora B activity is not compromised. We therefore considered whether scaling effects on spindle geometry might explain the chromosome mis-segregation in tetraploid cells. Surprisingly, pre-anaphase spindle length is the same in haploids, diploids triploids and tetraploids, whereas electron tomography demonstrated that the surface area of the spindle poles doubles with increased ploidy. We suggest that mismatches in spindle length, kinetochore geometry and spindle pole body size can, at least in part, explain the high levels of chromosome loss in polyplod cells. Thus, genetic constraints may have profound effects on genome stability; the mechanisms described here may be relevant in a variety of biological contexts, including disease states such as cancer.

Replicative Aging in a Symmetrically Dividing Fission Yeast

A. Dereli, I. Tolec-Norrellykke; MPI-CBG, Dresden, Germany

Aging process in organisms is generally described by a decrease in the ability to respond to stress, a reduced capacity to produce offspring, and an increased risk of disease and death. One of the simplest organisms that undergoes replicative aging is budding yeast: individual cells die after about 20 divisions. Although this yeast has been widely used as an experimental system for investigating aging mechanisms, the results of those studies may not be directly relevant to higher eukaryotic cells that reproduce by symmetric division instead of budding. Here we investigate replicative aging in the fission yeast Schizosaccharomyces pombe which reproduces by apparently symmetric cell division. Our first objective was to see whether there is a difference in the division time and probability of death between older and younger cells. By our definition, older cells are those that inherit the old cell pole. We show that a single cell of fission yeast, starting its life from a spore, can undergo more than 50 divisions without showing aging phenomena. This work may help to elucidate mechanisms relevant for aging in more complex symmetrically dividing eukaryotic cells.

Acentrosomal Spindle Assembly in Cells with an Intact Interphase Microtubule Network

J. Hornick, C. Mader, E. Tebble, E. Hinchcliffe; Biological Sciences, University of Notre Dame, Notre Dame, IN

Several studies have demonstrated that bipolar mitotic spindles can form in the absence of intact centrosomes - their spindle assembly is nucleated by chromosomal factors. However, in these experimental studies, there is no pre-existing interphase microtubule network or MTOC. In contrast, normal spindle assembly in somatic cells occurs through the remodeling of an intact microtubule network that does not completely break down: instead the microtubules are drawn into the two spindle poles as they split and separate apart. To examine the role of the centrosome-containing "centrosome" in spindle assembly, BSC-1atubGFP cells were cut with a microcone between nucleus and centrosome generating karyoplasts (acentrosomal, nucleated cells); then followed by time-lapse fluorescence microscopy. Prior to the onset of mitosis, these cells re-form a single MTOC that nucleates an interphase microtubule network. These karyoplasts enter mitosis: ~70% of karyoplasts form a bipolar spindle and always cleave in the two. The generation of bipolarity in these acentrosomal cells appears to begin before nuclear envelope breakdown, as the two daughter cells are drawn into these daughter poles. In ~30%, the karyoplasts fail to form a bipolar spindle; the single interphase MTOC assembles a persistent monopolar spindle prior to NPB. Karyoplasts lacking spindles do initiate cytokinesis, assembling multiple furrows, which eventually retract, and the cell exits mitosis as a single daughter. Our observations reveal that in acentrosomal cells with an intact MTOC/microtubule network, spindle assembly begins before NEB as the single interphase MTOC assembles a functional acentrosomal spindle. This acentrosomal spindle is able to assemble a mitotic spindle through an acentrosomal pathway, but the molecular mechanism behind this process remains poorly understood. The acentrosomal spindle also has a role in establishing a bipolar mitotic spindle. To ensure spindle bipolarity, centrosome duplication must be precisely regulated. In this process, the coordinated dynamics of MTOCs functionally replaced centrosomes regarding microtubule nucleation and spindle organization. In ~30%, it is not possible to detect this process from a mechanistic perspective. Mitotic spindles in these cells show three main morphologies: 30 % are apparently normal bipolar spindles; 30 % barrel-shaped spindles and 40 % multipolar spindles. Importantly, they all lack astral microtubules, while γ-tubulin and centrosomin are often found as several foci near the poles and at the cell periphery. Experiments are on our way to investigate at high spatial and temporal resolution the process of spindle assembly in these cells by stable expression of GFP-α-tubulin. The ultimate goal will be to use the 1182-4 cells to perform a genome-wide RNAi screening for genes required for acentrosomal spindle assembly. For this purpose we have been concentrating on establishing RNAi conditions for these cells, as well as using phospho-histone H3 staining for automatic readout. We reasoned that inability to assemble a functional acentrosomal spindle would compromise mitotic progression in 1182-4 cells and lead to an increase in the mitotic index. Accordingly, preliminary results have indicated that 16 h of colchicine treatment cause a 10x increase in the mitotic index, indicating that phospho-histone H3 staining could be used as readout in the first step of the screening. Subsequently, a detailed analysis of spindle assembly will be performed after RNAi of candidate genes.

A New Model of Acentrosomal Spindle Assembly Revealed by 4D Imaging of Live Mouse Oocytes

M. Schuh, J. Ellenberg; Gene Expression Programme, European Molecular Biology Laboratory, Heidelberg, Germany

Homologous chromosome segregation in mammalian oocytes is driven by a microtubule spindle devoid of centrosomes. Our current understanding of acentrosomal spindle assembly is limited, and mainly based on experiments using cell free Xenopus egg extracts. Here, we present a new model of centrosome independent spindle assembly revealed by quantitative high resolution 4D imaging of fluorescently labeled chromosomes and microtubules in live maturing mouse oocytes. We show that spindle formation is based on the concerted action of more than 80 microtubule organizing centers (MTOCs) that formed de novo out of an interphase like microtubule network spanning the oocyte in prophase. Initially distributed throughout the oocyte cytoplasm, MTOCs rapidly bud off, and reorganized sequentially into several novel metastable intermediate assembly structures that led to the formation of a barrel-shaped bipolar spindle over the course of five hours. In this process, the coordinated dynamics of MTOCs functionally replaced centrosomes microtubule nucleation and spindle organization. Surprisingly, this acentrosomal spindle contained dynamic astral-like microtubules that appeared to participate in asymmetric spindle positioning by dynamically probing the cortex.

SZY-20 Regulates Centrosome Size and Centriole Assembly in C. elegans

M. Song, K. F. O'Connell; LBG, NIH/NNIDDK, Bethesda, MD

The central importance of cell division is transmitting a complete set of chromosomes to each daughter cell. In eukaryotes this is achieved via the function of the mitotic spindle. The centrosome serves as the primary microtubule-organizing center of the cell and plays an important role in establishing a bipolar mitotic spindle. To ensure spindle bipolarity, centrosome duplication must be precisely regulated. In this process, the coordinated dynamics of MTOCs functionally replaced centrosomes regarding microtubule nucleation and spindle organization. To identify additional factors that interact with ZYG-1 to regulate centrosome duplication, we performed a genetic screen for mutations that suppress the temperature-sensitive lethality of the zyg-1 (t252) mutation. The t252 mutation is among the suppressors identified and defines a gene szy-20 (for suppressor of zyg-1). szy-20 encodes a novel coiled-coil protein that localizes to the nucleus, nuclear periphery, cytoplasm and centrosome. The szy-20 (t252) mutation itself exhibits a strong temperature-sensitive embryonic lethality, marked by various defects in cell division including polar body splitting and separation, leading to a failure of spindle bipolarity. Thus, we conclude that a major function of the centriole-containing centrosome is to ensure spindle bipolarity.
formation, prometaphase positioning, A-P polarity, cytokinesis, and cell cycle timing. We further found that the zyg-1 (n25) mutation also suppresses the embryonic lethality of zyg-20 (hs52), demonstrating that there is mutual suppression between these two genes. That is while the zyg-20 (hs52) mutation restores centriole duplication to the zyg-1 (n25) mutant, the zyg-1 (n25) mutation rescues the prometaphase rotation and cytokinesis defects seen in zyg-20 (hs52) mutants. To understand how zyg-20 interacts with zyg-1 as a suppressor, we have analyzed centrosomes in the zyg-20 (hs52) mutant and found that the amount of pericentriolar material (PCM) at centrosomes is significantly increased. Our data indicate that SZY-20 limits centrosome size by negatively regulating PCM turnover. Thus, loss of SZY-20 activity likely restores centriole duplication in zyg-1 mutants by allowing increased amounts of ZYG-1 at centrosomes.

Requirement of Hc3enxin for Proper Mitotic Functions of Polo-like Kinase 1 at the Centrosomes

N. Seong1, Y. H. Kang1, K. Kamijo1, Y. Seong1, Y. Kao2, T. Mikiz, S. R. Kim, R. Kuriyama1, C. Giamb, K. S. Lee1, 1Metabolism, NIH/NCI, Bethesda, MD, 2Cell Biology, NIH/NCI, Bethesda, MD, 3Microbiology and Immunology, Uniformed Services University of the Health Sciences, Bethesda, MD, 4Biochemistry and Molecular Biology, Chungbuk National University, Cheongu, Republic of Korea, 5Genetics, Cell Biology and Development, University of Minnesota, Minneapolis, MN

Outer dense fiber 2 (ODf2) was initially identified as a major component of sperm tail cytoskeleton, and later was suggested to be a widespread component of centrosomal scaffold that preferentially associates with the appendages of the mother centrioles in somatic cells. Here we report the identification of two ODf2-related centrosomal components, Hc3enxin1 and Hc3enxin1 variant 1, that possess a unique C-terminal extension. Our results showed that Hc3enxin1 is the major isoform expressed in HeLa cells, whereas ODf2 is not detectably expressed. Mammalian pole-like kinase 1 (Plk1) is critical for proper mitotic progression and its association with the centrosome is important for microtubule nucleation and function. Interestingly, depletion of Hc3enxin1 by RNAi delocalized Plk1 from the centrosomes and the C-terminal extension of Hc3enxin1 was crucial to recruit Plk1 to the centrosomes through a direct interaction with the polo-box domain of Plk1. Consistent with these findings, the Hc3enxin1 RNAi cells exhibited weakened γ-tubulin localization and chromosome segregation defects. We propose that Hc3enxin1 is a critical centrosomal component whose C-terminal extension is required for proper recruitment of Plk1 and other components crucial for normal mitosis. Our results further suggest that the anti-ODf2 immunoreactive centrosomal antigen previously detected in non-germline cells is likely Hc3enxin1.

CEP192 Is Required for the Assembly and Function of Mitotic Centrosomes

M. A. Gomez-Ferreria1, D. R. Rines1, D. J. Sharp1 1Physiology and Biophysics, Albert Einstein College of Medicine, Bronx, New York, NY, 2Genomics Institute of the Novartis Research Foundation, San Diego, CA

The centrosome is the major microtubule organizing center (MTOC) in animal cells. During mitosis, the nucleation of microtubules from centrosomes drives spindle assembly and chromosome capture and segregation. CEP192 is a centrosomal protein initially identified in a proteomic analysis of the human centrosome (Andersen et al., 2003) and recently implicated as an important mitotic protein in a human genome-wide screen (Rines et al., 2006). To gain insight into the specific functions of CEP192, we have examined the function and composition of centrosomes throughout the cell cycle following siRNA knockdown of CEP192. Following the depletion of CEP192, MTOCs disperse at the onset of prophase, and spindle microtubules appear to nucleate form chromosomes or the remnants of the nuclear envelope. The resulting spindle fibers are severely deformed and generally do not complete mitosis. Immunofluorescence indicates that centrioles are still present in these cells but the pericentriolar material (PCM) proteins gamma-tubulin and pericentrin. Moreover, mother and daughter centrioles were often observed abnormally dissociated from one another during mitosis. We propose a model in which CEP192 stabilizes the centrosome by fixing together both centrioles and the PCM to the centriole pair. Why the role of CEP192 is specific for mitosis is currently under investigation.

The RanGTP Gradient Is Sufficient for Mitotic Spindle Assembly in Xenopus Egg Extracts

D. R. Halpin, P. Kalab, K. Weis, R. Heald1 MCB, University of California, Berkeley, California, CA

Mitotic chromosomes generate biochemical signals that promote spindle assembly. This mechanism is most apparent in systems lacking centrosomes, such as metaphase-arrested Xenopus egg extracts. Chromatin itself, in the form of plasmid-DNA coated beads, is sufficient to induce spindle assembly in egg extracts, but the molecular pathways behind this phenomenon are not well understood. One known component of the chromatin pathway is the Ran GTPase, which like other small GTPases of the Ras superfamily, cycles between GTP- and GDP-bound forms. Ran’s guanine nucleotide exchange factor, RCC1, is localized to chromosomes while its GTPase activating protein, Ran GAP and co-factors are cytosolic. During mitosis, this distribution of GEF and GAP activities creates a gradient of RanGTP/RanGDP with the concentration of RanGTP highest at the chromosomes and decreasing abruptly as the distance from the chromosomes increases. While mitotic functions for the RanGTP gradient have been demonstrated, the sufficiency of this pathway for spindle assembly is unclear. We have developed RCC1 microbeads with high enzymatic activity that generate RanGTP gradients in egg extracts. RCC1 beads are sufficient to induce microtubule polymerization and organization into bipolar arrays in the absence of other chromatin components. Structural and functional analyses of RCC1 bead-generated spindles are currently underway.

787

Plasticity of the Centromere in Vertebrates: Implications for the Mechanism of Spindle Assembly

O. Kisurina-Evgenieva1, P. Hergert1, J. Loncarek1, T. Vinogradova1, S. La Terra1, T. Kapoor2, A. Khodjakov1 1Wadsworth Center, Albany, NY, 2The Rockefeller University, New York, NY

The vertebrate centromere is a unique structure that governs mitotic chromosome movement. Centromeres can be either facultative (i.e., zebrafish) or obligate (i.e., human) and they can exhibit a wide variety of morphologies. One known component of the chromatin pathway is the Ran GTPase, which like other small GTPases of the Ras superfamily, cycles between GTP- and GDP-bound forms. Ran’s guanine nucleotide exchange factor, RCC1, is localized to chromosomes while its GTPase activating protein, Ran GAP and co-factors are cytosolic. During mitosis, this distribution of GEF and GAP activities creates a gradient of RanGTP/RanGDP with the concentration of RanGTP highest at the chromosomes and decreasing abruptly as the distance from the chromosomes increases. While mitotic functions for the RanGTP gradient have been demonstrated, the sufficiency of this pathway for spindle assembly is unclear. We have developed RCC1 microbeads with high enzymatic activity that generate RanGTP gradients in egg extracts. RCC1 beads are sufficient to induce microtubule polymerization and organization into bipolar arrays in the absence of other chromatin components. Structural and functional analyses of RCC1 bead-generated spindles are currently underway.

The Ndc80 Complex and Dynein-dependent Mechanisms of Kinetochore Attachment to Microtubules during Mitosis

V. V. Vorozhko1, M. Kallio2, M. J. Emanuele1, P. T. Stukenberg2, G. J. Gorbsky1 1Cell and Developmental Biology, Oklahoma Medical Research Foundation, Oklahoma City, OK, 2Genomics Institute of the Novartis Research Foundation, San Diego, CA

Kinetochore dynamics are essential for accurate chromosome segregation during mitosis. Kinetochores must efficiently capture and stabilize microtubules to ensure proper chromosome segregation. The Ndc80 complex is a conserved component of kinetochores that has been implicated in microtubule capture and maintenance. Microtubule capture is thought to be mediated by the Ndc80 complex, which is required for proper attachment of kinetochores to microtubules. In the absence of centrosomes, kinetochores must form bipolar spindles independently of microtubule capture. We have been investigating the role of the Ndc80 complex in microtubule capture during mitosis in the absence of centrosomes. We have found that the Ndc80 complex is required for proper attachment of kinetochores to microtubules during mitosis in the absence of centrosomes. This result has important implications for our understanding of the mechanisms that govern kinetochore attachment to microtubules.
Spatial Heterogeneity of Microtubule Dynamics in Metaphase *Xenopus laevis* Egg Extract Spindles Reveals Organization of Different Driving Mechanisms

G. Yang,1 L. A. Cameron,2 P. S. Maddox,1 E. D. Salmon,2 G. Danuser1; 1Dept of Cell Biology, The Scripps Research Institute, La Jolla, CA, 2Dept of Biology, Univ. of North Carolina, Chapel Hill, NC, 1Dept of Cellular and Molecular Medicine, UCDSD, La Jolla, CA

Steady poleward flux is a fundamental property of microtubule dynamics in metaphase spindles of higher eukaryotic cells. Understanding its molecular mechanisms is essential to understanding the regulation of metaphase spindle structure and generation of chromosome alignment and segregation force. We use quantitative fluorescent speckle microscopy to obtain high-resolution readouts of the spatial and temporal dynamics of microtubule flux in control and perturbed *Xenopus laevis* egg extract spindles. Our results show that microtubule flux is spatially heterogeneous in control spindles, with a systematic slowdown of ~20% in flux rate near the poles. Statistical clustering analysis confirms that the flux distribution follows a mixture of two normal distributions. Similar flux rate and spatial heterogeneity are also observed in plasmid DNA-coated magnetic bead spindles, suggesting that such heterogeneity is independent of microtubules and centrosomes. Inhibition of kinesin 5 using monastrol at low concentration significantly reduces flux rate and changes the spatial distribution of microtubule flux. However, further increase in monastrol concentration does not cause further changes in flux rate and spatial distribution. These results support an organizational model of barrel-like spindle architecture with antiparallel microtubule fibers in the middle connected with focused microtubule fibers near the pole. In addition, these results indicate that microtubule flux is driven by the synergy of kinesin 5-based antiparallel microtubule sliding in the middle and additional monastrol-insensitive mechanisms near the poles.

E-cadherin as a Spatial Cue to Orientate Cell Division

N. den Elzen, C. Buttery, A. Yap; Institute for Molecular Bioscience, University of Queensland, St Lucia, Qld, Australia

Ordinary cell division is critical for precise tissue patterning both during development and in post-developmental life. Simple epithelia, symmetrical division of cells within the plane of the monolayer is likely to be important to preserve tissue architecture. The plane of cell division is determined by the orientation of the mitotic spindle, which in turn depends on spindle interactions with the cell cortex. In dividing mammalian cells in vitro, mitotic spindle orientation has been shown to be affected both by cell shape, orienting along the long axis of the cell, and by extracellular cues, orienting towards the extracellular matrix. However, in cultured sheets of polarised columnar epithelial cells, mitotic spindles orient in the plane of the epithelium, perpendicular to the long axis of the cell and parallel to the extracellular matrix at the basal surface, rather than towards it. Clearly, other mechanisms must exist to orient spindles in the plane of the monolayer in symmetrical divisions of epithelial cells. E-cadherin is an epithelial cell surface receptor required for cell-cell adhesion and the establishment of cell polarity, whose function influences normal cleavage plane orientation in *Drosophila* and zebralis embryos. As a key morphogenetic regulator concentrated at adherens junctions at the apical/basolateral border of cells, it is an attractive candidate cortical cue to orientate spindles in the plane of the epithelial monolayer. We found, using E-cadherin siRNA, mutants and antibody blocking experiments, that E-cadherin acts as a spatial cue, orienting mitotic spindles in the plane of the monolayer in symmetric divisions of MDCK and MCF10a cells. Effects of disrupting E-cadherin on the localisation of NuMA, LGN and other cortical and spindle-associated proteins implicated in spindle dynamics, and their likely role downstream of E-cadherin in orientating spindles in the plane of the monolayer will also be presented.

Inhibition of Centrosome-dependent Microtubule Plastization and Block of Mitosis by the Small Organic Compound HMN-176

M. DiMaio,1 A. Mikhailov,2 C. Rieder,2 R. E. Palazzo2; 1Department of Biology and Center for Biotechnology and Interdisciplinary Studies, Rensselaer Polytechnic Institute, Troy, NY, 2Wadsworth Center-New York State Dept. of Health, Albany, NY

HMN-176, a small organic compound that promotes centrosome-dependent cell cycle arrest, was shown to delay the G2/M transition in tumor cells. We have characterized the effects of HMN-176 on spindle assembly in *Spisula solidissima* oocytes and mammalian tumor cells. HMN-176 blocked aster formation and spindle assembly in live *Spisula* oocytes but had no effect on nuclear envelope breakdown or chromosome structure. The drug inhibited centrosome-dependent aster assembly in cytoplasmic extracts prepared from activated oocytes. Importantly, HMN-176 inhibited the ability of isolated *Spisula* centrosomes to nucleate microtubules and organize asters in defined media, an effect that is reversible following drug removal. HMN-176 had no significant effect on the polymerization of either three cycled *Spisula* oocyte tubulin, sea urchin egg tubulin, or glutamate-purified tubulin from these sources. Treatment of human CFPAC-1 cells with HMN-176 resulted in a significant delay in M-phase of mitosis, but had no effect on the timing of any other phase of the cell cycle. Importantly, immunofluorescence analysis of CFPAC-1 cells revealed that HMN-176 induced the assembly of multipolar spindles, perhaps due to inhibition of centrosome function. Finally, HMN-176 inhibited the ability of isolated human HeLa S3 centrosomes to nucleate microtubules and assemble asters in defined media. We conclude that HMN-176 inhibits centrosome-dependent microtubule nucleation. We hypothesize that the mechanism of action of HMN-176 is to inhibit interactions between α/β-tubulin dimers and γ-tubulin or γ-tubulin ring complexes, which are required for centrosome-dependent microtubule nucleation. Importantly, this effect is reversible. To our knowledge this is the first report of an anti-centrosome drug and the first demonstration that the centrosome is a potential target for therapeutics.

Disruption of Cell Adhesion and Mitotic Delay in Paclitaxel-induced Apoptosis

E. Yoon, S. Yu, J. Lee, W. Lee, S. Kim; Kongju National University, Gongju, Republic of Korea

Paclitaxel (Taxol), an antimicrotubule agent, promotes the formation of highly stable microtubules that resist depolymerization by specifically binding to the N-terminal region of α/β-tubulin dimers and γ-tubulin ring complexes, which are required for centrosome-dependent microtubule nucleation. HMN-176 blocked aster formation and spindle assembly in live *Spisula* oocytes but had no effect on nuclear envelope breakdown or chromosome structure. The drug inhibited centrosome-dependent aster assembly in cytoplasmic extracts prepared from activated oocytes. Importantly, HMN-176 inhibited the ability of isolated *Spisula* centrosomes to nucleate microtubules and organize asters in defined media, an effect that is reversible following drug removal. HMN-176 had no significant effect on the polymerization of either three cycled *Spisula* oocyte tubulin, sea urchin egg tubulin, or glutamate-purified tubulin from these sources. Treatment of human CFPAC-1 cells with HMN-176 resulted in a significant delay in M-phase of mitosis, but had no effect on the timing of any other phase of the cell cycle. Importantly, immunofluorescence analysis of CFPAC-1 cells revealed that HMN-176 induced the assembly of multipolar spindles, perhaps due to inhibition of centrosome function. Finally, HMN-176 inhibited the ability of isolated human HeLa S3 centrosomes to nucleate microtubules and assemble asters in defined media. We conclude that HMN-176 inhibits centrosome-dependent microtubule nucleation. We hypothesize that the mechanism of action of HMN-176 is to inhibit interactions between α/β-tubulin dimers and γ-tubulin or γ-tubulin ring complexes, which are required for centrosome-dependent microtubule nucleation. Importantly, this effect is reversible. To our knowledge this is the first report of an anti-centrosome drug and the first demonstration that the centrosome is a potential target for therapeutics.

Microtubule-dependent Spindle Pole Body Positioning in Interphase Ensures Proper Mitotic Spindle Alignment

I. Raabe, S. K. Vogel, I. Tolic-Norrelykke; MPI-CBG, Dresden, Germany

In all eukaryotic cells, spindle orientation perpendicular to the cleavage plane is important for a successful segregation of complete chromosome sets into daughter cells. It is not well understood when and how a spindle becomes properly aligned within the cell. We explored the dynamics, the causes and effects of spindle alignment in a single-cell assay throughout mitosis in the fission yeast *Schizosaccharomyces pombe*. We show that the spindle is aligned with the cell axis already at the beginning of spindle formation. During prometaphase this alignment is lost to some extent through apparently random movements of the spindle. Anaphase onset is not delayed in cells with misaligned spindles compared to cells with well-aligned spindles, which is not consistent with a spindle orientation checkpoint. Contrary to the wild-type cells, in a set of mutants with microtubule-related defects the spindle was misaligned at the onset of mitosis. Our results thus suggest a novel role for interphase microtubules: besides determining the nuclear and hence the division plane position, they also determine the initial alignment of the mitotic spindle.

Elucidating the Chromosomal Functions of Linker Histone H1 throughout the *Xenopus* Egg Extract Cell Cycle

B. S. Freedman; Molecular and Cell Biology, UC Berkeley, Berkeley, CA

H1 “linker” histones help compact beads-on-a-string nucleosomal arrays into a thicker chromatin fiber. However, it is unclear how H1 affects higher order chromosome architecture, or whether linker histone function is regulated in a cell-cycle dependent fashion. We have examined the structure and function of mitotic and interphase sperm chromosomes lacking histone H1 using.
**Cortical Granule Exocytosis Contributes to Eggshell Formation and Requires Separase Activity in C. elegans**

J. N. Bembenek, J. M. Squarrell, J. G. White; Molecular Biology, UW Madison, Madison, WI

Separase is a widely conserved protease that promotes chromosome segregation by cleaving a subunit of the cohesin complex that tethers sister chromatids together. In several systems, separase also promotes late anaphase events independent of its role in chromosome segregation. Inactivation of the *C. elegans* orthologue of separase, sep-1, causes not only chromosome nondisjunction but also osmotic and mechanical sensitivity due to abnormal eggshell formation. To investigate novel functions of separase in *C. elegans*, we analyzed the nature of the eggshell defect. Newly fertilized wild-type embryos are permeable and lack a chitinous eggshell whereas an impermeable eggshell is present by the first mitosis. Live cell imaging revealed a wave of exocytosis during anaphase of meiosis I which initiates near the mitotic spindle then spreads over the entire embryo. By TEM a unique population of cortical vesicles was observed in these embryos. Analysis with both fluorescent-labeled lectins and a GFP fusion to a resident Golgi protein also showed unique patterns in pre-meiosis I embryos. Wheat germ agglutinin, which recognizes N-acetylglucosaminase, the precursor for chitin, labeled vesicles in meiosis I embryos and the eggshell in older embryos. Based on these data, we conclude that eggshell components are deposited by cortical granule exocytosis. Other osmotic and mechanically sensitive mutants identified by genome-wide RNAi screens exhibited defects in the formation, movement or exocytosis of cortical granules. In particular, depletion of sep-1 led to the retention of cortical granules. Interestingly, we found that SEP-1-GFP not only localized to chromosomes but also colocalized with the outer kinetochore protein HIM-10 to cortical filaments. During anaphase of meiosis I, SEP-1-GFP moved from these filaments to cortical granules and was lost during the exocytic wave. These data indicate that separase may regulate cortical granule exocytosis through a pathway that coordinates chromosome segregation with anaphase events in *C. elegans*.

**Kinetochores Activity Determines the Mechanism of Pole Organization in Mammalian Cells**

A. L. Manning, D. A. Compton; Dartmouth Medical School, Hanover, NH

Tightly focused spindle poles are required for chromosome movement in mammalian cells, and it has been suggested that spindle poles anchor microtubules to resist poleward force generated by kinetochore (Pac-man activity). Pac-man activity is predicted to generate significant force, and we hypothesize that poleward force from kinetochores would influence the mechanism of spindle pole focusing. To test this idea, we examined spindle pole organization in cells lacking specific kinetochore proteins after inhibition of the pole focusing proteins NuMA and HSET. We show that cells deficient in the outer kinetochore protein Nu2 build focused spindle poles despite inhibition of NuMA alone or both NuMA and HSET. In contrast, spindle poles are splayed following inhibition of NuMA and HSET activity in cells deficient in MCAK, CENP-B, or poleward microtubule flux. This demonstrates a specific kinetochore activity associated with Nu2 that influences the requirements for spindle pole focusing. Interestingly, many chromosomes in cells deficient in Nu2, NuMA and HSET activities build Ca++-stable kinetochore fibers. However, those kinetochores lack Pac-man activity because the intercentromere distance is reduced and chromosome movement is suppressed. Thus, active focusing of microtubules at spindle poles by motor activities associated with NuMA and HSET is only required when Pac-man activity is present at kinetochores. In the absence of Pac-man activity, passive crosstalks between spindle microtubules and astral microtubules emanating from centrosomes are most likely responsible for the appearance of focused poles.

**Self-regulated Plk1 Recruitment to Kinetochores by the Plk1-PBP1 Interaction Is Critical for Proper Chromosome Segregation**

Y. H. Kang, J. Park, L. Yu, N. Soung, S. Yun, J. K. Bang, Y. Seong, H. Yu, S. Garfield, T. D. Veenstra, K. S. Lee; 1Biochemistry, Stanford University School of Medicine, Stanford, CA, 2Proteomics and Analytical Technologies, National Cancer Institute, Bethesda, MD, 3Pharmacology, University of Texas Southwestern Medical Center, Dallas, TX, 4Experimental Carcinogenesis, National Cancer Institute, Bethesda, MD, 5Mammalian polo-like kinase 1 (Plk1) has been studied extensively as a key element in regulating cellular proliferation. The polo-box domain (PBD) of Plk1 has an essential role in targeting the catalytic activity of Plk1 to specific subcellular structures critical for mitosis. However, how Plk1 is recruited to the kinetochores and what Plk1 does at this site remain elusive. Here we demonstrated that a novel PBD-binding protein, PBP1, is crucial for recruiting Plk1 to the interphase and mitotic kinetochores. Unprecedently, Plk1 phosphorylated PBP1 at T78, creating a self-tethering site that specifically interacted with the PBD of Plk1, but not with the PBD of Plk2 or Plk3. Later in mitosis, Plk1 also induced PBP1 degradation in a T78-dependent manner, thereby enabling itself to interact with other components critical for proper kinetochore functions. Absence of the p-T78-dependent PBP1 localization induced a chromosome congressing defect and compromised the spindle checkpoint due to diminished levels of 3F3/2 epitope and improper localization of Mad2, thus ultimately leading to aneuploidy. We propose that Plk1 self-regulates the Plk1-PBP1 interaction to timely localize to the kinetochores and this event is critical for promoting chromosome congressing while contributing to spindle checkpoint activation.

**Astral Microtubules Positively Influence Contractile Ring Assembly at the Cell Equator during Anaphase**

L. I. Strickland, K. G. Thorne, D. R. Burgess; 1Biochemistry, Stanford University School of Medicine, Stanford, CA, 2Department of Biology, Boston College, Chestnut Hill, MA

In dividing echinoderm eggs, contact between astral microtubules (MTs) and the cell cortex during anaphase results in spatial and temporal specification of cytokinesis. Two models make opposite predictions regarding the role of astral MTs in furrow initiation. The equatorial stimulation model proposes that astral MTs oriented toward the equator promote cytokinesis. Alternatively, the polar relaxation model suggests that astral MTs oriented toward the polar cortex suppress cytokinesis by locally relieving cortical tension. To test these models, we locally perturbed the interaction between astral MTs and the cell cortex by applying nocodazole to either the equatorial or polar surface of anaphase-stage eggs. Microinjection of GFP-EBi1 allowed for observation of astral MT elongation and microinjection of a GFP actin binding domain (GFP-eABD) allowed for observation of the assembly and activity of the contractile ring. Application of nocodazole to the equatorial surface of anaphase-stage eggs resulted in suppression of cytokinesis at the site of nocodazole exposure. Application to the polar surface caused initial displacement of the contractile ring toward the opposite pole, followed by repositioning toward the plane of the former metaphase plate during ingression. Our findings support the equatorial stimulation model, but raise the possibility for a spindle midzone signal, for furrow ingression.

**Phosphoregulation of the Essential E. pomea Contractile Ring Protein Cdc15**

R. H. Roberts, C. A. Thorne, J. Chen, K. L. Gould; Department of Cell and Developmental Biology, HHMI & Vanderbilt University Medical School, Nashville, TN

For cells to undergo cytokinesis with appropriate timing, all scaffolding and cytoskeletal proteins that ultimately form the contractile actin ring must arrive, function, constrict and dissociate in a coordinated and tightly controlled manner. In the fission yeast, PCh-family founding member Cdc15 is essential for cytokinesis. We propose that Plk1 self-tethering site that specifically interacted with the PBD of Plk1, but not with the PBD of Plk2 or Plk3. Later in mitosis, Plk1 also induced PBP1 degradation in a T78-dependent manner, thereby enabling itself to interact with other components critical for proper kinetochore functions. Absence of the p-T78-dependent PBP1 localization induced a chromosome congressing defect and compromised the spindle checkpoint due to diminished levels of 3F3/2 epitope and improper localization of Mad2, thus ultimately leading to aneuploidy. We propose that Plk1 self-regulates the Plk1-PBP1 interaction to timely localize to the kinetochores and this event is critical for promoting chromosome congressing while contributing to spindle checkpoint activation.
800 Mitosis-specific Mechanosensing and Contractile Protein Redistribution Control Cell Shape
J. C. Effer, Y. Kee, J. Berk, M. Tran, P. Iglesias, D. Robinson; 1Electrical Engineering, Johns Hopkins University, Baltimore, MD, 2IMMH, Johns Hopkins University, Baltimore, MD, 3Cell Biology, Johns Hopkins University, Baltimore, MD

Cells utilize numerous mechanisms to control their progression through the cell cycle. Cell division is typically portrayed as a well-ordered sequence of biochemical events. However, cytokinesis, an inherently mechanical process, must be mechanically controlled to ensure that two equivalent daughter cells are produced with high fidelity. We hypothesized that cells have the ability to sense and correct shape asymmetries from applied forces by utilizing mechanosensing and mechanical feedback. Because the mitotic spindle and myosin-II mechanozyme are vital to many aspects of cell division; we explored the roles of these proteins in responding to shape perturbations due to cell division. Using micropipette aspiration, we demonstrate that the contractile-ring protein, myosin-II and centralspindlin, redistribute in response to shape perturbations only during anaphase through cytokinesis. Further, the response is independent of microtubules and spindle orientation. Dividing cells require myosin-II to correct shape perturbations; myosin-II null cells exhibit higher failure rates and divide grossly asymmetrically under mechanical load. In addition, this response does not depend upon extracellular calcium. Our data provide evidence for a mechanosensory system that directs contractile proteins to regulate cell shape during anaphase through cytokinesis completion. This study establishes a framework for a systems-level analysis of the biochemical and mechanical regulation of cell shape that enables robust cytokinesis.

801 Assembly of the Cytokinetic Contractile Ring from a Broad Band of Nodes in Fission Yeast
J. Wu, MCDH Yale University, New Haven, CT

We observed live fission yeast expressing pairs of fluorescent fusion proteins to test the popular models that the cytokinetic contractile ring assemblies from a single myosin-II progenitor or a Cdc12p-Cdc15p spot. Under our conditions anillin-like protein Mid1p establishes a broad band nodes in the equatorial cortex. These nodes mature by the addition of conventional myosin-II (Myo2p, Cdc4p, and Rll1p), IQGAP (Rag2p), PCH protein (Cdc15p), and formin (Cdc12p). We find that most of the nodes contain all the seven proteins. The node formation depends on Mid1p but not on actin filaments. We did not observe assembly of contractile rings by extension of a leading cable from a single spot or progenitor. These results suggest that nodes might be the basic units for contractile-ring assembly. We propose a lateral contraction model to explain our data. Formin Cdc12p nucleates actin filaments and remain attached to their barbed ends in vitro so they may also anchor the filaments in nodes of dividing cells. As actin subunits add to barbed ends associated with Cdc12p, we presume that the pointed ends of these filaments radiate from nodes. Actin filaments from one node might encounter myosin-II in adjacent nodes. Movement of myosin-II toward the barbed end of an actin filament anchored in an adjacent node might pull nodes together as they coalesce into a compact ring. Observation of actin filaments using GFP-tagged calponin motif of IQGAP Rag2p during coalescence supports our model. Our lateral contraction model also shares some features with models of cytokinesis in animal cells. Since proteins are spatially and temporally correlated during node formation, they might physically interact with each other. We are investigating the physical interactions between Mid1p and other node proteins using genetic and biochemical methods. This will be another important step to establish a quantitative model to understand cytokinesis.

802 Independent Functions of Centralspindlin and the Chromosomal Passenger Complex in Cytokinesis Ring Assembly and Constriction
L. K. Lewellyn, A. Maddox, A. Desai, K. Oegerle; Cellular and Molecular Medicine, Ludwig Institute for Cancer Research, La Jolla, CA

An integral part of cell division is the separation of daughter cells via cytokinesis. Recent data have demonstrated that membrane delivery to the cleavage furrow plays a key role in furrowing and abscission. Indeed, we have previously shown that Fip3-dependent endosome targeting to the cleavage furrow is required for abscission in mammalian cells. While Fip3 is implicated in regulating cytokinesis, it remains unclear how FIP3 is targeted to the cleavage furrow and regulates abscission. We speculate that FIP3 interacts and possibly regulate other proteins involved in cytokinesis(107,409),(898,450). To test this we have immunoprecipitated FIP3 with anti-FIP3 antibodies and used mass spectrometry to identify its binding partners. Interestingly, MgcRacGAP/CYK4 was identified as a putative FIP3-interacting protein. It has been established that MgcRacGAP/Cyk4 binds to MKLP1 to form a central spinidlin complex that is known for its role in cytokinesis. Mapping the interaction domains revealed that Fip3 binds to N-terminus part of MgcRacGAP/Cyk4. Interestingly, the same MgcRacGAP/Cyk4 domain was implicated in binding Ect2 (Rho GEF). The centralspindlin-dependent recruitment of Ect2 to the midzone of dividing cells appears to play a key role in activation of RhoA, a key regulator of cytokinesis. Here we show that MgcRacGAP/Cyk4 domain is implicated in binding Ect2 (Rho GEF). The centralspindlin-dependent recruitment of Ect2 to the midzone of dividing cells appears to play a key role in activation of RhoA, a key regulator of cytokinesis. We hypothesized that cells have the ability to sense and correct shape asymmetries from applied forces by utilizing mechanosensing and mechanical feedback. Because the mitotic spindle and myosin-II mechanozyme are vital to many aspects of cell division, we explored the roles of these proteins in responding to shape perturbations due to cell division. Using micropipette aspiration, we demonstrate that the contractile-ring protein, myosin-II and centralspindlin, redistribute in response to shape perturbations only during anaphase through cytokinesis. Further, the response is independent of microtubules and spindle orientation. Dividing cells require myosin-II to correct shape perturbations; myosin-II null cells exhibit higher failure rates and divide grossly asymmetrically under mechanical load. In addition, this response does not depend upon extracellular calcium. Our data provide evidence for a mechanosensory system that directs contractile proteins to regulate cell shape during anaphase through cytokinesis completion. This study establishes a framework for a systems-level analysis of the biochemical and mechanical regulation of cell shape that enables robust cytokinesis.

803 Sequential Binding of Ect2 and Fip3 to Centralspindlin Complex Regulates Furrowing and Abscission during Cytokinesis
G. C. Simon, E. Schonteich, C. C. Wu, M. Glotzer, R. Prekeris; 1Cell and Developmental Biology, University of Colorado Health Sciences Center, Aurora, CO, 2Pharmacology, University of Colorado Denver Health Sciences Center, Aurora, CO, 3Cell Biology, University of Chicago, Chicago, IL

Assembly of the Cytokinetic Contractile Ring Complex

An integral part of cell division is the separation of daughter cells via cytokinesis. Recent data have demonstrated that membrane delivery to the cleavage furrow plays a key role in furrowing and abscission. A recently identified Fip3 protein is a member of FIP protein family and has homology to the Drosophila protein, Cytoplasmic enhancer of cell shape (Cez). While Fip3 is implicated in cytokinesis, it remains unclear how FIP3 is targeted to the cleavage furrow and regulates abscission. We speculate that FIP3 interacts and possibly regulate other proteins involved in cytokinesis. To test this we have immunoprecipitated FIP3 with anti-FIP3 antibodies and used mass spectrometry to identify its binding partners. Interestingly, MgcRacGAP/CYK4 was identified as a putative FIP3-interacting protein. It has been established that MgcRacGAP/Cyk4 binds to MKLP1 to form a central spinidlin complex that is known for its role in cytokinesis. Mapping the interaction domains revealed that Fip3 binds to N-terminus part of MgcRacGAP/Cyk4. Interestingly, the same MgcRacGAP/Cyk4 domain was implicated in binding Ect2 (Rho GEF). The centralspindlin-dependent recruitment of Ect2 to the midzone of dividing cells appears to play a key role in activation of RhoA, a key regulator of cytokinesis. We hypothesized that cells have the ability to sense and correct shape asymmetries from applied forces by utilizing mechanosensing and mechanical feedback. Because the mitotic spindle and myosin-II mechanozyme are vital to many aspects of cell division, we explored the roles of these proteins in responding to shape perturbations due to cell division. Using micropipette aspiration, we demonstrate that the contractile-ring protein, myosin-II and centralspindlin, redistribute in response to shape perturbations only during anaphase through cytokinesis. Further, the response is independent of microtubules and spindle orientation. Dividing cells require myosin-II to correct shape perturbations; myosin-II null cells exhibit higher failure rates and divide grossly asymmetrically under mechanical load. In addition, this response does not depend upon extracellular calcium. Our data provide evidence for a mechanosensory system that directs contractile proteins to regulate cell shape during cytokinesis completion. This study establishes a framework for a systems-level analysis of the biochemical and mechanical regulation of cell shape that enables robust cytokinesis.

804 Cytokinetic Abscission Proceeds by Asymmetric Midbody Disassembly
P. Steinemann, S. Maar, D. Gerlich; Institute of Biochemistry, ETH Zurich, Zurich, Switzerland

Cytokinetically induced furrow ingression and subsequent completion of cytokinesis by abscission are temporally separated events in many mammalian cell types. The mechanism of abscission is unknown, but both membrane and cytoskeletal dynamics at the midbody have been proposed to drive abscission. Here, we have investigated by quantitative live cell microscopy a collection of fluorescent reporter cell lines expressing the midbody and cytoskeletal proteins. We found that abscission proceeds by rapid asymmetric disassembly of midbody microtubule bundles, accompanied by secretory vesicle fusion with the plasma membrane. Asymmetric midbody disassembly depended on active Aurora B, as chemical inhibition by Hesperadin led to premature and symmetric midbody microtubule disassembly. Using photobleaching assays, we further show that midbody microtubules were generally stable. Dynamic microtubules were strictly confined to two narrow bands within the central midbody, adjacent to, but not overlapping with midbody-localized chromosomal passenger complex. Inhibition of Aurora B increased microtubule dynamics throughout the entire midbody. Based on these observations, we propose a model where abscission is initiated by midbody localization of Aurora B, leading to asymmetric midbody disassembly.

805 Cep55 Associates with Centralspindlin to Control the Midbody Integrity and Cell Abscission during Cytokinesis
W. Zhao, A. Seid, G. Fang; Biological Sciences, Stanford University, Stanford, CA

We have developed an efficient functional screen for novel mitotic regulators by combining information on the gene expression profiling, cellular localization and loss-of-function studies. Our genomic analysis was based on the prediction that expression of genes in the core cell cycle machinery tends to co-vary during tumorigenesis, as these regulators function as one module during tumor proliferation. Using the co-variation pattern with known cell cycle genes in tumor tissues, we identified novel cell cycle regulators whose functional specificity to mitotic/cytokinesis was...
Further defined by their induction in G2/M. The physiological activities of these novel genes were analyzed by their localization to mitotic/cytokinesis structures and by their loss-of-function phenotypes by RNAi. This approach has led to the identification of multiple novel microtubule-associated proteins essential for mitosis and cytokinesis. We will present data on the function of these mitotic regulators. For example, we identified Cep55 as a regulator required for the completion of cytokinesis. We found that Cep55 localizes to the mitotic spindle during prometaphase/metaphase and to the spindle midzone/midbody matrix during anaphase/cytokinesis. At the terminal stage of cytokinesis, Cep55 organizes the midbody structure required for the completion of cytokinesis. Cep55 knockdown cells lack the midbody matrix, and the structural and regulatory components of the midbody, such as Aurora B, MKLP2 and PRC1, are either absent or mislocalized. Cep55 also facilitates the membrane fusion at the terminal stage of cytokinesis by controlling the localization of endobrevin, a v-SNARE required for cell abscission. On the other hand, Cep55 is under the control of centralspindlin, as Cep55 directly interacts with centralspindlin and as knockdown of centralspindlin abolishes the localization of Cep55 to the spindle midzone. Our study defines a cellular mechanism that links centralspindlin to Cep55, which, in turn, controls the midbody structure and membrane fusion at the terminal stage of cytokinesis.

Membrane remodeling during cytokinesis in the C. elegans Embryo

J. M. Squirell, J. Campbell, J. G. White; Laboratory for Molecular Biology, University of Wisconsin, Madison, WI

In order to successfully complete the division of one cell into two, seemingly disparate cellular systems, including cell cycle regulators, cytoskeletal networks, RNA processing and membrane trafficking pathways, must be coordinated in both time and space. We are studying scission, the final phase of cytokinesis in which midbody components must be removed and membrane inserted to close the channel that remains between the daughter cells. We have used multiphoton microscopy to observe live embryos either expressing GFP fusion proteins or labeled with membrane-specific probes, in conjunction with electron microscopy, to examine the process of membrane deposition during scission. We have found that membrane accumulates at the scission site and that this accumulation is subsequently resolved by endocytic events stimulated by the apoposis of astral microtubules from the rotating P1 spindle. The presence and removal of this excess membrane is supported by ultrastructural study showing folds of membrane along the cytokinetic furrow adjacent to the spindle midbody, as well as the apparent internalization of excess membrane after cytokinesis is complete. Our observations indicate that the spindle midzone, together with furrow-localized centralspindlin, play an essential role in directing the proper membrane accumulation at the site of scission. We are using compartment specific labeling and high-speed imaging in an effort to determine the dynamics of membrane insertion and the source of the inserted membrane.

Cytokinetic Furrow Induction in Toroidal, Binucleate, and Anucleate C. elegans Embryonic Cells

J. K. Baruni, E. M. Munro, G. von Dassow; Friday Harbor Labs, University of Washington, Friday Harbor, WA

In a classic study, Rappaport created toroidal sand dollar eggs and showed that juxtaposition of two mitotic asters suffices to induce furrowing, absent a spindle or chromatin between them. However, recent studies on other cell types implicate the central spindle or chromosomal passenger proteins, suggesting that cells may rely on different parts of the mitotic apparatus for cleavage induction. We attempted Rappaport's key experiment in C. elegans embryos, forming toroidal cells by perforating them with a glass rod, in order to spatially separate aster-dependent inductive cues from cues dependent on the central spindle. In toroidal cells, the surface obstacle from the central spindle by the perforation either did not ingress or formed unstable furrows. The unobstructed side generally ingressed to completion. However, the obstructed side generally recruited GFP-mycosin to the equatorial cortex, even when no ingress was apparent. Myosin also recruited to the side of the perforation adjacent to the central spindle. This implies that the far side of the probe receives the normal signal to initiate a furrow, but cannot sustain it, whereas furrows that form around a central spindle complete. We occasionally observed, in the second round of division, furrows and myosin recruitment between two unconnected by a central spindle, but the tendency of spindles to reorient within uninuclear blastomers made this difficult to repeat. As an alternate approach we used a laser to fuse cells, creating a single cell with two nuclei. In cases where the two nuclei remained separate, they formed distinct spindles within the common cytoplasm, and cleaved from one to four cells. This outcome requires furrows to form between two unasters unconnected by a spindle. Finally, we find that anucleate cells, containing only a pair of centrosomes and no spindle or nucleus, make repeated attempts at cytokinesis.

Calcium Binding to Fip3 Is Essential for Cytokinesis

G. C. Simon,1 J. R. Junutula,2 H. Matern,3 T. Katuladelz,1 R. Prekeris;1 1Cell and Developmental Biology, University of Colorado Health Sciences Center, Aurora, CO; 2Genentech, Inc, South San Francisco, CA; 3Exelixis, Inc, South San Francisco, CA; 4Pharmacology, University of Colorado Health Sciences Center, Aurora, CO

Cell division is a highly synchronized process that is regulated by a variety of different signaling mechanisms. In addition to a cyclin-dependent kinase system, second messengers, such as calcium, have also been suggested to play an important role in cell division. Accumulating evidence demonstrates that localized elevations of cytosolic free calcium ions are associated with several cytokinesis steps, including initiation and propagation of the cleavage furrow in Xenopus, Drosophila, zebrafish and newt. The mechanism of calcium function during cytokinesis remains to be determined. It was suggested that calcium may regulate the contraction of acto-myosin ring, thus initiating the cleavage furrow. Furthermore, calcium was suggested to regulate mitotic spindle formation as well as vesicle transport to the cleavage furrow. Interestingly, a portion of Fip3, a Rab11 GTPase interacting protein that is required for cytokinesis, shares a sequence similarity with EF-hands. EF-hand domains are responsible for calcium binding and signal transduction in many calcium binding protein. Thus, we tested whether calcium binding to Fip3 EF-hands may directly regulate Fip3 function during cytokinesis. First, we used a combination of NMR, isothermal titration calorimetry and circular dichroism to demonstrate that calcium binds to Fip3-EF hands. Second, we used immunofluorescence and time-lapse microscopy to demonstrate that calcium binding regulates the recruitment of Fip3 to the cleavage furrow. Third, we used calcium-binding Fip3 mutants to demonstrate that Fip3 interaction with calcium is required for successful completion of cytokinesis. We propose that calcium-induced calcium binds to Fip3-EF hands. EF-hand domains are responsible for calcium binding and signal transduction in many calcium binding protein. Thus, we tested whether calcium binding to Fip3 EF-hands may directly regulate Fip3 function during cytokinesis. First, we used a combination of NMR, isothermal titration calorimetry and circular dichroism to demonstrate that calcium binds to Fip3-EF hands. Second, we used immunofluorescence and time-lapse microscopy to demonstrate that calcium binding regulates the recruitment of Fip3 to the cleavage furrow. Third, we used calcium-binding Fip3 mutants to demonstrate that Fip3 interaction with calcium is required for successful completion of cytokinesis. We propose that calcium-induced conformational change in Fip3 is required for Fip3 delivery to the mitotic cleavage furrow and regulating the completion of cytokinesis.

Polar Relaxation and Equatorial Stimulation Coexist in the Cytokinesis of Silksworm Spermatoocytes

W. Chen, D. Zhang; Zoology/CGRB, Oregon State University, Corvallis, OR

Polar relaxation and equatorial stimulation are two prevailing models proposed to explain induction of cytokinesis in animal cells. These two models, though contradicting, have been consistently supported by their own evidence in the last few decades. As microtubules are recognized to play a more important role in signaling the cortex to position the cleavage furrow, we wonder whether these two models can be unified under the basis of microtubules. Because the asters are naturally detached from the spindle in silkworm spermatoocytes, we established primary cell culture of silkworm spermatoocytes as a working system to test the two contradictory models. Following microinjection of Alexa 568 tubulin and Alexa 488 phalloidin to label microtubules and actin filaments, we imaged individual spermatoocytes driven by micromanipulated microtubules using a spinning disc confocal microscope. When asters are brought to the cortex of one spindle pole by a micromanipulation needle, actin filaments are excluded away from the asters to the opposite pole, thus the proximal pole becomes relaxed by the asters. This actin exclusion can be blocked with a microinjected placed in the cortical flow of actin filaments, resulting in accumulation of actin filaments on the side of the needle closer to the asters. The polar relaxation depends on the dynamics of astral microtubules, as it is sensitive to stabilization of microtubules with taxol treatment. When astrer-driven actin flow is completely blocked, however,
accumulation of actin filaments is still prominent at the plus-ends of spindle microtubules. We reason such accumulation results from equatorially stimulated or de novo assembly of actin patches at the plus-ends of microtubules, as it occurs regardless of microtubule dislocations by micromanipulations. This microtubule plus-end stimulation is not induced by taxol. Our results suggest that the astral relaxation and the equatorial stimulation mechanism coexist in the cytokinesis of silkworm spermatocytes.

811 Exploring the Function of Anillin in Cytokinesis
A. J. Piecky, M. Glotzer; Molecular Genetics and Cell Biology, The University of Chicago, Chicago, IL
The actin binding protein anillin regulates cytokinesis in several eukaryotic systems. Anillin depletion results in an unusual phenotype in both S2 and HeLa cells. Furrow ingression initiates, but then the contractile ring appears to ‘oscillate’ and cytokinesis fails. Anillin binds to active myosin and a live probe showed that myosin moves in concert with the changing of the furrow in anillin-depleted cells (Straight et al., 2005). We have further explored the role of anillin in cytokinesis. In anillin-depleted cells, YFP-RhoA also moves in concert with the oscillating furrow. This movement initiates upon furrow formation, occurs for about 7-8 minutes and is followed by furrow regression. We have previously shown that depletion of the central spindle component MKLP1 causes an expansion of RhoA localization, but many cells still form ingrowing furrows. In cells depleted of both MKLP1 and anillin, YFP-RhoA localization is dramatically altered and furrows fail to form, suggesting that anillin has a nonessential role in furrow formation. Anillin localizes to the furrow discretely during early anaphase and is dependent on the upstream RhoA regulators RhogEFT C2 and MgcRacGAP CYK-4. Similar to our observations for RhoA, we find that the localization of anillin is sensitive to loss of the central spindle. Depletion of the central spindle component MKLP1, or inhibition of the upstream regulator Aurora B, causes expansion of anillin localization. Although anillin depleted cells form ingrowing furrows, RhoA cannot be detected in fixed cells. However, YFP-RhoA can be visualized in live cells as described earlier. Thus, anillin’s role in cytokinesis is complex; it contributes to maintaining a pool of RhoA at the site of the furrow that is essential for stable furrow formation. Further, anillin also functions redundantly with the central spindle for furrow formation. We are in the process of evaluating if these functions are molecularly related.

812 Failure of Cytokinesis in Cancer Cells
Q. Wu, R. Sahasrabudhe, W. Saunders; Department of Biological Sciences, University of Pittsburgh, Pittsburgh, PA
In some cancer cells, mitotic spindles have more than two poles which can cause chromosome mis-segregation and aneuploidy. Our previous data strongly support the model that failure of cytokinesis is the mechanism for cells to amplify pole number in tested HEK-293 cells and UPC1:SCC103 oral cancer cells. Recent studies in the lab focused on why the cancer cells fail in cytokinesis. We found that myosin regulatory light chain (MLC) phosphorylation, which is the key regulator for the activity of myosin, is reduced in the tested oral cancer cell line. It is known that myosin light chain kinase (MLCK) and myosin phosphatase are two critical enzymes to control the phosphorylation of MLC, so the MLCK and phosphatase expressions in different cell lines were examined. Interestingly, the MLCK is deficient in most cancer cell lines compared to normal cells and phosphatase levels are varied. The knockdown of the myosin phosphatase targeting subunit expression by siRNA increased the phosphorylation level of MLC and resulted in a reduction of the multinucleation and multipolarity in tested cancer cells. Additionally, live cell analysis suggested that cytokinesis failure is partially rescued in the best cases, after reduction of phosphatase activity. In conclusion, we believed that the defects of phosphorylation of MLC is the main reason for failure of cytokinesis in some cancer cell lines, which are due to deficiency of MLCK and relatively high levels of myosin phosphatase.

813 Human Discs-longs (hDlg) Localizes to the Midbody via the Guanylate Kinase Homology Domain and Regulates Cytokinesis
K. Unno, T. Harada, A. H. Chishti; Pharmacology and UIC Cancer Center, University of Illinois College of Medicine, Chicago, IL
The human homologue of the Drosha discs-long tumor suppressor (hDlg), a member of the membrane associated guanylate kinase (MAGUK) family, has been implicated in human tumorigenesis although its precise mechanism remains poorly understood. It was reported that hDlg protein shows a highly concentrated localization at the mitotic spindle midbody structure of the cells at the cytokinesis phase. Since a number of proteins have been identified that localize to the midbody and play functional roles in completing cytokinesis, we hypothesized that hDlg may also be an important component required for the completion of cytokinesis. Failed cytokinesis leads to subsequent cell fusion, creating binucleated cells, or an abnormal segregation of chromosomes (aneuploidy), which is a hallmark of malignant cells. We used human derived cell lines HeLa and U2OS to determine the localization of various hDlg constructs in the cytokinesis phase. These results established that the guanylate kinase homology (GUK) domain is both necessary and sufficient for the localization of hDlg to the midbody of the cells captured in the cytokinesis process. Interestingly, the GUK domain of another MAGUK protein, p55, did not localize to the midbody suggesting the specificity of hDlg in the regulation of this function among MAGUKs. When over-expressed in HeLa and U2OS cells, the DrsRed-GUK-hDlg protein functioned as a dominant negative leading to failed cytokinesis and a significant increase in the formation of binucleated cells. Down-regulation of hDlg using siRNA also resulted in significant increase in the number of multinucleated cells in HeLa and U2OS cells. Together, these results indicate that the guanylate kinase homology domain is essential for the localization of hDlg to the midbody, and this localization is important for the efficient completion of cytokinesis. This novel function of hDlg may contribute to the tumor suppression mechanism during progression of some human cancers.

814 Biochemical Identification of Novel Types of Interactions Involving Ubiquitin-Conjugating Enzymes, Cullin 3, and a BTB-containing Substrate Adaptor
K. S. Pfister, S. M. Pfister; Cell Biology, University of Oklahoma Health Sciences Center, Oklahoma City, OK
BTB (broad complex, Tramtrack, Bric-a-brac) domains are present in a large number of proteins and have been implicated in numerous cellular processes including transcriptional regulation, cytoskeleton organization, and ion channel regulation. It was recently discovered that BTB-containing proteins function in ubiquitin-mediated proteolysis as substrate adaptors for cullin3-based ubiquitin ligases. These multi-subunit ligases typically consist of the cullin3 scaffold bound to a BTB-containing protein at one end and a RING-finger protein/ubiquitin conjugating enzyme complex at the other end. We have found that the ubiquitin conjugating enzyme, UBE2E3, interacts with RCBTB1, a BTB-containing protein that modulates the activity of the anгиотенсин II receptor (AT1A). Interestingly, UBE2E3 and AT1A, bind an overlapping domain of RCBTB1, implying a functional link between the three proteins. Guo et. al. have demonstrated that removal of this domain from RCBTB1 results in a dominant-negative protein that blocks the ability of angiotensin II to induce cellular hypertrophy. We have found that RCBTB1 can dimerize, bind cullin3, and interact with 3 different ubiquitin conjugating enzymes, one of which has no detectable affinity for cullin3. Through biochemical binding assays, we have found that the interaction of UBE2E3 with RCBTB1 is independent of a RING-finger protein. Mutants of UBE2E3 that are deficient in RING-finger binding, interact with RCBTB1 more robustly than the wild type enzyme. In addition, we found that both wild type and RING-finger binding mutants of UBE2E3 bind cullin3. The ability to bind cullin3 without a bridging RING-finger protein appears to occur as a result of UBE2E3 interacting with the amino-terminal half of the cullin. Two enzymes closely related to UBE2E3 also interacted with this domain of cullin3. Together, these findings expand the repertoire of cullin3-based ubiquitin ligases that can form and imply that ubiquitin conjugating enzymes may have multiple roles within these complexes.

815 MyoGEF Differentially Interacts with Mouse Centrosome/Spindle Pole-associated Protein (CSPP) Isoforms
M. Asiedu, D. Wu, Q. Wei; Department of Biochemistry, Kansas State University, Manhattan, KS
We previously reported that MyoGEF, a guanine nucleotide exchange factor, localizes to the cleavage furrow in anaphase cells, interacts with nonmuscle myosin II, and plays an important role in regulating cytokinesis (Cell Cycle, 5(1234-9, 2006). In support of these findings, we have now confirmed that the N-terminal region of MyoGEF (amino acids 71-388) is important for MyoGEF-myosin II interaction. Here we also provide evidence suggesting that MyoGEF can further interact with centrosome/spindle pole-associated protein (CSPP) that localizes to the spindle pole and central spindle during cytokinesis. We have identified three mouse CSPP isoforms, mCSPP-1, 2 and 3, which contain 703, 1142 and 416 amino acids, respectively. GFP-tagged mCSPP-2 and 3 (but not mCSPP-1) localize to the spindle pole and central spindle during cytokinesis. A region corresponding to 104 amino acids, which is present in mCSPP-2 (amino acids 290-393) and mCSPP-3 (amino acids 398-416) but not in mCSPP-1, is required for the localization of the mCSPP-2 and mCSPP-3 proteins to the cleavage furrow and central spindle. Co-immunoprecipitation experiments showed that MyoGEF interacts with GFP-tagged mCSPP-2 and 3 (but not mCSPP-1) in transfected HeLa cells, indicating that the 104-amino-acid region is also important for MyoGEF-mCSPP interaction. Further, in vitro GST pull-down assays indicate that the C-terminal region of MyoGEF (amino acids 392-780) is required for MyoGEF-mCSPP-2 interaction. Taken together, our results suggest that the interactions among MyoGEF, myosin II and mCSPP might play an important role in coordinately regulating cytokinesis.
816 Centrosome Disruption Suppresses Multipolar Spindle Formation after Cytokinesis Failure

F. G. Pruefer, J. Zhou, R. Wollman, G. Goshima, R. Vale; Physiology Course 2006, Marine Biological Laboratory, Woods Hole, MA

Multipolar spindles (MS) are frequently observed in cancer cells, and may play a role in genomic instability. Although polyplaid cells induced by cytokinesis failure seem to increase MS frequency in various cell types, the underlying mechanism is unclear, since centrosome number, chromosone/kinetochore number, total protein amount and cell size increase all after cytokinesis failure. In this study using the Drosophila S2 cell line as a test system we employed RNAi screening and automated microscopy to investigate which factors/genes are important for MS formation. First, we confirmed that cytokinesis failure induced by Pavarotti(Kinesin-6) RNAi significantly increased MS formation in S2 cells (from 15% to ~35). The multiple poles often contain mature centrosomes, but acentrosomal poles (non-γ-tubulin containing) were also observed. We then used double RNAi treatment (Pavarotti + gene X) to identify genes that suppress or enhance MS formation. Of the 19 genes selected in this double RNAi screen, two genes (CNN, SAK) were identified that rescued Pavarotti-induced MS formation. Both of these genes affect centrosome function, CNN by inhibiting γ-tubulin recruitment to centrosomes and SAK by blocking centriole duplication. The rescue by CNN RNAi was particularly striking, resulting in almost all spindles showing bipolar shapes (spindles formed by chromosome-mediated nucleation). These results indicate that increased numbers of centrosomes is the critical factor in MS formation.

817 How Random Is Pollen Tube Growth in A. thaliana?

S. F. Stewman, A. R. Dinner, D. Preuss; 1Chemistry, University of Chicago, Chicago, IL; 2Molecular Genetics and Cell Biology, University of Chicago, Chicago, IL

The reproductive process in Arabidopsis and other higher plants involves complex and highly regulated interactions between pollen tubes and ovules. Although genetic and biochemical approaches identified many of the relevant genes, proteins, tissues, and small molecules, the process of pollen tube guidance is poorly understood. We employed a simplified semi-in vitro system to study how pollen tubes and measured their growth paths in the presence and absence of wild-type ovules. To further understand the effects of specific ovule tissue on guidance, we compared the results of wild-type ovules with mutant ovules that have specific defects in guidance or development (myo98b-1, dif1a, and mol-1). The results were consistent with a path that is fit by a path drawn in the presence of a normal wound present in its guidance ability. This shows that the guidance of pollen tubes in vivo can be mimicked in vitro by the removal of the ovule.

818 Dynamics of LIM and SH3 Protein-1 (lasp-1) and Dynamin-2 (dyn-2) in Living HeLa Cells in the Presence of Epidermal Growth Factor (EGF) or Forskolin

T. E. Rajapaksa, C. S. Chew, T. Okamoto; 1Department of Pharmaceutical Sciences, University of Southern California, Los Angeles, CA; 2Institute of Molecular Medicine and Genetics, Medical College of Georgia, Augusta, GA

Lasp-1 is a multidomain-containing protein that colocalizes with F-actin in structures actively involved in remodeling of F-actin, such as lamellipodia and filopodia. It also interacts with the endocytosis-regulating protein dyn-2 in vitro and colocalizes with dyn-2 in several cell types, particularly in regions of active remodeling of the plasma membrane. This study examines how lasp-1 and dyn-2 interaction may regulate actin dynamics in living HeLa cells treated with EGF or forskolin, which elevate intracellular cAMP. HeLa cells were transiently transfected with either: enhanced Green Fluorescent Protein (eGFP) tagged, wild-type (wt) lasp-1 (lasp-eGFP); dyn-eGFP; or, dyn-eGFP + lasp-wt constructs. Time-lapse imaging was performed in the presence or absence of EGF or forskolin. In addition, for each treatment condition, cells were plated on coverslips, fixed, and immunostained for lasp-1, dyn-2 and F-actin. Time-lapse imaging of lasp-eGFP transfected cells treated with EGF versus untreated showed increased formation of lasp-1-containing membrane ruffles, increased motility of lasp-1-containing filopodia, and formation of structures believed to be involved in macropinosome formation. Dyn-eGFP transfected cells showed increased formation of membrane ruffles upon EGF treatment; however, dyn-2 was not localized to filopodia. In dyn-eGFP + lasp-eGFP co-transfected cells, dyn-2 was also localized to filopodia, and these cells showed increased formation of membrane ruffles and increased motility of filopodia compared to cells transfected with dyn-2 alone. In the presence of forskolin, lasp-eGFP transfected cells showed decreased formation of membrane ruffles and decreased formation/motility of filopodia compared to untreated EGF-treated cells. For both EGF and forskolin treatments, lasp-eGFP or dyn-eGFP were also found to be associated with structures resembling F-actin tail with short curvy paths. These results suggest that lasp-1, possibly together with dyn-2, may regulate signaling-dependent cortical membrane dynamics such as membrane ruffling and filopodia formation/motility may also be involved in actin comet tail formation.

819 CRP1 Bundling of F-actin Requires LIM1 Domain and Adjacent Glycine Rich Region

H. Jang, J. A. Greenwood, Biochemistry and Biophysics, Oregon State University, Corvallis, OR

Cysteine rich proteins (CRPs) have been implicated in cell differentiation, cytoskeletal remodeling, and transcriptional regulation. CRP1 contains two LIM domains, each followed by a glycine rich region that CRP1 regulates the actin cytoskeleton by directly bundling actin microfilaments [Tran et al. (2005) BMC Cell Biology 6: 819]. Previously, we demonstrated that CRP1 contains two LIM domains, each followed by a glycine rich region that CRP1 regulates the actin cytoskeleton by directly bundling actin microfilaments [Tran et al. (2005) BMC Cell Biology 6: 819]. In this study using the S2 cell line as a test system we employed RNAi screening and automated microcopy to investigate which factors/genes are important for CRP1 bundling of F-actin. Furthermore, domain swapping experiments replacing GR1 with GR2 resulted in the loss of CRP1 bundling activity identifying critical amino acid residues. These results highlight the importance of the glycine rich region for CRP1 bundling activity and provide mutual proteins for examining the function of the cytoskeletal population of CRP1. Results from experiments examining the influence of CRP1 mutants on cell adhesion and migration will be presented.

820 The Tobacco LIM Protein WLM1 Is an Actin Bundling Protein

A. A. Steinmetz, C. Thomas, C. Hoffmann, M. Dieterle; 1Plant Molecular Biology, CRP-Sante, Luxembourg, Luxembourg, 2CRP-Sante, Luxembourg, Luxembourg

The tobacco protein WLM1 (NiWLM1) one of the five LIM proteins identified so far in tobacco. Transcripts of the gene have been detected in all the plant organs analyzed but its biological expression is still unknown. We have used confocal microscopy and in vitro analyses to show that this protein is a novel actin-binding and -bundling protein in plants. In BY2 cells the GFP-tagged protein accumulated in the nucleus and cytoplasm where it associated predominantly with actin cytoskeleton, as demonstrated by colabeling and treatment with actin-depolymerizing latrunculin B. High-speed cosedimentation assays revealed the ability of WLM1 to bind directly to actin filaments with high affinity. Fluorescence recovery after photobleaching and fluorescence loss in photobleaching showed a highly dynamic in vivo interaction of WLM1-GFP with actin filaments. Expression of WLM1-GFP in BY2 cells significantly delayed depolymerization of the actin cytoskeleton induced by latrunculin B treatment. WLM1 also stabilized actin filaments in vitro. Importantly, expression of WLM1-GFP in Nicotiana benthamiana leaves induced significant changes in actin cytoskeleton organization, specifically, fewer and thicker actin bundles than in control cells, suggesting that WLM1 functions as an actin bundling protein. This hypothesis was confirmed by low-speed cosedimentation assays and fluorescence microscopy which allowed direct observation of F-actin bundles that formed in vitro in the presence of WLM1. These data identify WLM1 as a novel actin binding protein that increases actin cytoskeleton stability by promoting bundling of actin filaments.

821 The Tobacco Protein WLM2 Is an Actin-binding LIM Domain Protein

S. Gatti, C. Thomas, C. Hoffmann, W. Shen, E. Frederich, A. A. Steinmetz; 1Plant Molecular Biology, CRP-Sante, Luxembourg, Luxembourg, 2Institute of Plant Molecular Biology, CNRS, Strasbourg, France, 3CRP-Sante, Luxembourg, Luxembourg

Sporophytic tissue from tobacco express two WLM proteins: WLM1 and WLM2. These two proteins differ by about 40% in their amino acid sequence and appear to some extent differentially expressed since only WLM2 has been detected in cells from BY2 suspension cultures. Of the two proteins, WLM1 was recently shown to bind and stabilize actin filaments and to promote their assembly into bundles. To see if WLM2 has a similar localization and actin binding properties we have fused its coding sequence to GFP under the control of the dexamethasone-inducible promoter and analyzed the localization of the fusion protein in BY2 cells following Agrobacterium tumefaciens transformation, as well as in leaf epidermal cells following agroinfiltration. In contrast to the sharply defined labeling that we observed with WLM1, WLM2 appeared to associate more loosely with the actin cytoskeleton, with much of the protein remaining free in the cytoplasm. When expressed in animal cells, the two proteins strongly accumulated in the nucleus, and only WLM1 gave a sharply defined cytoskeletal labeling along stress fibers and in focal adhesions. In contrast, cytoplasmic WLM2 remained predominantly unbound, with only a weak labeling of actin cables. However, in high- and low-speed
severing protein and promotes rapid turnover of actin structures in vivo. Mammalian twinfilin sequesters ADP-G-actin and caps filament barbed ends: implications in motility.

In the present study, we have elaborated on the nature of PIP2 binding and identified its binding site in CP. We therefore compared homology models of mouse and S. pombe CPs from these individual events. The fast association (2.6x10^7 M^-1 s^-1) and slow dissociation (0.0003 s^-1) rates for mouse CP are similar to published values from bulk assays. The affinity of fusion yeast CP for vertebrate actin is a thousand-fold less than mouse CP, owing to its slow association (4x10^7 M^-1 s^-1) and fast dissociation (0.004 s^-1) rates. Addition of micelles of the polyphosphoinositides (PPiS), PIP, and PIP2 reduced the concentration of mouse capping protein available to bind barbed ends. However, PPIs did not change the rate of dissociation of mouse CPs from pre-capped filaments. We replicated the appearance of uncapping in bulk assays, but found that this was due to filament breakage together with rapid sequestration of free mouse CP by PPIs, rather than to uncapping. Therefore, PPIs likely lower the affinity of vertebrate CP for filaments by mass action, rather than by allosteric inhibition. In contrast, PPIs had no effect on either the association or dissociation of fusion yeast CP at barbed ends. We therefore compared homology models of mouse and S. pombe CP for clues to potential PPI binding sites in the vertebrate CP crystal structure. A large area of positive potential on the mouse CP β subunit is absent in pombe CP. PPI binding to this patch would sterically hinder actin binding and is thus a strong candidate for the PPI binding site.

Phosphatidylinositol-4,5-bisphosphate (PIP2) plays an important role in cell signaling at membranes in response to extracellular stimuli that lead to actin-based motility. PIP2 interacts with actin Capping protein (CP) by antagonizing its capping activity and by uncapping previously capped actin filaments, which may be important in vivo to promote actin assembly at membranes. In the present study, we have elaborated on the nature of PIP2 binding and identified its binding site in CP. By in vitro actin polymerization and intrinsic tropomyosin quenching assays, we find that neither the individual head or tail groups, in the form of DAG or IP3, inhibited the capping activity of CP. PIP2 micelles, probably through their anionic surface, bind to and inhibits CP with an affinity of ~300 nM. Truncation and point mutants of CP were used to identify PIP2 binding sites. The actin-binding C-terminal region of the CP alpha subunit helps to bind PIP2, while that of the beta subunit is dispensable. Computational docking of PIP2 with CP predicted a cluster of solvent-exposed basic residues on the surface of CP to be the binding site for PIP2 and Point mutations of the key residues confirm this prediction in the actin. So that the presence of PIP2 probably blocks capping of actin filaments via steric hindrance. The results are consistent with uncapping occurring via a “wobble” state in which CP is attached to the barbed end only by its flexible beta subunit C-terminus.

A. Bacconi, 1 S. Hitchcock-DeGregori, 2 G. Danuser, 1 R. Fischer 1; 1Cell Biology, The Scripps Research Institute, La Jolla, CA, 2Department of Neuroscience and Cell Biology, Robert Wood Johnson Medical School, Piscataway, NJ

Actin cytoskeleton forms a cortical network underneath plasma membrane. During cell movement this network forms a polarized protrusion machinery comprising two F-actin modules: the lamellipodium and the lamella, as defined by their actin dynamics (Ponti et al. Science 2004). Actin dynamics in the lamellipodium are dependent on the activities of the Arp2/3 complex and cofilin, while in the lamella they appear to be Arp2/3 independent (Ponti et al. Biophys.J.2005). The relationship between these two networks is still unclear. The aim of this work is to investigate how troponymosin may be involved in these processes in relation to both lamellipodium and lamella networks. We hypothesize that during edge advancement lamella filaments may escape troponymosin decoration, giving way to Arp2/3-mediated branching and thus forming a new lamellipodium towards the cell membrane from the lamella. Immunoblotting analysis of total cell extracts using a variety of specific anti-troponymosin antibodies showed that both long (TM2 and TM3) and short (TM2N1/M2 and TM4) troponymosin isoforms are present in PtK1 cell lines, which was confirmed by mass spectrometry analysis. We prepared total extracts from cell pseudopodia and immunoblot analysis suggested that only short troponymosin isoforms are present. By repeating the previous study with a troponymosin-4 antibody, we demonstrated that at least this isoform is present at the leading edge. Ratiometric analysis of troponymosin-4/F-actin in protruding cells suggests a reduction of troponymosin-4 in the lamella/lamellipodium overlap region, as compared to lamella only region and it is undetectable where the lamellipodium expands beyond the lamella, in support of our hypothesis. Our next step will be to confirm this result by ratiometric analysis of cells with perturbed lamellipodium/lamella filament ratio and by measuring transients of troponymosin-4 decor recruitment of F-actin during cell protrusion. 2006 ASCB Annual Meeting Abstracts

centrifugations WLIM2 cosediments with actin filaments and actin bundling, as does WLIM1. These data suggest that, although WLIM2 can bind and bundle F-actin, it does so with a lower affinity and has therefore probably a less pronounced stabilizing effect on the actin cytoskeleton than WLIM1. This work is supported by the Luxembourg Ministry of Culture, Higher Education and Research.
Cytoskeletal Tropomyosins Are Not Subject to Feedback Regulation

G. Schevzov,1 B. Vrhovski,1 N. Vlahovich,1 J. Hook,1 F. Lemcere,1 E. Hardeman,1 D. F. Wieczorek,1 P. W. Gunning1

Altering the actin cytoskeleton are fundamental features of many diseases including cancer. However, compounds that target actin ubiquitously act on actin in heart and diaphragm rendering them highly toxic. This study investigates whether the potential target, tropomyosin (Tm), is made in limiting amounts. Four mammalian genes encode Tm proteins with over 40 isoforms although it causes a profound decrease in cardiac Tm levels. The distinct spatial sorting and independent regulation of the muscle and cytoskeletal Tms make the cytoskeletal Tms an attractive drug target for manipulation of functionally distinct populations of actin filaments. I.Gignetti and Friederich, 2003, Prog Cell Cycle Res, 5:511 Z.Muthuchamy et al, 1995, J Biol Chem, 270: 36593 J.Palermo et al, 1996, Cir. Res, 78: 504 K.Murat et al, 1997, PNAS USA, 94: 4406

Tip Growth in the Moss Physcomitrella patens Is Dependent on Profilin Function and Regulation

L. Vidali, R. C. Augustine, M. Bezanilla; Biology, University of Massachusetts, Amherst, MA

Tip growth is indispensable for plant growth and reproduction. It is well established that the actin cytoskeleton is the central regulator of tip growth in plant cells, but the precise mechanisms of this regulation remain obscure. To gain insights into the regulation of actin, we are investigating the role of the abundant actin monomer-binding protein profilin. Profilin regulates actin polymerization and has been shown to control for actin function in a variety of organisms. In addition to binding to actin, profilin has a conserved poly-L-proline binding site where it binds regulatory molecules. The moss Physcomitrella patens offers an ideal genetic system for the functional analysis of the actin cytoskeleton during tip growth. In its protonemal phase, this moss grows as single cell thick filaments via tip growth. In addition, Physcomitrella is amenable to homologous recombination and efficient RNA interference (RNAi). Physcomitrella has three profilin genes, with profilin2 as the predominant isoform expressed in protonema. We have used RNAi to inhibit the expression of all isoforms to address the function of profilin during tip growth. Plants lacking profilin show a dramatic inhibition in tip growth and reduced viability, they also have small rounded cells, indicating loss of polarized growth. This phenotype is rescued by the RNAi insensitive expression of profilin. To address the role of actin and poly-L-proline binding in vivo, we have performed transient complementation analysis of profilin RNAi using mutant profilins that do not bond to actin (K87E) or that do not bond to poly-L-proline (Y6D). We found that the ability of profilin to bind actin is indispensable for tip growth. However, poly-L-proline binding is not essential but is required for optimal tip growth, since the Y6D mutant only partially complements. These results indicate that profilin-actin interactions and their regulation are critical for tip growth in plant cells.

Effects of Silencing Profilin-1 on Endothelial Proliferation, Migration, and Cord Morphogenesis

Z. Ding,1 P. Roy2; 1Bioengineering, University of Pittsburgh, Pittsburgh, PA, 2Bioengineering and Pathology, University of Pittsburgh, Pittsburgh, PA

Although profilin-1 (Pfn1) was previously implicated in capillary morphogenesis of endothelial cells (ECs), its role in cellular functions that are important for capillary morphogenesis such as EC proliferation and migration remains unknown. To address this gap, we evaluated the effects of loss of Pfn1 expression on proliferation, migration and extracellular matrix (ECM)-induced morphogenesis of ECs. By using RNA interference, a time-dependent progressive loss of Pfn1 expression with ~97% gene-silencing was achieved within 96 hours after transfection in human umbilical vein endothelial cells (HUVECs). Loss of Pfn1 expression was associated with significant decrease of actin filaments and focal adhesions in ECs. Wound-healing experiments showed increasing inhibition of directed cell migration with progressive loss of Pfn1 expression. Time-lapse imaging revealed that Pfn1-deficient cells have reduced protrusive ability, both in terms of its magnitude and directional persistence. Silencing Pfn1 expression also significantly inhibits EC proliferation without affecting cell viability, at least in the short-term. Further cell-cycle profile analyses showed that loss of Pfn1 expression inhibits transition from G1 to S phase with concomitant increase in the expression of p27Kip1. Finally, Pfn1-deficient cells were found to be significantly impaired in forming cords-like structures on ECM. Since cord morphogenesis is an early endothelial rearrangement necessary for capillary formation by ECs, these data lay the foundation for future studies to explore Pfn1’s role in capillary formation by ECs.

Roles of Profilin in Cell Spreading and Migration

O. C. Danciu, S. Kojima, G. G. Borisy; Cell and Molecular Biology, Feinberg School of Medicine, Northwestern University, Chicago, IL

Profilins, actin-binding proteins, are known to block polymerization at the pointed ends and to suppress spontaneous nucleation of actin filaments, thus polarizing actin polymerization to the barbed ends of existing actin filaments. This polarization is presumably important for cell migration which is believed to be driven by actin polymerization at the barbed ends of actin filaments. However, direct tests of this hypothesis in vivo have been limited in nature. In order to evaluate the role of polarized polymerization in cell spreading and migration, we performed RNA interference of profilin in mouse melanoma B16F1 cells. Microarray analysis indicated that profilin1 was the dominant profilin species in melanoma cells; therefore we focused on profiling depletion of profilin1 by 5 days after transfection as revealed by Western blotting. Profilin-depleted cells showed delay in spreading. While 80% of control cells formed lamellipodia 1 hour after plating on laminin-coated coverslips (n=87), only 15% of knockdown cells showed enrichtment of actin at the cell periphery, but the structures looked different from typical lamellipodia. Profilin-depletion also inhibited cell migration. Knockdown cells were poorly polarized and their translocation velocities averaged 30% that of control cells (0.30 ± 0.23 μm/min vs. 0.95 ± 0.20 μm/min, p<0.05). Our results demonstrate that polarized actin polymerization facilitated by profilin is necessary for efficient cell spreading and migration. In the absence of profilin, the pointed ends likely add G-actin, decreasing productive polymerization at the barbed ends, thus slowing cell spreading, degrading cell polarization and reducing the overall speed of cell motility. Supported by NIH GM 64346.

Role of Cortactin in Invadopodia Formation Downstream of Src Kinase

L. C. Kelley, A. G. Ammer, D. C. Flynn, S. A. Weed; Program in Cancer Cell Biology, West Virginia University, Morgantown, WV

Invadopodia are actin-rich ventral membrane protrusions found in oncogenic kinase transformed fibroblasts and metastatic cancer cell lines. Cortactin is an Arp2/3 activating and actin-binding protein initially identified as a major substrate in v-Src transformed cells, and is a core invadopodia component. Cortactin is necessary for invadopodia formation and function in breast cancer cell lines, and the level of tyrosine phosphorylation in invadopodia correlates with their ability to degrade the extracellular matrix. However, a complete understanding of the molecular role of cortactin in invadopodia has not been reported. It is proposed that the role of cortactin in invadopodia formation in response to Src transformation, we introduced a GFPP-tagged temperature sensitive mutant of v-Src (tsLa29-GFP) into Src-deficient (SYF) fibroblasts. Invadopodia formation is induced when cells expressing tsLa29-GFP are switched from the non-permissive temperature (41°C) to the permissive temperature (35°C) as determined by confocal fluorescence microscopy and rhodamine phalloidin labeling of the actin cytoskeleton. Invadopodia are enriched with actin of v-src and cortactin phosphorylated at the major Src-targeted residue, tyrosine 421. Inhibition of cortactin expression by siRNA substantially diminished the ability of tsLa29-GFP to induce invadopodia formation at the permissive temperature. Pretreatment of SYF cells expressing tsLa29-GFP for 2 h with the Src/Abl small molecule inhibitor AZD0530 also ablated invadopodia formation at the permissive temperature. AZD0530 treatment inhibits Src activity as determined by Western blot analysis of tyrosine 215, and inhibited phosphorylation of cortactin at tyrosine 421. Collectively, these findings indicate that cortactin is required for Src-mediated invadopodia formation and that downregulation of Src activity correlates with inhibition of invadopodia formation and cortactin tyrosine phosphorylation. We are currently using mutational analysis to investigate the contributions of the functional domains, as well as serine and tyrosine phosphorylation on invadopodia formation and function.
The Actin-binding Repeat of Cortactin Binds F-actin in a Dynamic Manner and Affects Inter-subunit Contacts in F-actin
L. A. Selden,1 D. Chereau,2 R. Dominguez,1 E. Reisler;1 Department of Chemistry/Biochemistry and Molecular Biology Institute, UCLA, Los Angeles, CA, 3Boston Biomedical Research Institute, Watertown, MA, 4Institute, Watertown, MA, 3School of Medicine, University of Pennsylvania, Philadelphia, PA
Cortactin is a ubiquitous actin- and Arp2/3-binding protein, involved in extracellular signal communication, regulation of cytoskeleton dynamics and cortical actin-associated structures. Cortactin presents a unique F-actin-binding domain known as the cortactin repeat, which consists of 6 1/2 repeating sequences of 37 amino acids. Recent EM and 3D reconstruction studies showed that the binding of cortactin to F-actin facilitates the lateral interprotomer contacts, widening the gap between two filament strands (Pant et al. 2006). To assess the effect of cortactin on both lateral and longitudinal interprotomer contacts in F-actin, we employed two yeast actin mutants: Q41C and S265C. Cysteines inserted in the DNase I binding (C41) and hydrophobic (C265) loops allowed for longitudinal or lateral cross-linking of Cys74 of adjacent actin protomers in F-actin. Using disulfide and DDB cross-linking, we found that the actin-binding domain of cortactin (amino acids 83-306 of murine cortactin) inhibits strongly the rate of disulfide and DDB cross-linking across both the lateral and longitudinal interfaces, indicating a potential weakening of interprotomer contacts. This effect was strengthened for the lateral interstrand cross-linking. These results provide evidence for cortactin-induced changes at the sites of lateral and longitudinal interprotomer contacts in F-actin. To assess the dynamics of the cortactin actin-binding domain, we created cortactin cysteine mutants. We found that pairs of cysteines placed at the N- and C-terminal ends of the cortactin repeat could be cross-linked by reagents of varying spans (0-9.6 Å) such as disulfide bonds (zero length), DDB (4.4 Å) and MTS-6 (9.6 Å). The cross-links formed intra-molecular bridges between these cysteines, suggesting that the cortactin repeat is flexible and unstructured, and binds F-actin in a highly dynamic manner.

Direct Interaction between Caldesmon and Cortactin
R. Huang, J. Kordowska, C. L. A. Wang; Muscle and Motility Group, Boston Biomedical Research Institute, Watertown, MA
Actin polymerization and depolymerization play a central role in controlling a wide spectrum of cellular processes. There are many actin-binding proteins in eukaryotic cells. Their roles in the remodeling of the actin architecture are just beginning to be understood and whether they work cooperatively remains an intriguing question. Both caldesmon (CaD) and cortactin are actin-binding proteins present in mammalian cells, the former being known to stabilize actin filaments and regulate the actomyosin interaction, whereas the latter, primarily found in the cell cortex, being implicated to promote Arp2/3-mediated actin branching. There have been no reports suggesting that CaD and cortactin interact with each other or work as partners. We now present evidence that CaD binds cortactin directly by a number of independent approaches, including overlay, pull-down assays, ELISA and column chromatography. The interaction involves the N-terminal region of cortactin and the C-terminal region of CaD, and seems enhanced by divalent metal ions. Cortactin competes with both full-length CaD and its C-terminal fragment for actin binding. Binding of cortactin to CaD is significantly enhanced by the addition of ATPase activity, which can be demonstrated in vitro, the two proteins also appear to co-localize in activated cells at the leading edges, although the distribution of cortactin is wider than that of CaD. Since under these conditions CaD is largely phosphorylated, we propose that cortactin preferentially targets phosphorylated CaD in vivo. The functional significance of such interactions awaits further investigation. Supported by a grant from NIH (P01-AR41637).

Cortactin presents a unique F-actin-binding domain known as the cortactin repeat, which consists of 6 1/2 repeating sequences of 37 amino acids. Recent EM and 3D reconstruction studies showed that the binding of cortactin to F-actin facilitates the lateral interprotomer contacts, widening the gap between two filament strands (Pant et al. 2006). Glutathionylation of cellular actin occurs during conditions of oxidative stress and correlates with changes in the actin cytoskeleton. We have investigated the effects of glutathionylation on cofillin-depoxidimerization of mammalian non-muscle F-actin. F-actin (FA) or glutathionylated F-actin (GS-FA) was copolymerized with 5% pyrene-actin. Depolymerization, indicated by a decrease in pyrene fluorescence, was induced by 100-fold dilution into buffer containing vitamin D binding protein (DBP), followed by quick mixing/severing with a pipette tip. A reproducible filament number (~2 nM) was verified. In the presence of DBP, depolymerizing actin subunits cannot re-associate with filament ends and the depolymerization rate is (k_b + k_p)m, where m is the number of filament ends and k_b and k_p are the depolymerization rate constants from the barbed and pointed ends of the filament, respectively. Initial experiments showed that GS-FA depolymerized approximately three times faster than FA. When GS-FA was pre-incubated with equimolar cofillin prior to dilution, the depolymerization rates were similar to samples which had not been pre-incubated with cofillin, suggesting a similar number of filament ends and rapid dissociation of the cofillin-F-actin complex upon dilution. When we pre-incubated GS-FA with cofillin and included excess cofillin in the dilution buffer to prevent dissociation of cofillin-F-actin complexes, we found that cofillin-GS-FA depolymerized 2 times faster than FA, consistent with a 3-fold increase in k_p (assuming k_b = 7.2/s and k_p = 0.26/s for FA). We found that glutathionyl-GS-FA depolymerized approximately three times faster than cofillin-GS-FA. The 3-fold increase in the depolymerization rate constant of GS-FA over FA, and the 3-fold increase in the depolymerization rate constant of cofillin-GS-FA over cofillin-GS FA results in a 9-fold overall increase in the depolymerization rate constant of cofillin-GS-FA over that of FA. This could contribute to cytoskeletal changes during oxidative stress. Supported by Department of Veterans Affairs.

838 The Role of the Formin Homology 1 Domain in Actin Filament Elongation A. S. Paul, T. D. Pollard; Molecular Biophysics and Biochemistry, Yale University, New Haven, CT

Formin proteins nucleate actin filaments de novo for various cytoskeletal structures in eukaryotic organisms. The presence of the polypeptide-rich Formin Homology (FH) 1 domain, N-terminal to the actin-binding FH2 domain, increases the rate of elongation of formin-associated filaments in the presence of profilin-actin, presumably through direct interaction of profilin with individual polyproline tracts. The rate of elongation varies between FH1FH2 constructs from different formins, but all respond bi-phasically to the concentration of profilin (Kovar et al. Cell 124: 432-35, 2006). These features suggest that formins act with a common mechanism toward profilin-actin. In the present work, we sought to elucidate the molecular details of this process by measuring the elongation rate of filaments associated with S. cerevisiae Bni1(FH1FH2) consisting of FH1 domains with different numbers of polyproline tracts. In the presence of S. cerevisiae profilin, the rate of elongation associated with TIRF microscopy of individual filaments increases with the number of polyproline tracts in FH1, nearing a plateau at ~33 subunits/sec with 6 polyproline tracts at 1.5 µM actin. With 1.5 µM actin monomers, all constructs gave a maximum rate of elongation at about 2.5 to 5 µM profilin. Higher concentrations of profilin reduced the elongation rate. We also measured the elongation rate of filaments associated with the FH2 domains from either S. pombe Cdc12p or mouse mDia2 fused to the FH1 domain of Bni1p. Bni1[FH1]-Cdc12(FH2)-associated filaments exhibit elongation rates in the presence of profilin significantly less than those of Bni1[FH1FH2]. By contrast, at most concentrations of profilin, Bni1[FH1]-mDia2(FH2)-associated filaments grew faster than those of mDia2(FH1FH2) and similar to filaments associated with Bni1[FH1FH2]. These results best support a model in which profilin-actin binds to individual polyproline tracts in the FH1 domain. In mammalian cells, direct filament dissociation is the primary mechanism for formation of branched actin networks.

839 ForA Is a Diaphanous-related Formin Required for Phototaxis and Normal Development of Dicyostelium Cells N. Ramalingam, J. Faix, M. Schleicher; 1Department of Cell Biology, Ludwig-Maximilians-University, Munich, Germany, 2Department of Biophysical Chemistry, Hannover Medical School, Hannover, Germany.

Formins are large, multi-domain proteins involved in the nucleation of linear actin filaments. These proteins were shown to be important for cytokinesis, cell polarity, microtubule dynamics and the formation of filopodia. The sequencing of the Dicyostelium genome revealed 10 formins. Here we present evidence for the role of ForA in cell motility during the development of D. discoideum. ForA is a unique Diaphanous-Related Formin that harbouring a protein kinase C conserved region 2 (C2). Biochemical analysis of a recombinant FH2 fragment showed ForA-mediated nucleation and assembly of actin filaments in a dose-dependent manner in vitro. In contrast to DmDia2 that exclusively binds to profilin II (Shntenbeck et al. Nat Cell Biol. 2005: 769-74), ForA interacts specifically with the profilin I isoform. The characterization of the ForA-null mutant revealed multiple defects during early and late stages of the developmental cycle. We observed broken streams during early aggregation and severe inhibition of slug motility during phototaxis. These defects could be partially rescued by ectopic expression of the full-length forA. The data suggest that ForA is required for directed cell motility during the multicellular stage of development.

840 Myosin5a Tail Associates with Rab3A in Neuronal Cells T. Woelffert, Y. Lee, J. A. Mercer, D. W. Provance; 1Department of Biophysics and Biochemistry, Yale University, New Haven, CT, 2Department of Microbiology and Immunology, Dartmouth College, Hanover, NH, 3McLaughlin Research Institute, Great Falls, MT

The major RabGTPase in brain, Rab3A, is known to associate with synaptic vesicles (SV) and is involved in SV trafficking. We performed experiments to determine whether Rab3A is involved in myosin-Va (Myo5a) mediated transport of neuronal vesicles. In vitro motility assays performed with axoplasm from the squid giant axon showed a direct involvement of Myo5a in SV transport. The formation of the Myo5a-SV complex was not affected by the presence of Rab3A, but the transport of the complex was reduced in the presence of Rab3A. This suggests that Rab3A is required for the transport of Myo5a-SV complexes.

841 Nuclear Localization Sequences and Phosphorylation on Serine 1650 in the Globular Tail Domain of Myosin Va Determines Its Translocation to and Distribution within the Nucleus M. M. A. Baqui, M. C. S. Pranechievucis, S. R. Banzi, E. M. Espefaco, R. E. Larson; 1Cell and Molecular Biology, Faculdade de Medicina de Ribeirão Preto, University of Sao Paulo, Ribeirão Preto, Brazil

The globular tail domain of myosin Va is essential for its attachment to cargos, which include cytoplasmic organelles, membrane vesicles, and mRNA. Recently, we demonstrated the presence of myosin Va (MVa) within the nucleus, co-localized with nuclear speckles. The globular tail domain of MVa has two nuclear localization sequences (NLSs), as identified by peut nib-ac, one of which is adjacent to Ser1650 (mouse sequence), a site phosphorylated by calmodulin-dependent protein kinase II (CaMKII). Recombinant globular tail in fusion with EGFP translocates to the nucleus when transfected into B16-F10 or Si9-6 melanocytes, the latter being derived from dilute mice. The translocation was blocked by mutation of the basic amino acids of both NLSs to alanines, but not when only one NLS was mutated, suggesting that both are independently competent in determining nuclear localization. Mutation of Ser1650 to either alanine or glutamic acid did not affect nuclear localization. However, the ser/ala mutation altered the distribution of recombinant globular tail within the nuclear compartments. Similar to endogenous MVa, transfected wild-type globular tail was phosphorylated within the cell and co-localized with SC-35, a RNA splicing factor that earmarks interchromatin granule clusters in the nucleus, whereas the ser/ala mutant was not phosphorylated and was distributed diffusely throughout the nucleoplasm. Our data suggest that the translocation of MVa to the nucleus is determined by two NLSs and distribution within the nucleus involves phosphorylation of Ser1650. Financial support from FAPESP, FAEPB and CNPq.

842 Myosin 5c: A Molecular Motor for Actin-based Transport in Epithelial Cells D. T. Jacobs, R. E. Cheney; 1Cell and Molecular Physiology, University of North Carolina-Chapel Hill, Chapel Hill, NC

Class V myosins have been shown to function as motors for actin-based transport and polarized secretion. Vertebres express three class V myosins, each having a distinct tissue distribution. Myosin 5a is expressed chiefly in brain and melanocytes. Myosin 5b has a broader distribution pattern, and Myosin 5c (Myo5c) is most abundant in secretory epithelia (Rodriguez and Cheney, JCS, 115:991-1004). Myo5c exhibits a polarized localization to the apical domain of acinar cells in exocrine tissues including lacrimal gland, salivary glands, pancreas, prostate, and mammary gland. To investigate the role of Myo5c in organelle transport, we have utilized live-cell imaging to determine the distribution and dynamics of Myo5c in MCF-7 and HeLa cells. Immuno-staining of endogenous Myo5c reveals labeling of both cytoplasmic tubules and small puncta. The tubules span tens of micrometers through the cytoplasm and emanate from the cell center toward the periphery. In migrating MCF-7 cells, the small puncta exhibit a polarized localization near the leading edge. Live-cell imaging of tubules labeled by GFP-Myo5c shows outward, long-range translocations at a rate of ~0.5 um/s. The addition of norecordal (0.5 um) induces a rapid loss of these translocations, indicating that these structures are undergoing microtubule-dependent movement. Time-lapse imaging using Total Internal Reflection Fluorescence (TIRF) microscopy reveals that GFP-Myo5c labeled puncta move more slowly (~0.03 um/s), are closely associated with the ventral cell surface, and can be tracked for long periods of time (40+ minutes). Unlike the tubules, the velocity and distribution of the GFP-Myo5c puncta

843 Myosin-Vb Remains Available for Actin Binding during Microtubule-based Transport
D. W. Provan, J. A. Mercer; McLaughlin Research Institute, Great Falls, MT
Cellular organization involves the intracellular trafficking of components through both actin- and microtubule (MT)-based movement. Sensitized Y119G mutant (and wild-type control) myosin-Vb was tagged with eGFP, expressed in HeLa cells and imaged before and after the microinjection of Nb-phenylethyl ADP (PE-ADP), which selectively and specifically inhibits the sensitized mutant myosin-Vb by inducing its tight binding to actin (Provan et al., PNAS 101:1868, 2004). Two prominent sites of myosin-Vb localization were observed: tubulovesicular structures in the cell periphery and discrete vesicles. The peripheral structures had highly dynamic edges from which vesicles budded. The discrete vesicles exhibited both actin- and microtubule-based movement, categorized on the basis of their speeds, trajectories, and sensitivity to latrunculin A or nocodazole treatment. In cells expressing the sensitized mutant myosin-Vb and injected with PE-ADP, all movement ceased within 2 min. The tubulovesicular peripheral structures became static and spherical. Vesicles also were no longer observed to originate from them and other vesicles froze within the cytoplasm. None of these effects were observed under control conditions consisting of wild-type myosin-Vb with PE-ADP, wild-type myosin-Vb injected with tracer only, or sensitized mutant myosin-Vb with tracer only. We conclude that this cessation of movement under experimental conditions is a direct result of sensitized mutant myosin-Vb binding to actin. Our data strongly support a model in which myosin-Vb cooperates with MT-based motors on peripheral endosomes to create opposing forces necessary for vesicle formation. Furthermore, those vesicles, which continue to be labeled by eGFP-tagged myosin-Vb, are apparently constantly capable of interacting with actin through myosin-Vb activity, even when they are passengers on vesicles undergoing MT-based transport.

844 A Role for Myosin Va in mRNP Transport
A. J. Lindsay, M. W. McCaffrey; Biochemistry, University College Cork, College Road, Cork, Ireland
The yeast class V myosin, Myo4p, has a well established role in mediating the transport of messenger ribonucleoprotein particles (mRNPs). In contrast little evidence has been published to suggest a similar role for class V myosins in eukaryotic cells. There are three myosin V isoforms in mammals, with the majority of work to date focusing on their roles in membrane transport. While comparing the localisation of endogenous myosin Va and myosin Vb in HeLa cells we observed that in addition to localising to vesicles distributed throughout the cytoplasm, myosin Va also labelled several large cytoplasmic ‘foci’. We subsequently determined that these foci were P-bodies (PBs), cytoplasmic structures that are involved in mRNA degradation. PBs and stress granules (SGs) are dynamically linked and indeed myosin Va redistributes from PBs to SGs upon exposure to various forms of cellular stress. We also found that myosin Va disassociated from PBs upon treatment with translational inhibitors, a characteristic of several PB components. We have found that in myosin Va-null S. cerevisiae cells a number of PB components do not localise to characteristic cytoplasmic foci despite being expressed at levels similar to that seen in wild-type cells. In the S91 cells we also observed that a subset of RNA binding proteins, including the Fragile X Mental Retardation Protein (FMRP), appear trapped in a large perinuclear structure whereas in myosin Va-expressing cells these proteins are distributed in a punctate pattern throughout the cell. FMRP also fails to associate with ribosomes in S91 cells, as determined by a polysome sedimentation assay. Taken together these results implicate myosin Va in mRNA transport and turnover, a role that has long been established for yeast myosin V.

845 Myosin Vc Cycling between Rab3D-enriched Secretory Vesicles and Rab11-enriched Endosomes in Lacrimal Acinar Epithelial Cells Is Stimulated by Carbachol
R. Marchelletta,1 D. Jabobs,2 A. Monroy,1 R. Cheney,2 S. Hamm-Alvarez1; 1University of Southern California, Los Angeles, CA, 2University of North Carolina, Chapel Hill, NC
Lacrimal acinar cells are secretory epithelia that support health of the ocular surface through the secretagogue-induced release of tear proteins. Myosins are a superfamily of proteins sharing a conserved motor domain that hydrolyzes ATP to generate movement along actin filaments but expressing diverse tail domains. Myosin Vc is highly expressed in epithelial cells, particularly acinar epithelial cells including lacrimal acini. Here we report that Myosin Vc associates with membranes enriched in the mature secretarial vesicle marker, Rab3D, and the apical endosomal marker, Rab11, in a secretagogue-dependent manner in primary cultured rabbit lacrimal acini. Confocal fluorescence microscopy revealed that Myosin Vc and Rab3D are both distributed in subapical secretory vesicles in unstimulated acini but that the extent of co-localization of total pixels associated with Myosin Vc with Rab3D is significantly decreased following stimulation of secretion with carbachol (CCH, 100 μM) from 42% to 29% (p<0.05, n=7). Rab11 and Myosin Vc were markedly co-localized on subapical membranes, and the extent of co-localization of the total pixels associated with Myosin Vc with Rab11 was significantly increased by CCH stimulation from 44% to 52% (p<0.05, n=6). Our previous studies have shown that expression of Myosin Vc tail fused to GFP, a dominant negative construct, in rabbit lacrimal acini using adenovirus results in labeling of mature secretory vesicles. Moreover, overexpression of GFP-Myosin Vc-tail significantly inhibited CCH-stimulated release of two secretory products, co-transduced syncollin-GFP which is found in Rab3D-enriched membranes and secretory component derived from polymeric immunoglobulin A receptor which is found in Rab3D- and Rab11-enriched membranes. These results suggest that a population of Myosin Vc is redistributed from mature secretory vesicles to apical endosomes by CCH stimulation and support a model in which myosin Vc on mature secretory vesicles aids in actin-dependent exocytosis of secretory vesicles and/or recycling of secretory vesicle membrane to apical endosomes.

846 Identification and Characterization of a Minimal Myosin V Binding Site within an Intrinsically Disordered Region of Melanophilin
N. C. Geeth, J. A. Spudich; Department of Biochemistry, Stanford University, Stanford, CA
Melanophilin directly binds to myosin V and is tethered to the melanosome membrane via Rab27a. We undertook a study to describe the biochemical nature of the interaction between myosin V and melanophilin. Here we demonstrate that the myosin V binding domain of melanophilin is an intrinsically disordered protein. We also conclude that myosin V binds to melanophilin in this disordered state and that binding does not induce the global folding of melanophilin. Using highly purified recombinant proteins we find that the myosin V globular tail domain binds a 9 amino acid peptide within this disordered segment. The interaction is characterized by a dissociation constant of 0.5 micromolar that is driven by a favorable enthalpy of binding as measured by isothermal titration calorimetry. We also find that phosphorylated myosin V tail domain binds with the same affinity to melanophilin, which suggests that phosphorylation of myosin V serine 1650 does not directly alter myosin V’s interaction with melanophilin.

847 The C-tail Domain, Not the Motor, Determines the In Vitro Behavior and In Vivo Function for Yeast Myo4p
B. D. Dunn, P. A. Takizawa; Cell Biology, Yale University, New Haven, CT
Saccharomyces cerevisiae contains two class V myosins: Myo4p which transports Ash1 mRNA to the bud tip and Myo2p which transports secretory vesicles and other organelles. Whether the biochemical properties of Myo4p and Myo2p differ to suit their different types of cargo is unknown. We purified and analyzed the activities of native Myo4p and Myo2p. Unlike Myo2p and other class V myosins, Myo4p is a monomer. In actin gliding assays, decreasing Myo4p concentration increases filament velocity. In contrast, decreasing Myo2p concentration decreases filament velocity, indicative of a nonprocessive motor. To determine if these different motor properties are physiologically important, we engineered chimeric myosins containing the motor domain of one myosin and the C-tail of the other. A Myo2p motor -Myo4p tail chimera has Myo2p kinase activity and Myo4p properties. In addition, the Myo2p motor -Myo4p tail rescues Ash1 mRNA localization in myo4Δ cells. The reverse Myo4p motor -Myo2p tail chimera is unable to substitute for the conditional myo2Δ mutant at the restrictive temperature. Thus, at least for Myo4p, the tail domain regulates both motor activity and cargo binding, while the motor domain is less critical for effective cargo transport.
Myosin VI mRNA Co-localizes with β-actin mRNA and ZBP1 in Fibroblasts and Neurons

A. L. Wells, A. J. Rodriguez, J. S. Condeelis, R. H. Singer; Anatomy and Structural Biology, Albert Einstein College of Medicine, Bronx, NY

In many cell types, messenger RNA (mRNA) localizes to subcellular compartments defining cell fate, polarity and cell motility. In migrating fibroblasts, mRNA for actin, and several other proteins involved in actin polymerization, localizes to the leading edge. Localization of these proteins allows the functional actin polymerization machinery to be targeted to the leading edge where the protein products are used for lamellipod protrusion. Myosin VI is a protein localizing to membrane ruffles at the leading edge and may be involved in Arp2/3-mediated actin polymerization. Myosin VI is the only actin-based motor protein known to move toward the minus end of actin filaments and has functions in membrane trafficking and remodeling events, endocytosis, and cell migration. When myosin VI is depleted, lamellipodial protrusion and cell migration are inhibited, implicating myosin VI in membrane dynamic functions leading to cell movement. Here we show that expression of Myosin VI mRNA is also localized to the leading edge of fibroblasts along with β-actin and Arp2/3 mRNAs. Additionally, myosin VI mRNA co-localizes with β-actin mRNA and its translational repressor, zipcode binding protein (ZBP1) to neuronal dendrites where myosin VI protein may function in AMPA receptor internalization. We propose that the localization of myosin VI mRNA is a mechanism by which the cell 1) compartmentalizes and regulates myosin VI activity, 2) positions the motor protein at the barbed end of actin filaments in order for it to move towards the pointed end and 3) targets the translation and assembly of macromolecular complexes with which myosin VI functions.

How Myosin VI Coordinates Its Heads during Processive Movement

S. S. Rosenfeld; H. L. Sweeney; H. L. Sweeney; 2Neurology, Columbia University, New York, NY, 3Physiology, University of Pennsylvania, Philadelphia, PA

Introduction: Optimal processive movement requires coordination between the heads of dimeric motor proteins. In myosin V, this coordination involves a coupling of the lever arm position with ADP release in a process that is controlled by the intramolecular strain. However, the lever arm positions are reversed for myosin VI, and therefore this mechanism cannot be used to gate the head of a processive myosin VI dimer. In this study, we have examined the kinetics of nucleotide binding to and release from monomeric and dimeric constructs of myosin VI in order to develop a model of how processivity is maintained in this motor. Results: Utilizing the fluorescent nucleotide analogues 2’-deoxy 3’-mamT and ATP and ADP (2’dmT, 2’dmD) we found that intramolecular strain had no appreciable effect on most of the steps in the myosin VI ATPase cycle, including phosphate release, the weak-to-strong binding transition, and ADP release. By contrast, the kinetics of 2’dmT binding were markedly affected by strain, with binding of nucleotide to the leading head occurring only after the trailing head had dissociated. Deletion of a unique insertion found only in myosin VI abolished this strain-dependent gating of the two motors of a myosin VI dimer. Conclusions: Our results are consistent with a model in which rearward strain blocks ATP binding to the leading head head once it has released its ADP. The structural basis for this unique gating mechanism involves an insertion near the nucleotide-binding pocket that is found only in class VI myosin. While this mechanism is unlike that of any other myosin superfamily member, it bears remarkable similarities to that of another processive motor from a different superfamily—kinesin I.

Myosin VI, Unlike Myosin V, is ubiquitously Expressed in PC12 Cells and upon Stimulation Accumulates in Perinuclear Area and Nucleus

M. Sobczak, 1L. Majewski, 2A. Walski, 2M. J. Redowicz; 1Department of Muscle Biochemistry, Nencki Institute of Experimental Biology, Warsaw, Poland, 2Department of Cell Biology, Nencki Institute of Experimental Biology, Warsaw, Poland

Myosin VI (MVI) is an unusual actin-based motor walking towards the minus end of actin filaments, in the opposite direction to the other known myosins. It is believed that MVI is involved in subcellular transport of membrane-containing structures, including clathrin-based endocytosis, as well as cell spreading and migration. Here, we aimed at testing the role of MVI in secretory bovine adrenal medulla and rat pheochromocytoma cells (PC12). MVI, but not myosin I and IIB, was detected in chromaffin granules and resided on the apical side of the vesicles. This association is very tight, because only addition of Triton X100 has removed it from the vesicles. EDC crosslinking carried out on PC12 cytosolic fraction indicates that MVI is a dimer. Myosin VI is ubiquitously distributed within PC12 and cultured adrenal medulla cells, as it partially colocalizes with the markers of the following cytoplasmic compartments: Golgi, endoplasmic reticulum, mitochondria, clathrin-coated pits, early endosomes and secretory granules, it is also visible next to plasma membrane. It has also been found within the nucleus what has been confirmed with three different anti-myosin VI antibodies. The nuclear localization was even more pronounced after 2-5 min cell stimulation with 56 mM KCl; myosin VI occupied the areas lacking heterochromatin. This may indicate involvement of this molecular motor in the gene transcription. In contrast, upon stimulation myosin V seemed to translocate to the peripheral area, where its colocalization with chromaffin granule marker was more pronounced. These data seem to indicate different roles for these two myosins in secretory cells.

Intracellular Targeting of Myosin VI Requires Protein-Protein Interactions and Lipid Binding

G. Spudich, 1M. Chibalin, 2C. Puri, 2J. Au, 2F. Bass, 2J. Kendrick-Jones; 1MRC Laboratory of Molecular Biology, Cambridge, United Kingdom, 2Clinical Biochemistry, CIRM, University of Cambridge, Cambridge, United Kingdom

Myosin VI is a minus end directed actin based motor protein. It localises to intracellular compartments, such as membrane ruffles, endocytotic clathrin-coated and uncoated vesicles, as well as secretory vesicles and the Golgi complex. Targeting of myosin VI to specific cellular localisations involves a number of binding partners, for example optineurin, Dab2 and GIPC. Using a combination of mammalian two-hybrid and pull-down assays we have identified two independent binding sites on the C-terminal region of myosin VI tail. Mutation of Thr1184 to Leu in this region abolishes myosin VI binding to Dab2 but has no effect on binding to GIPC or optineurin, whereas mutation of RRL (aa 1107-1109) to AAA abolishes GIPC and optineurin binding. These results indicate that the C-terminal tail of myosin VI contains two hot spots for cargo binding, which bind multiple binding partners. In addition, the C-terminal tail domain contains a lipid binding region. In sedimentation and FRET-based binding assays the tail binds with high affinity and specificity to phosphatidylinositol-4,5-bisphosphate (PIP2) containing liposomes. To investigate the role of lipid and protein binding on the in vivo functions of myosin VI, we expressed in HEA cells a GFP-tagged myosin VI tail with mutated PIP2, Dab2 and GIPC binding regions. When myosin VI tail strongly co-localised with clathrin-coated structures (CCS), recruitment of the PIP2 mutant to CCS was significantly reduced. Mutating the Dab2-binding site completely abolished targeting to CCS in vivo, whereas mutation in the GIPC binding site had no effect. Our current studies at the ultrastructural level together with functional assays in polarised cells are focused on determining the role of myosin VI in clathrin-mediated endocytosis.

Roles of Myosin-X (Myo10) in Filopodia Formation, Intracellular Motility, and Cell Spreading

A. B. Bohil, 1O. A. Quintero, 1T. Yin, 1D. T. Jacobs, 1M. M. Divito, 1M. L. Kerber, 1R. E. Cheney; 1Cell and Molecular Physiology, University of North Carolina at Chapel Hill, Chapel Hill, NC, 2Biology, Franklin and Marshall College, Lancaster, PA

Filopodia and related structures that contain a core of bundled actin filaments are thought to play important roles in cell motility and cell-cell signaling. Despite their importance, the molecular mechanisms regulating filopodia formation and function are not yet clear. Myo10 is a vertebrate specific MyTH4-FERM myosin that localizes to the tips of filopodia and is hypothesized to function as a motor for intrafilopodial motility. Here we report that transfection with GFP-Myo10 and other constructs that have previously been shown to induce massive increases in dorsal filopodia also lead to ~3-fold decreases in the spread area of COS-7 cells. Only Myo10 constructs that are able to induce filopodia lead to decreased cell spreading. Conversely, inhibiting the formation of the numerous dorsal filopodial structures in HeLa cells by transfecting cells with (1) siRNA to Myo10, (2) a dominant negative Myo10 construct, or (3) dominant negative Cdc42 each increase cell spreading ~2-fold. Together this data suggests an inverse correlation between filopodia formation and cell spreading. To investigate the role of Myo10 dimerization in tip localization, we show that forced dimerization of a construct consisting of the head, neck, and first 34 amino acids of the tail is sufficient to endow tip localization. Although both Myo10 and formins are thought to be components of the filopodial tip complex, live cell imaging of HeLa cells co-transfected with GFP-Myo10 and constitutively active GFP-mDia2 indicates that these constructs sometimes localize to distinct puncta within retraction fibers and do not always move coordinately. Finally, we have used live cell imaging and TIRF microscopy to show that transmembrane enrichment of Myo10 as integral underpinning transport with Myo10.
allowing Shigella to spread from cell to cell and produce hemmorhagic plagues. Intracellular motility is a vital facet of S. flexneri's pathogenesis and requires that the bacterium usurp the host cell's actin machinery. Previous studies have successfully reconstituted actin-based motility of S. flexneri and Listeria monocytogenes (another bacteria that undergoes intra- and intercellular actin-based motility) in vitro by providing a small number of actin-binding proteins, and show that in extracts myosin motors are unnecessary. However, we found that in living HeLa cells, GFP-Myosin X (Myo10), a recently described unconventional myosin, concentrates in the actin tails of motile Shigella, as well as along the sides of filopodia containing Shigella. Under the same experimental conditions we have found that Myo10 fails to localize to Listeria-induced actin structures. Immunofluorescence microscopy utilizing a specific anti-Myo10 antibody corroborated these findings. siRNA knock-down of endogenous Myo10 resulted in a significant reduction in S. flexneri speeds by one third, as compared to infected cells transfected with control siRNA (avg 0.059 um/s +/- 0.002 SEM, n = 396 compared to 0.088 um/s +/- 0.002 SEM, n = 336, respectively, p < 0.0001). Knock-down of Myo10 had no effect on L. monocytogenes intracellular speeds. We conclude that in addition to actin, Shigella, but not Listeria, utilizes Myo10 for efficient intracellular movement in living host cells.

854  Myosin-10 Functions to Maintain Spindle Integrity during Mitosis

S. Woolner, W. Bennett; Department of Zoology, University of Wisconsin-Madison, Madison, WI

Myo10 (Myo10) is a vertebrate unconventional myosin that can bind to both filamentous actin (F-actin) and microtubules. We have previously shown that Myo10 plays a key role in the Xenopus laevis oocyte, where it is required for proper nuclear anchoring and meiotic spindle assembly. We believe that Myo10 may function in these processes by mediating interactions between F-actin and microtubules. Here we report new findings that Myo10 plays a crucial role in mitosis. We find, by immunofluorescence, that Myo10 localizes close to the poles of the mitotic spindle, a position that it maintains throughout mitosis. Moreover, knockdown of Myo10 using a morpholino antisense oligo in Xenopus embryos, leads to a clear and reproducible mitotic phenotype. The mitotic spindles in Myo10 morpholino injected embryos exhibit a delay in metaphase and then begin to develop multiple additional poles. All extra poles show an accumulation of the spindle pole marker, gamma-tubulin, suggesting that these poles may result from fragmentation of the bona fide poles. To investigate this further, we have used live imaging to follow the development of the extra spindle poles in vivo, and it appears that these poles do indeed arise from the bona fide poles. We therefore propose that Myo10 acts to stabilize the mitotic spindle. We are currently investigating the mechanism by which Myo10 fulfills its role in the mitotic spindle.

855  Using Small Molecules to Study the Role of Myosin Light Chain (TgMCL1) in Toxoplasma gondii Motility and Invasion

A. T. Heaslip, K. L. Carey, D. M. Warshaw, N. J. Westwood, G. E. Ward; Dept. of Microbiology and Molecular Genetics, University of Vermont, Burlington, VT, Dept. of Molecular Physiology and Biophysics, University of Vermont, Burlington, VT, Centre for Bimolecular Sciences, University of St. Andrews, St. Andrews, United Kingdom

Toxoplasma gondii is an obligate intracellular parasite that can cause life-threatening disease in immunocompromised individuals. The pathology of the disease is caused in part by repeated cycles of host cell invasion, parasite replication and host cell lysis. Our lab is interested in identifying parasite proteins involved in the invasion process. To this end we developed a high-throughput screen to identify small molecule inhibitors of invasion. Of 12,160 small molecules screened, 24 were shown to inhibit invasion and 21 of these inhibitors were also found to significantly inhibit parasite motility. A membrane associated complex of proteins, termed the glideosome, powers gliding motility and host cell penetration in T. gondii. The glideosome consists of four major proteins: TgMyoA, an unconventional class XIV myosin, myosin light chain (TgMCL1); and glideosome-associated proteins 45 and 50 (TgGAP45, TgGAP50). In an attempt to identify the targets of the motility/invasion inhibitors we immunoprecipitated the glideosome complex from parasites treated with each inhibitor to determine if any of the inhibitors changed its composition. Treatment with one or two inhibitors results in the immunoprecipitation of a modified form of MLC with the glideosome; the modified form shows increased electrophoretic mobility on SDS PAGE gels. The nature of the modification is being determined by mass spectrometry analysis. We have developed a method for isolating the glideosome for in-vitro motility assays and shown that TgMyoA has a velocity of 5um/s, in good agreement with previously published data. Experiments to determine the functional effects of the MLC modification in this in vitro motility assay are currently underway. By identifying the nature of the MLC modification and determining the functional effects of this modification we will gain new insights into the role of myosin light chain in regulating glideosome function and parasite motility.

856  Myo1 Localizes to Phagosomes in Tetrahymena

R. E. Hosen, R. H. Gavin; Biology, Brooklyn College—CUNY, Brooklyn, NY

Myo1 is one of 12 Tetrahymena myosins that form a subclass in myosin Class XIV. An earlier study showed that in a Myo1 knockout, the rate of phagosome formation was significantly reduced, and macronuclear elongation failed to occur in some cells. Recent investigations of actin localization and phagosome motility revealed actin filaments as prominent extensions from one or two regions at the periphery of phagosomes. Phagosomes moved randomly in the cytosol of knockout cells in contrast to directed movement toward the posterior end in wild-type cells. In the present study, localization of Myo1 was undertaken in further to demonstrate the association of Myo1 with both phagocytosis and macronuclear division. Polyclonal antibodies were generated against a peptide in the Myo1 motor domain and used for immunolocalisation and immunofluorescence microscopy. The antibody detected a 180-kDa polypeptide on immunoblots of wild-type cell-lysate proteins resolved by SDS-PAGE. The 180-kDa polypeptide was not present on immunoblots of knockout cell-lysate proteins. Prior to fixation for immunofluorescence microscopy, cells were challenged with fluorescent beads as markers for phagosomes. Confocal x-z scans showed that in wild type, Myo1 localized to the periphery of phagosomes. Some phagosomes in wild type appeared to be unlabeled. Labeled phagosomes were frequently observed at the periphery of the macronucleus, although the antibody did not label the macronucleus. In the Myo1-knockout only background fluorescence was observed. We conclude that localization of Myo1 is consistent with a role in phagocytosis and macronuclear division. Supported by NSF Grant 0517083.

857  VwkA, an Unconventional Protein Kinase Involved in the Regulation of Contractile Vacuole Dynamics in Dictyostelium discoideum

V. Betapudi, T. T. Egelhoff; Physiology and Biophysics, Case Western Reserve University, Cleveland, OH

Earlier, we reported VwkA, a novel unconventional protein kinase localized to contractile vacuoles and Golgi complex like structures in Dictyostelium discoideum. This VwkA protein carries an N-terminal von Willebrand Factor A (vWFA) motif and a catalytic domain having sequence homology with the catalytic domain sequence of nonmuscle myosin II in Dictyostelium and ion-channel kinases in mammalian cells. Although, the purified VwkA protein failed to phosphorylate nonmuscle myosin II in vitro, but have significant effects on many myosin II-dependent functions inDictyostelium discoideum. Here, we report characterization of VwkA sub-domains and its involvement in the regulation of contractile vacuole functions in Dictyostelium discoideum. VwkA and overexpressing (VwkA++) cells display altered osmotic shock responses. The size and shape of the contractile vacuicles in vwkA- cells were found different from those in wild type cells. GFP-VwkA carrying a mutant catalytic domain failed to localize to contractile vacuoles in the cells. These studies suggest that VwkA involves in the regulation of contractile vacuole dynamics in Dictyostelium discoideum.

859  Mitotic Kinesin Eg5 Achieves Processive Stepping by Alternating Site ATP Hydrolysis

T. C. Krzysziak, S. P. Gilbert; Biological Sciences, University of Pittsburgh, Pittsburgh, PA

Eg5/KSP is a member of the Kinesin-5 (BimC) family of homotetrameric motors. These N-terminal kinesins provide a plus-end-directed force associated with sliding microtubules during centrosome separation to assemble the bipolar spindle. To define the cooperative interactions between the motor heads and the microtubule, a dimeric motor was engineered. This Eg5 dimer is processive with its motor heads binding along a single protofilament (Valentine et al. 2006. Nature Cell Biol. 8, 470 ; Krzysziak et al. 2006. EMBO J. 25, 2263). The steady-state and presteady-state kinetics show that ATP binding occurs as a two-step process with an ATP-dependent isomerization at 50 s-1, which forms the ATP-hydrolysis competent intermediate. Single-turnover experiments were required to detect a presteady state burst of ATP hydrolysis. At ATP concentrations in which only one head participates, the rate was ~5 s-1; however, at ATP concentrations where both heads of the dimer participate, the rate is observed at approximately half. In addition, the kinetics of P i release and ATP-promoted microtubule dissociation are observed at the rate of ATP hydrolysis. Microtubule association and mantADP release are fast steps in the pathway. However, mantADP release is biphasic with an initial fast phase followed by a second slow phase. These kinetics are consistent with ATP hydrolysis as the rate-limiting step and an alternating cycle of ATP turnover in which the active sites are coordinated to establish processive stepping along the microtubule. Dynamics of Molecular Motors Studied by FLAP

M. Uteng, T. Surrey; Cell Biology & Biophysics, EMBL, Heidelberg, Germany

Motor proteins are known to be essential for the reorganization of the cytoskeleton during cell division. However, to what extent the kinetic properties of these molecular motors determine their function during cell division is not understood. We present here a new kinetic assay to measure unbinding rates and diffusion constants of molecular motors in vitro at steady state. In this assay, the molecular motors are fused to a Photoactivatable GFP, and the Fluorescence Loss After Photoactivation (FLAP) is monitored. The method was validated by measuring diffusion and unbinding rate of conventional kinesin from a single microtubule, and the results were in agreement with data described in literature. Presently, we are applying this assay on the mitotic motor, Kip3, whose unbinding rate is unknown. The analysis of Kip3 is being done on a single microtubule and inside bundled microtubules. This will hopefully give us an understanding of how the microtubule organization affects Kip3’s kinetics, and consequently how it functions within the established mitotic spindle.

The Homotetrameric Kinesin-5, KLP61F, Antagonizes Ncd in Motility Assays

L. Tao,1 A. Mogilner,1 G. Civelekoglu-Scholey,1 R. Wollman,1 J. Evans,2 S. Henning,2 J. M. Scholey,2 1Center for Genetics and Development, UC Davis, Davis, CA, 2Section of Molecular and Cellular Biology, UC Davis, Davis, CA

We have tested the hypothesis that the purified antagonistic mitotic motors, KLP61F (a kinesin-5) and Ncd (a kinesin-14), can generate a force-balance that could position spindle poles at a constant steady-state length in Drosophila embryo spindles (Sharp et al., 1999b). KLP61F and Ncd were purified in high yield and purity from insect cells and found to behave as homotetrameric and homodimeric species, respectively, with identical hydrodynamic properties to the native proteins in embryo extracts. A region of the stalk containing residues 631-790 of KLP61F, which lacks the spindle-targeting “BimC box”, is required for tetramerization. Using fluorescence microscopy and cryo EM, we find that purified KLP61F and Ncd are capable of crosslinking MTs into bundles in the presence of MgATP. In multiple-motor motility assays, KLP61F and Ncd drove plus-end and minus-end-directed MT sliding at 0.04 and 0.1 µm/s, respectively. Competitive MT gliding assays using mixtures of the two motors reveal that the rate of motility of either motor is decreased by the increasing the mole fraction of the opposing motor. We identified a “balance point” at which the mean velocity of MT motility was zero, but where MTs paused briefly or displayed episodes of stochastic oscillations, taking ~0.3 µm excursions at ~0.2 µm/s in the plus then minus-end direction every 15s or so. The results, when analyzed by quantitative modeling suggest that opposite-polarity motors could act as “brakes” on one-another to modulate the rate of spindle pole separation, but additional factors would be needed to produce a stable, prometaphase spindle length.

Plus End-specific Depolymerase Activity and Plus End-directed Motility of Kip3 (Kinesin-8) Explain Its Role in Positioning Mitotic Spindles during Asymmetric Cell Division

M. L. Gupta,1 P. Carvalho,1 D. Rout,2 D. Pellman3; 1Pediatric Oncology, Dana-Farber Cancer Institute, Boston, MA, 2Program in Cell and Molecular Biology, University of Pennsylvania, Philadelphia, PA

Budding yeast Kip3 is a member of a conserved family of microtubule motors (Kinesin-8) required for microtubule-cortical interactions, normal spindle assembly, and kinetochore dynamics. We demonstrate that Kip3 is both a plus end-directed motor and plus-end specific depolymerase, a unique combination of activities not found in other kinesins. The Kip3 ATPase activity was activated by both microtubules and unpolymerized tubulin. Furthermore, Kip3 in the ATP-bound state formed a complex with unpolymerized tubulin. Thus, motile Kinesin-8s may depolymerize microtubules by a mechanism that is similar to that used by non-motile Kinesin-13 proteins. Fluorescent speckle analysis established that in vivo Kip3 moved toward and accumulated on the plus ends of growing microtubules, suggesting that motor activity brings Kip3 to its site of action. Globally, and more dramatically upon cortical contact, Kip3 promoted catastrophes, pausing, and inhibited microtubule growth. These findings explain the role of Kip3 in positioning the mitotic spindle in budding yeast and possibly other processes controlled by Kinesin-8s.

A Microtubule-destabilizing Kinesin-13 Affects Meiotic Spindle Length and Position in Oocytes

J. Zou, C. D. Yankel, K. Su, S. A. Endow; Cell Biology, Duke University Medical Center, Durham, NC

The Kinesin-13, Klp10A, is a microtubule depolymerizer in Drosophila that regulates microtubule dynamics in mitosis. Klp10A binds to mitotic spindle poles and centromeres, and depolymerizes microtubule minus ends, promoting poleward flux - slow poleward movement of spindle microtubules. During interphase, Klp10A is targeted to microtubule plus ends by EB1, where it is reported to stimulate catastrophes, growth-to-shrinkage transitions. Up to now, little is known about Kinesin-13 proteins in meiosis. Here we show that full-length Klp10A-GFP is associated with the unusual pole bodies of meiotic meiosis I spindles in klp10A-gfp oocytes, and decorates meiotic chromosome centromeres and cortical microtubules. The pole bodies of meiosis I spindles can be observed bound to fluorescently labeled cortical microtubules in klp10A-gfp oocytes, indicating that Klp10A binding both to the pole bodies and cortical microtubules could anchor spindles to the cortex. Treatment of klp10A-gfp oocytes by the microtubule destabilizing drug colchicine results in rudimentary spindles that are displaced towards the oocyte interior and ~2-fold longer Klp10A-GFP signals on cortical microtubules compared to controls. Treatment by the microtubule stabilizing drug paclitaxel results in either elongated or foreshortened spindles that are displaced from the cortex and ~2-fold shorter Klp10A-GFP signals on cortical microtubules than controls. A dominant negative Klp10A-GFP causes spindles to be shorter than wild type and suppresses the effects of colchicine and paclitaxel on spindle length and displacement from the oocyte cortex. These results show that microtubule dynamics, mediated by Klp10A, plays an important role in maintaining oocyte meiotic spindle structure and anchoring to the cortex. They demonstrate that Klp10A binds with higher affinity to destabilized than stabilized microtubules in oocytes, enhancing the destabilizing effects of colchicine. Our findings contrast with a previous report that Klp10A targets to polymerizing, rather than depolymerizing microtubule plus ends during interphase.

The Role of the Kinesin-13 Neck in Microtubule Depolymerization

C. A. Moore,1 J. Cooper,1 M. Wagenbach,1 Y. Ovechkina,1 L. Wordeman,2 R. A. Milligan3; 1Department of Crystallography, Birkbeck College, London, United Kingdom, 2Department of Physiology and Biophysics, University of Washington School of Medicine, Seattle, WA, 3Department of Cell Biology, The Scripps Research Institute, La Jolla, CA

To ensure genetic integrity, replicated chromosomes must be accurately distributed to daughter cells - a process that is accomplished on the microtubule spindle. Kinesin-13 motors play an essential role in this process by performing regulated microtubule depolymerization. We set out to dissect the depolymerization mechanism of these kinesins, and in particular, their role of their conserved neck sequence. We used a monomeric kinesin-13 MCAC construct, consisting of the neck and motor core, which has strong depolymerizing activity. In the presence of a non-hydrolysable ATP analogue, this construct induced formation of rings around microtubules. The rings are built from tubulin protofilaaments that are bent by the kinesin-13 motor engaged at the ATP-binding step of its ATPase cycle. Our data suggest that the ring-microtubule interaction is mediated by the neck and support the idea of a role for the kinesin-13 neck in depolymerization efficiency, acting by optimising release of tubulin from microtubule ends.

Functional Studies of Human Kip3 Kinesins
Kinesins of the kip3 family (Kip3s) have been shown to play important roles in mitosis in several organisms including S. cerevisiae, S. pombe and D. melanogaster. Genetic and cell biological evidence suggests that these kinesins function either directly or indirectly to increase microtubule instability. We have identified 3 human kinesins that are members of the Kip3 family. Two of these, Kip3a and Kip3d, are more highly expressed in proliferating tissues and are down regulated in differentiated neurons, suggesting that they are mitotic kinesins. Immunofluorescence staining with a peptide antibody directed against Kip3d reveals localization to the ends of spindle microtubules. Depletion of Kip3d mRNA by siRNA in SK-OV-3 cells results in a mitotic arrest with elongated bipolar spindles. Time-lapse imaging of Kip3d depleted SK-OV-3 cells demonstrates that these cells undergo a prolonged period of mitotic arrest, frequently followed by cell death. Addition of purified recombinant Kip3d motor domain, expressed in E.coli, to microtubules caused a decrease in the number of microtubules assessed by a microscopic assay and polymer mass in a sedimentation assay. All of these data together suggest that Kip3d has an essential role in mitosis and acts to regulate microtubule dynamics by directly destabilizing microtubules.

Human Kif18, A Member of Kinesin-8 Family, Regulates Microtubule Dynamic Instability in Mammalian Cells
C. Zhu, S. Sandall, A. Desai, W. Jiang; 1The Barham Institute for Medical Research, La Jolla, CA, 2Ludwig Institute for Cancer Research, University of California, San Diego, La Jolla, CA
Kinesins are microtubule (MT) motor proteins that regulate many cellular processes including MT dynamic instability. Previously, we identified at least 12 human kinesins involved in mitosis/cytokinesis using RNA interference (RNAi), immunofluorescence microscopy and time-lapse analysis. Here, we describe the characterization of Kif18, a member of kinesin-8 family, in regulating MT dynamic instability in mammalian cells. Immunoblotting and immunofluorescence analysis indicate that expression and subcellular localization of Kif18 is regulated during the cell cycle. In interphase, the expression levels of Kif18 are low with the majority of Kif18 protein localized to the nucleus and a minority of Kif18 protein associated with plus-ends of MTs in the cytoplasm. During mitosis, the expression levels of Kif18 are increased dramatically with Kif18 associated with mitotic spindle MTs, kinetochores and plus-ends of astral MTs in early mitosis and then translocated to spindle midzone/midbody in late mitosis and cytokinesis. Kinetochoore localization of Kif18 is MT-dependent since such localization can be abolished by treatment of MT depolymerizing drug, nocodazole. In contrast, localization of kinetochores and plus-ends of astral MTs of Kif18 is enhanced by treatment of MT stabilizing drug, taxol. Time-lapse microscopy shows that depletion of Kif18 by Kif18 siRNA in HeLa cells results in prolonged delays of the prometaphase to metaphase and the metaphase to anaphase transitions. Long mitotic spindle MTs that cross over the metaphase plate are often observed in Kif18 depleted cells. Using GFP-E2B as a marker, we observe increased numbers of spindle MT polymerization in Kif18 depleted cells. Consistently, overexpression of Kif18 in CHO cells results in depolymerization of MTs network in vivo. In addition, recombinant Kif18 purified from insect cells using baculovirus expression system shows that Kif18 has MT depolymerizing activity in vitro. These data demonstrate that Kif18 functions as a MT depolymerase that regulates MT dynamic instabilities in mammalian cells.

The Kinesin KIF17 Is Part of the EB1 Microtubule TIP Tracking Complex in Mammalian Epithelial Cells
F. Jaulin, G. Kretzner; Cell and Developmental Biology, Weill Medical College of Cornell University, New York, NY
Microtubule “Search and Capture” is an evolutionarily conserved process involved in cell polarization. EB1, a core protein in the microtubule TIP-tracking complex, associates with polymerizing microtubules which dynamically search the cell cortex. Local activation of membrane associated proteins leads to the cortical capture of microtubules, initiating cytoskeletal remodeling and cell polarization. Microtubule polymerization by EB1 is dependent on the interaction with EB1 by a kinesin for polarized cell growth in S. pombe; in multi-cellular organisms however, no kinesin has yet been described to contribute to polymerization through microtubule “Search and Capture”. Using epithelial cells as a model for polarization, we screened by GST pull-down for kinesins that interact with EB1. We found that KIF17, a kinesin family member, interacts with EB1. We confirmed the relevance of the interaction between KIF17 and EB1 by co-immunoprecipitation of endogenous proteins from epithelial cell lysates. In vitro binding assays revealed that the interaction of KIF17 with EB1 is direct and we have mapped the domains responsible for this interaction. In epithelial cells, KIF17 localizes to microtubule plus ends and colocalizes with ~50% of the EB1 present on microtubule tips. Overexpression of KIF17 recruits KIF17 to microtubule plus-ends. We hypothesize that, similar to currently using RNA interference to knock-down KIF17 and EB1 and analyze the functional relationship between these two proteins. Our experiments demonstrate that EB1 interacts with and currently using RNA interference to knock-down KIF17 and EB1 and analyze the functional relationship between these two proteins. Our experiments demonstrate that EB1 interacts with and then translocates to spindle midzone/midbody in late mitosis and cytokinesis. Kinetochoore localization of KIF17 is MT-dependent since such localization can be abolished by treatment of MT depolymerizing drug, nocodazole. In contrast, localization of kinetochores and plus-ends of astral MTs of KIF17 is enhanced by treatment of MT stabilizing drug, taxol. Time-lapse microscopy shows that depletion of KIF17 by KIF17 siRNA in HeLa cells results in prolonged delays of the prometaphase to metaphase and the metaphase to anaphase transitions. Long mitotic spindle MTs that cross over the metaphase plate are often observed in KIF17 depleted cells. Using GFP-E2B as a marker, we observe increased numbers of spindle MT polymerization in KIF17 depleted cells. Consistently, overexpression of KIF17 in CHO cells results in depolymerization of MTs network in vivo. In addition, recombinant KIF17 purified from insect cells using baculovirus expression system shows that KIF17 has MT depolymerizing activity in vitro. These data demonstrate that KIF17 functions as a MT depolymerase that regulates MT dynamic instabilities in mammalian cells.

Kinesins-2 in Phagosome Transport in the Retinal Pigmented Epithelium
T. Diemer, D. Gibbs, D. Williams; Pharmacology and Neurosciences, UCSD, La Jolla, CA
As part of an essential photoreceptor outer segment (POS) renewal process, the retinal pigment epithelial (RPE) cells phagocytose and digest the distal POS disk membranes on a regular basis. The phagosomes are transported from the apical RPE to the basal RPE, where they are degraded. Defects in phagocytosis or degradation of POS membranes underlie several forms of retinal degeneration. We have shown that myosin VIIa (MYO7A) facilitates the transport of phagosomes through the F-actin-rich apical domain. We have hypothesized that MYO7A then delivers the phagosomes to a microtubule motor for transport to the basal RPE, since microtubules appear to be required for this event. In support of a relay between F-actin to microtubule motors, we find that imaging of primary cultures of RPE cells indicates that phagosomes move in with two distinct velocities, similar to that expected for MYO7A and for a faster (>1 um/sec) microtubule phagosomes to a microtubule motor for transport to the basal RPE, since microtubules appear to be required for this event. In support of a relay between F-actin to microtubule motors, we find that imaging of primary cultures of RPE cells indicates that phagosomes move in with two distinct velocities, similar to that expected for MYO7A and for a faster (>1 um/sec) microtubule motor. To test specifically for kinesin-2 function, primary cultures of RPE cells were prepared from mice carrying floxed Kif3a genes. Treatment of these cells with lentiviral-CRE-GFP was found to deplete the cells of KIF3A, the obligate motor subunit of kinesin-2, after 3 days. An assay in which the cells are challenged with POSs was used to measure the rate of phagosome degradation in these kinesin-2 deficient RPE cells. Cells were fixed at different times and the undigested POSs were identified with apo-B antibodies. Cells lacking kinesin-2 showed significantly slower phagosome degradation than control cells. These results support our hypothesis that phagosomes are delivered by MYO7A to kinesin-2, which then transports phagosomes efficiently to the basal RPE where they are degraded.

Regulation of Caveolar Traffic by Kinesin
S. S. Siddiqui, Z. Siddiqui, Y. Husain, A. B. Malik, R. M. Minshall; Pharmacology, University of Illinois, Chicago, Chicago, IL
Endothelial cells play an important role in barrier function, and trans-endothelial delivery of nutrients. We report here that endothelial cells express two kinesins that interact with caveolin-1 (KIF1A and KIF3A). KIF1A is involved in targeting of caveolin-1 to caveolae derived vesicles. The dynamics of vesicular trafficking of CAV-1-GFP labeled vesicles were measured in the control and KIF3B specific siRNA treated endothelial cells. We discovered that KIF3B siRNA treated cells showed altered mobility and direction of movement of CAV-1-GFP labeled vesicles. These data suggest a potentially important role of KIF3B motor in regulating the caveolar vesicles.

Autoinhibition Is a General Regulatory Mechanism for Kinesin Motors
J. W. Hammond,1 D. Cai,2 K. J. Verhey1; 1Cell and Developmental Biology, University of Michigan, Ann Arbor, MI, 2Biophysics Research Division, University of Michigan, Ann Arbor, MI
The kinesin superfamily of proteins (Kifs) mediates intracellular transport of cargoes along microtubule tracks. Regulation of motor activity is required to ensure that energy is not wasted under unproductive transport. In the absence of cargo, kinesin-1 (formerly conventional kinesin or KIF5) is inactive due to a folded and autoinhibited state. The molecular mechanism of motor regulation has not been well studied for other kinesin family members. We propose that autoinhibition is a general mechanism of regulation for kinesin motors. To test this, we studied the activity and autoregulation of members of the Kinesin-2 family, specifically KIF17 and KIF3A, and of the Kinesin-3 family, specifically KIF7A. To study kinesins under physiological conditions, fluorescently-tagged motor protein polypeptides were expressed in mammalian cells. Using permeabilized cells treated with AMPNP, we show that full length Kif3a/3b is active in vivo.
for microtubule binding whereas Kif17 and Kif1A are inactive. C-terminal truncations of Kif17 and Kif1A result in microtubule binding, demonstrating that autoinhibition requires the non-motor regions. These results suggest that autoinhibition is intrinsic to homodimeric kinesins such as Kif1A and Kif17. In contrast, heteromeric kinesins such as Kif5 and Kif1A require coexpression of accessory proteins, kinesin light chain and KAP3, respectively, for autoinhibition.

872 A Role for a C-terminal Kinesin in Microtubule Organization

T. Yeh, C. L. Brown, K. Maier, T. A. Schroer; Department of Biology, Johns Hopkins University, Baltimore, MD

KIFC3 is a ubiquitous, minus end-directed microtubule-based motor of the kinesin-14 family. KIFC3 has been reported to be involved in Golgi positioning and intracellular trafficking, but it may perform additional functions in cells. We find that endogenous KIFC3 is predominantly localized to centrosomes, suggesting a role in microtubule organization and dynamics. We engineered a series of KIFC3 fragments and determined their effect on microtubule organization. Overexpression of GFP-tagged full-length (FL) KIFC3 or a fragment containing just the stalk, neck and motor domains (AA 257-709) led to dramatic microtubule bundling and a loss of centrosomally-anchored microtubules in COS-7 cells. KIFC3-FL-decorated microtubules colocalized with Glu-tubulin and were resistant to cold nocodazole treatment. A KIFC3 fragment containing just the neck and motor domains (AA 315-709) also decorated microtubules but caused less microtubule bundling and defocusing. Surprisingly, overexpression of motorless KIFC3 (AA 1-393), the dominant negative mutant used in previously published work (Noda et al., J. Cell Biol. 155: 77-88), resulted in neither bundled nor disrupted radial microtubule arrays. All KIFC3 constructs examined localized to centrosomes, suggesting that KIFC3 is targeted to centrosomes via both motor-dependent and independent mechanisms. KIFC3-FL was also found to partially colocalize with endogenous cytoskeleton but not vimentin, suggesting that it may coordinate interactions between microtubules and intermediate filaments in some cell types. Together, these data provide evidence that KIFC3 plays a number of previously undescribed roles in the organization, dynamics and interactions of cytoskeletal filaments.

873 Mouse Liver Early Endosome Motility Is Mediated by Kif5B and Kif1C

S. Nath, L. Hassanis, S. Sarkar, R. J. Stockert, A. O. Sperry, J. W. Murray, A. W. Wolkoff; 1Anatomy and Structural Biology, Marion Bessin Liver Research Center, Albert Einstein College of Medicine, Bronx, NY; 2Marion Bessin Liver Research Center, Albert Einstein College of Medicine, Bronx, NY; 3Anatomy and Structural Biology, Brody School of Medicine at East Carolina University, Greenville, NC

In previous studies we showed that early endosomes isolated from rat liver 5 min after intra-portal injection of Texas red asialoorosomucoid (ASOR) move on microtubules via the plus- and minus-end directed kinesins Kif5B and Kif1C, respectively. We find that this study was designed to test the effect of overexpression of ASOR by hepatocytes from WT or K/O mice. Studies of endosomes in vitro also showed no difference between WT and K/O mice. Similar to the rat, mouse vesicles utilized Kif5B for plus-end motility. Approximately 50% of both WT and K/O early endosomes moved towards the minus-end of microtubules. This minus-end directed movement was inhibited by 1 mM AMP-PNP (kinesin inhibitor) but not by 5 µM vanadate (dynein inhibitor). Immunoblot analysis showed that in contrast to early endocytic vesicles from rat liver, mouse liver vesicles were not associated with Kif2. Rather they were associated with another minus-end kinesin, Kif1C. That Kif1C is functional in these vesicles was shown by substantially reduced minus-end motility and fusion following preincubation with Kif1C antibody. Decreased minus-end motility was compensated for by an increase in plus-end motility, consistent with colocalization of Kif5B and Kif1C in this population of vesicles. This study indicates that different species may have devised parallel but distinct solutions for complex physiological processes.

874 A Novel Leishmania Kinesin with a Potential Role in Kinetoplast Morphology

N. J. Gerald, I. Coppens, D. M. Dwyer; 1Lab of Parasitic Diseases, NIAID, NIH, Bethesda, MD, 2Dept. of Molecular Microbiology and Immunology, Bloomberg School of Public Health, JHU, Baltimore, MD

Kinesins are microtubule motor proteins with diverse cellular functions that include trafficking and cytoskeletal reorganization in eukaryotic cells. Kinesins are likely to play important roles in the cell biology of the protozoan Leishmania donovani, a medically important parasite of humans. Leishmania parasites have an extensive microtubule cytoskeleton and a large complement of novel kinesin genes, however, few of these parasite kinesins have been experimentally characterized. Previously, we showed that the Leishmania K39 kinesin binds along the cortical microtubules and that it accumulates at the posterior pole of the parasite. The objective of this study was to determine the cellular role of the closely related parasite kinesin K39B. RT-PCR showed that the K39B message was produced in both the promastigote stage (vector) and amastigote stage (host) of L. donovani parasites. To investigate the function of K39B, we cloned the gene and designed GFP fusion proteins for expression in L. donovani parasites. Confocal microscopy indicated that K39B-GFP fusion proteins localized near the flagellar pocket and the kinetoplast - the coiled assembly of mitochondrial DNA that is physically tethered to the flagellar basal bodies. Immunoelectron microscopy demonstrated that these fusion proteins were localized to the region between the basal bodies and the kinetoplast. Cell fractionation showed that K39B-GFP proteins associated tightly with purified flagella/kinetoplasts after extraction with detergent and high salts. Overexpression of dominant negative K39B fusion proteins caused defects in the structure of kinetoplast DNA and in the morphology of the flagellar pocket. These results suggest that K39B may have a role in kinetoplast morphology, possibly through the organization of the cytoskeleton in this region.

875 An Unexpected Role of Kinesin Superfamily Protein: KIF4 Regulates Activity-dependent Neuronal Survival by Suppressing PARP-1 Enzymatic Activity

R. Midorikawa, Y. Takei, N. Hirokawa; Anatomy and Cell Biology, Tokyo University, Faculty of Medicine, Tokyo, Japan

In brain development, apoptosis is a physiological process that controls the final numbers of neurons. Here we report that the activity-dependent prevention of apoptosis in juvenile neurons is regulated by kinesin superfamily protein 4 (KIF4), a microtubule-based molecular motor. The C-terminal domain of KIF4 is a module that suppresses the activity of poly (ADP-ribose) polymerase-1 (PARP-1), a nuclear enzyme known to maintain cell homeostasis by repairing DNA and serving as a transcriptional regulator. When neurons are stimulated by membrane depolarization, calcium signaling mediated by CaMKII induces dissociation of KIF4 from PARP-1, resulting in upregulation of PARP-1 activity, which supports neuron survival. After dissociation from KIF4, KIF4 enters into the cytoskeleton from the nucleus, moves to the distal part of neurites in a microtubule-dependent manner. We suggested that KIF4 controls the activity-dependent survival of postmitotic neurons by regulating PARP-1 activity in brain development.

876 Characterization of Motor-domain Mutants of the Mitotic Kinesin RAB6KIFL (Mklp2, Kif20a)

E. L. de Hostos, Y. Lee, R. Sakowicz, L. Belmont; Cytokinetics, Inc., South San Francisco, CA

RAB6KIFL is a kinesin motor protein involved in cytokinesis. siRNAs targeting RAB6KIFL cause the failure of cytokinesis and the generation of binucleate cells (Neef et al. 2003, J Cell Biol. 161: 863-75; Zhu et al. 2005, Mol Biol Cell. 161:3187-99). We have engineered three motor domain mutations to explore the biochemical activity and biological function of this motor protein. Based on studies of kinesin heavy chain and Kar3 (Yun et al. 2001, EMBO J. 20:2611-8), two of the mutations, T167N (Switch I), were predicted to lock the motor domain into a microtubule bound rigor state, and the third, R379A (Switch II), was predicted to lock the motor in the weak microtubule binding state. The mutations were generated in a motor domain-only construct for expression in E. coli. All threemutations abolish microtubule-stimulated ATPase activity. Unlike the G411A and R379A mutants, the T167N mutant expressed poorly in bacteria and did not bind microtubules. It is likely that this protein does not fold properly. Wild-type, G411A and R379A versions of a full-length GFP-RAB6KIFL fusion were expressed in HeLa cells under the control of a native RAB6KIFL promoter fragment. Localization of the wild-type fusion is indistinguishable from that of endogenous RAB6KIFL, and is concentrated in the central region of the midbody connecting daughter cells. Unlike the wild-type fusion, however, the R379A fusion and the G411A mutant in particular, appear to be broadly distributed along midbody but are absent from the central region of the bridge. While mutant fusions localize aberrantly, at the level of expression achieved by these constructs they do not seem to have a dominant-negative effect on cytokinesis. This strategy is useful for the correlation of biochemical activity and biological function and is broadly applicable to the study of other kinesin motors.
Kinesin motors release nucleotide upon interaction with microtubules, then bind and hydrolyze new ATP to move along the microtubule. Although crystal structures of kinesin motors with bound nucleotide have been solved, nucleotide-free structures have not yet been reported. To understand the structural changes in kinesin motors bound to microtubules, we studied the 3D structure of microtubules decorated with a Kinesin-14 motor, Kar3, without nucleotide, as well as with ADP and AMP~PNP, using electron cryo-microscopy and computer 3D reconstruction. The resolution of the 3D maps obtained is unusually high, ~10-12 Å, sufficient to observe helices, e.g., tubulin helices H3, H11 and H12, and the motor Switch II helix, α4. Although differences between the ADP and AMP~PNP states were relatively small, consistent with published X-ray crystallographies, we found large structural changes in the motor bound to microtubules without nucleotide, including melting of helix α4, closure of the nucleotide-binding pocket, and movement of loop L7 towards the microtubule. The movement of L7 was accompanied by distortion of the central β-sheet, reminiscent of nucleotide-free myosin crystal structures (Reubold et al., 2003; Courreux et al., 2003). Contrary to reports by others for the Kinesin-3 motor, Kif1A (Kikkawa et al., 2001), the Kar3 motor domain did not rotate between the motor-MT ADP and ATP-like states. We propose that the Switch II region of the motor controls docking of the Kar3 neck by conformational changes in the central β-sheet, similar to myosin, rather than by rotation of the motor domain, as proposed for Kif1A.

Kif5B Interacts with β-catenin and Regulates its Sub-cellular Localization

S. Taya, K. Kaibuchi; Department of Cell Pharmacology, Nagoya University Graduate School of Medicine, Nagoya, Japan

β-catenin performs important functions in both the cytoplasm, as a component of adherens junctions and in the nucleus, as a Wnt stimulated transcription factor. However, the molecular mediators of β-catenin localization to these functionally distinct cellular pools have not been elucidated fully. The kinesin family of microtubule-associated motors mediates a variety of intracellular transport events and therefore is a good candidate regulator of β-catenin sub-cellular distribution. Here, we report that β-catenin co-localizes with Kif5B, a Kinesin-I family member, both in the cytoplasm and at adherens junctions of MDCK cells. Furthermore, we find that endogenous Kif5 interacts with β-catenin in both MDCK and HEK293 cells.

Biochemical analysis revealed that this interaction is mediated by the C-terminal tail region of the KIF5B heavy chain and is independent of kinesin light chains. Exogenously expressed single molecule imaging in vivo, our work provides the first direct observations of single protein molecules expressed and localized in the cytoplasm of mammalian cells.

Axonal Transport by Kinesin-1 Is Blocked by Stress, but Not by Neuritic Deposits of Amyloid-β

Z. Muresan, V. Muresan; Physiology and Biophysics, Case Western Reserve University, Cleveland, OH

It is generally admitted that a deficient axonal transport may be one of the initial events that lead to neuronal degeneration and neurotic plaque formation in Alzheimer’s disease (AD). However, it is not known if abnormal generation and intraneuronal accumulation of amyloid-β (Aβ) is always a direct cause of axonal transport deficiencies. We established a cell culture system, where neuronal cells (CAD) produce and accumulate large amounts of Aβ peptide, similar to what is believed to occur in brain neurons, in the initial phases of AD. In these cells, Aβ is distributed throughout the neurites, and concentrates at their terminals. We analyzed the cytoskeleton and the transport of vesicular cargoes within the neurites that contained Aβ accumulations. We found that, although the growth cones that contained Aβ appeared dystrophic, the distribution of microtubules and actin filaments was normal. We examined transport and localization of phosphorylated APP and JNK-interacting protein-1 (JIP-1), two vesicular cargoes of the microtubule motor, kinesin-1. We found that transport of these two proteins occurred at normal rates in neurites that contained extensive accumulations of Aβ. By contrast, transport of JIP-1 and APP (phosphorylated and not phosphorylated) was completely blocked in cells subjected to osmotic stress (by treatment with 0.4 M sorbitol), a condition that activates JNK and leads to increased phosphorylation of APP, kinesin-1, as well as other proteins. Sorbitol treatment did not affect accumulation of Aβ in CAD cell processes. These results indicate that transport of vesicular cargoes into neurites does not generally appear to be perturbed by the presence of large amounts of Aβ.

We conclude that, while a deficient axonal transport may cause neurodegeneration, increased generation and neuritic accumulation of Aβ can occur in the absence of detectable signs of abnormal axonal transport.
A Novel Mechanism for Kinesin Spindle Protein (KSP) Modulation: Small Molecular Activators of KSP Basal ATPase

E. Miraldi,1 P. J. Thomas,2,3 L. Romberg4; 1Biochemistry, Oberlin College, Oberlin, OH, 2Mathematics, Case Western Reserve University, Cleveland, OH, 3Neuroscience, Oberlin College, Oberlin, OH, 4Physics, Oberlin College, Oberlin, OH

For nearly fifty years cooperative polymerization has been explained by a model that requires polymers to be "helical" or multistranded, whereas single-stranded, linear polymers are not evolutionarily conserved. 57 kD protein related to essential proteins in C. elegans and S. cerevisiae, and is similar to a yeast protein required for ribosome biogenesis, thus providing an enticing link between Chindogu function and ribosome or mrRNA transport by kinesin. Loss of zygotic Chindogu function has no obvious phenotype, but eggs lain by mothers lacking Chindogu fail to develop. This maternal effect lethal phenotype is also observed in embryos lacking determinants of embryonic polarity. We are currently generating new mutant alleles of Chindogu, using specific antisera to analyze the subcellular localization of Chindogu protein, and comparing the localization of developmental markers such as mrNA transcripts involved in oocyte polarity in wild type and Chindogu mutants, to further investigate a possible role for Chindogu in Drosophila embryogenesis and kinesin-mediated transport.

Characterization of Chindogu, a Drosophila Kinesin-1 Binding Protein

K. P. Weber, D. Yang-Zhou, J. G. Grindhart1; 1Department of Biology, University of Richmond, Richmond, VA, 2Department of Biology, University of Massachusetts Boston, Boston, MA

The microtubule motor protein kinesin-1 is essential for Drosophila development. During oogenesis, loss of kinesin-1 function causes defects in oocyte polarity, while kinesin-1 is also essential for anterograd e axonal transport in larva and adult. To better understand the function of kinesin-1 in vivo, a yeast two-hybrid screen was used to identify proteins that bind specifically to the kinesin tail domain. Previous results have demonstrated that specific protein-protein interactions with the kinesin tail domain are important for mediating and regulating interactions between kinesin and its intracellular cargos. We have identified Chindogu, a novel kinesin light chain-binding protein that is essential for Drosophila embryonic development. Chindogu is an evolutionarily conserved 57 kD protein related to essential proteins in C. elegans and S. cerevisiae, and is similar to a yeast protein required for ribosome biogenesis, thus providing an enticing link between Chindogu function and ribosome or mrRNA transport by kinesin. Loss of zygotic Chindogu function has no obvious phenotype, but eggs lain by mothers lacking Chindogu fail to develop. This maternal effect lethal phenotype is also observed in embryos lacking determinants of embryonic polarity. We are currently generating new mutant alleles of Chindogu, using specific antisera to analyze the subcellular localization of Chindogu protein, and comparing the localization of developmental markers such as mrNA transcripts involved in oocyte polarity in wild type and Chindogu mutants, to further investigate a possible role for Chindogu in Drosophila embryogenesis and kinesin-mediated transport.

Microtubule Dynamics: Computational Stochastic Modelling of Cellular Microtubule Network

A. A. Sheplak,1 E. S. Nakhedrina,1 Bioengineering and Bioinformatics, Moscow Lomonosov's State University, Moscow, Russian Federation, 2Institute of Protein Research of RAS, Moscow, Russian Federation

Microtubule network is a very dynamic structure, undergoing rapid reconstructions if cell is affected. It can show either central symmetry or chaotic arrangement of microtubules. Microtubule network rearranges during cell movement at polarization phase and at cell differentiation. We have developed computer model of microtubule behavior where microtubule dynamics is simulated as a chemical reaction of reversible polymerization. Microtubule is presented as a chain of objects. Each object is a tubulin in either GTP or GDP state. Engaging of a new object into chain occurs at chain ends by stochastic mechanism. The probabilities of engaging/disenengaging/changing state of objects are accounted by formulas analogous to chemical reaction equation. The coefficients are specified for 10 reactions (association/dissociation of GTP/GDP tubulin at minus/pus end, microtubule nucleation and tubulin status change), and program allows to change them easily. The rate of each reaction depends on its coefficient, on free tubulin concentration and on random numbers. Each object incorporates at random angle allowing microtubules to curve. The designed program properly simulated microtubule network: logarithmic growth of microtubules and steady-state with either dynamic instability or treadmilling. As simulation showed, the rate of changing from GTP status into GDP is more crucial for switching of dynamics between treadmilling and dynamic instability than critical concentration of tubulin. We also enter differentiation of reaction coefficients through program field to introduce “centrosomal” effects. We either increased nucleation rate in central square of the field or decreased tubulin exit from minus end (microtubule anchoring) in this square. We found that anchoring is much more important than augmented nucleation in forming microtubule radial array. The data predicted by program is highly similar to experimental results. In future our stochastic computer model is to be improved to simulate the inner cell geometric dependent processes and to introduce microtubule-dependent movement of organelles.

Microtubule Dynamics: Stochastic Simulations Reveal Predictable Nature of Complex Behaviors

I. V. Gregoretti,1 G. Margolin,2 M. S. Alber,3 H. V. Goodson1; 1Department of Chemistry and Biochemistry, University of Notre Dame, Notre Dame, IN, 2Department of Mathematics, University of Notre Dame, Notre Dame, IN

Microtubule dynamic instability plays a fundamental role in cell biology, enabling microtubules to find and interact with randomly distributed cargo and spatially localized signals. Microtubules in vitro transition between growth and shrinkage symmetrically, consistent with theoretical understanding of the mechanism of dynamic instability. However, microtubules in vivo commonly exhibit asymmetric dynamic instability, growing persistently in the cell interior and experiencing catastrophe near the cell edge. What is the origin of this behavior difference? One answer is that the cell edge causes the asymmetry by inducing catastrophe in persistently growing microtubules. However, the origin of the persistent growth itself is unclear. Using a simplified coarse-grained stochastic simulation of a system of dynamic microtubules, we provide evidence that persistent growth is a predictable property of a system of nucleated, dynamic, microtubules containing sufficient tubulin in a confined space - MAP activity is not required. Persistent growth occurs because cell-edge-induced catastrophe increases the concentration of free tubulin at steady state. Our simulations indicate that other aspects of MT dynamics thought to require MAPs are also predictable, perhaps unavoidable, outcomes of the "systems nature" of the cellular microtubule cytoskeleton. These include the mitotic increase in microtubule dynamics and the observation that defects in nucleation cause changes in the behavior of microtubule plus ends. These predictions are directly relevant to understanding of the microtubule cytoskeleton, but they are also attractive from an evolutionary standpoint because they provide evidence that apparently complex cellular behaviors can originate from simple interactions without a requirement for intricate regulatory machinery.

A New Model for Cooperative Polymerization: Conformational Changes Can Produce Critical Concentrations in Single-stranded Polymers

E. Miraki,5 P. J. Thomas,6,7 L. Romberg,8 Biochemistry, Oberlin College, Oberlin, OH, 5Mathematics, Case Western Reserve University, Cleveland, OH, 6Neuroscience, Oberlin College, Oberlin, OH, 7Biology, Oberlin College, Oberlin, OH

For nearly fifty years cooperative polymerization has been explained by a model that requires polymers to be "helical" or multistranded, whereas single-stranded, linear polymers are not thought to assemble cooperatively (Oosawa and Kasa, 1962). Assembly of FtsZ, the bacterial homolog of tubulin, cannot be described by either of these two models. Unlike tubulin, FtsZ can apparently complex cellular behaviors can originate from simple interactions without a requirement for intricate regulatory machinery.
888 Automatic Quantification of Microtubule Dynamics in Living Cells

L. D. Sironi, 1 A. Bancaud, 1 J. Selon, 1 D. Brunner, 1 J. Ellenserg 1; Gene Expression, EMBL, Heidelberg, Germany, 2LAAS - CNRS, Toulouse, France, 3Cell Biology, EMBL, Heidelberg, Germany

Microtubules (MTs) are dynamic polarized filaments essential for many cellular functions such as spatial rearrangement of the cytoplasm in interphase, intracellular membrane traffic and chromosome segregation during cell division. All these functions depend on the dynamic properties of MTs, which allow them to rapidly probe the cytoplasmic space. In HeLa cells, most MTs are nucleated from the centrosome with their fast-growing plus-ends directed towards the cell periphery. MT plus-ends display both in vitro and in vivo dynamic instability, which means that they alternate between phases of elongation and rapid shortening. We have established a quantitative and automatic protocol to measure MT growth speed and nucleation rate at the centrosome during the cell cycle in live S2 cells using a HeLa cell line expressing fluorescently tagged EB3, a plus-end tracking protein. Using spinning disk confocal microscopy we record high temporal and spatial resolution sequences of cells in interphase, prophase, prometaphase and anaphase. The raw data are then filtered automatically by computerized image processing to select only for the moving MT tips. To measure MT growth rates we use a multiple-particle tracking algorithm that reconstitutes individual tip trajectories and calculates tip velocities. To measure MT nucleation rates at the centrosome we perform a radial kymograph image analysis which automatically counts the number of tips that cross an interactively selected circular region around the centrosome. In summary we have developed a quantitative assay to study MT dynamics in an automatic fashion that we intend to use as a tool to identify and characterize regulators of microtubule dynamics by targeted RNA interference screens in live cells.

889 Observation of Tubulin Incorporation Events into Growing Microtubules Using Single Molecule Fluorescence

L. Breshears, 1 P. Partensky, 1 B. Shan Tseng, 1 M. Dogterom 2; 1Physiology Course 2006, Marine Biological Laboratory, Woods Hole, MA, 2FOM Institute AMOLF, Amsterdam, The Netherlands

Microtubules are hollow tubes consisting of typically 13 parallel protofilaments that in vitro and in vivo grow by the addition of tubulin dimers to their growing ends. It is generally believed that the growing ends of microtubules contain several individual protofilaments that after assembly first bind to each other laterally in a slightly outward-curved sheet and then close into a straight hollow tube. The kinetic details of the tubulin assembly process itself as well as the conformational changes of the sheet-like structures at the growing ends remain poorly understood. Fluorescence microscopy can be used to monitor the incorporation of fluorescently labeled tubulin subunits into single microtubules in vitro or in vivo. When low labeling ratios are used, so-called speckles are observed that result from spatial fluctuations in the distance between individual fluorescent labels. These speckles are a powerful tool in monitoring microtubule dynamics, transport and organization of MTs in the normal living state. Using TIRF microscopy and a very low labeling ratio we demonstrate the observation of single tubulin incorporation into microtubules growing from pure tubulin in vitro. With improved time resolution, the ability to observe tubulin addition at the single molecule level should allow for the observation of individual attachment as well as detachment events, which will help settle existing controversies about the off-rate for tubulin in growing microtubules. Also, tracking the lateral position of newly added tubulin subunits at nanometer resolution, should allow for the detection of straigtening events of putative outward-curved sheets at the ends of growing microtubules.

890 Microtubule Dynamics at the Nanoscale: Evidence for a Stable, GTP-free Structural Cap, and Implications for Cytoskeletal Restructuring

H. T. Schek, A. J. Hunt; University of Michigan, Ann Arbor, MI

The mechanisms underlying dynamic instability of microtubules (MTs) have remained enigmatic largely because direct studies of events at an MT tip have proven difficult. Studies following polymerization of dynamic MTs in real time are limited by low temporal resolution (often less than 0.05 Hz) and the light resolution limit, while bulk biochemical studies rely on large ensemble averages to infer individual MT behaviors. Cryo-electron-microscopy allows for detailed study of MT tip structure, but requires fixed samples that are no longer dynamic. By combining optical tweezers with custom-engineered nanoscale barriers to MT polymerization we are able to track events at the growing tip of a loaded dynamic MT with nanometer-scale precision. We find that MT growth rates under load are too variable to be explained by a model positing a simple first order reaction; polymerizing microtubules frequently transit between states that exhibit different growth dynamics. MTs under load often exhibit periods of stalled growth that last for up to several seconds without leading to a catastrophe event. Additionally, MTs often shorten up to tens of nanometers during a period of overall growth, without entering into a period of rapid shortening. These shortening events often result in a loss of length equivalent to 3-10 layers of subunits, calling into question the GTP-cap hypothesis for MT stability. Furthermore, the observed variability and shortening events demonstrate that MT polymerization from pure tubulin is a dissipative process. Cellular regulation mechanisms that prevent these dissipative events could provide the cell with a means to achieve faster polymerization as has been observed in vivo.

891 Self-organisation of Anastral Spindles by Synergy of Dynamic Instability, Autocatalytic Nucleation, and a Spatial Signalling Gradient

T. Clausen, K. Ribbeck; Gene Expression, EMBL, Heidelberg, Germany

Assembly of the mitotic spindle is a classic example of macromolecular self-organisation. A combined biochemistry-computer simulation approach reveals that the concerted activity of three processes - dynamic instability, autocatalytic nucleation, and a spatial signalling gradient - can self-organise the mitotic spindle. In anastral spindles, during cytokinesis, when there is no central spindle to dictate the mitotic spindle assembly system (Kalab et al. 2006. Nature 440 697), we have found that the presence of spatially autocatalytic gradients can dictate a mitotic spindle. These results indicate that Ran-regulated gradient of importin β cargo concentration to chromatin-driven mitotic spindle assembly is sufficient to direct chromatin-driven mitotic spindle assembly. The mechanism proposed here can generate and maintain a dissipative MT superstructure within a RanGTP gradient.

892 Analysis of Ran-regulated Importin β Cargo Gradient Contribution to Chromatin-driven Mitotic Spindle Assembly

P. Kalah, A. Prallé, D. R. Halpin, R. Heald, K. Weis; UC Berkeley, Berkeley, CA

RanGTP-ase regulated pathways contribute in a diverse fashion to mitotic spindle assembly in comparison of a variety of somatic cells and meiotic/embryonic Xenopus egg extract spindle assembly system (Kalab et al. 2006. Nature 440 697). Here we applied fluorescence resonance energy transfer (FRET)-based sensors and fluorescence lifetime microscopy (FLIM) to examine the role of Ran-regulated importin β cargo gradient in the primarily chromatin-driven spindle assembly in Xenopus egg extract model system. We confirmed that, as in HeLa cells, cytoplasm in mitotic Xenopus egg extracts contains majority of importin α-like importin β cargos in a free form and therefore potentially active to promote spindle assembly. Experiments with synthetic RCC1 beads demonstrated that a small further localized liberation of importin β cargos induces localized microtubule polymerization and mitotic spindle assembly. Interestingly, the ampltudes of importin β cargo gradients surrounding mitotic chromatin in X. laevis and X. tropicalis extracts are similar, in contrast to significantly smaller size of X. tropicalis mitotic spindles regardless of the source of chromatin. These results indicate that Ran-regulated gradient of importin β cargos is sufficient to direct chromatin-driven mitotic spindle assembly. On the other hand, the role of the chromatin-centered importin β cargo gradient in determination of mitotic spindle size is counteracted by dominant cytoplasmic activities.

893 Genes Required for Spindle Assembly in Drosophila S2 Cells

G. Goshima, 1 R. Wollman, 1 J. M. Scholey, 1 R. D. Vale, 1 N. Stuurman, 1 UC Davis, Davis, CA

Mitotic spindle assembly is a complex process controlled by many genes. While genes required for this process have been extensively identified in yeast and nematode, it is expected that more genes remain to be identified in higher eukaryotes that construct more complex-shaped spindles. Here we present a genome-wide RNAi screening of the metaphase spindle morphology in Drosophila S2 cells. After RNAi treatment of ~14,000 genes, we manually and computationally identified and analyzed 3.5 million immunofluorescence images of the metaphase spindle. This complementary analysis identified ~200 genes whose knockdowns show reproducibly clear defects in spindle morphology. 26 hit genes were further characterized by GFP tagging and were shown to act on the various aspects of metaphase spindle morphogenesis. As examples, we found a novel centriole protein essential for centriole duplication, a novel spindle protein important for recruitment of gamma-tubulin to the spindle, and four novel kinetochore proteins required for chromosome congression. Localization and RNAi analysis also revealed that calmodulin, a major transducer of calcium signals, functions for spindle pole focusing in metaphase by targeting Asp protein to spindle poles. Based upon these follow-up experiments, we propose models for protein assembly at kinetochore, centrosomes and spindle poles of S2 cells.
Cytoplasmic Dynin Motor Activity Is Necessary for Spindle Alignment and Fusion: Insights from Spindle Micromanipulation Studies

J. C. Gatlin, 1, A. Cameron, 2 A. C. Groen, 1 T. J. Mitchison, 2 E. D. Salmon 1
1 Biology, University of North Carolina, Chapel Hill, NC, 2 Systems Biology, Harvard Medical School, Boston, MA
Meiosis II bipolar spindles with replicated sister chromosomes at metaphase were assembled in Xenopus egg extracts. Previous studies have demonstrated that two spindles, positioned with their interpolar axes parallel to each other, align and fuse together into one metaphase spindle by two distinct mechanisms. If proximal ends of the spindles are overlapped then the spindles slide parallel to their axes until the chromosomes and poles align respectively. However, if spindles are positioned with no overlap between poles, but close enough to each other, then nearest poles come together and their spindles pivot around their shared pole, “jackknifing” into a bipolar metaphase spindle. Individual spindle integrity seems to be maintained during alignment and fusion. These processes are inhibited by orthovanadate, suggesting that cytoplasmic dynin might be the responsible motor. In this study we sought to better understand the origin of the alignment forces. To determine whether flux dependent mechanisms were involved, we created monopolar spindles by biochemical inhibition of the Eg5 kinesin motor. When two monopoles were placed within ~50 μm of each other, a central spindle of overlapping microtubules formed between the poles, shortening as the poles came together. The velocity of fusion was dependent upon the distance between the poles, and decreased significantly when the two poles became closer. Analysis of chromosome localization revealed that monopole fusion does not require the presence of chromosomes in between the two fusing asters. Formation of interpolar “bridging” microtubule bundles and pulling were blocked by 200μM orthovanadate but not by 2μM okadaic acid, indicating that both are caused by cytoplasmic dynin. These data support a mechanism in which minus end directed “pulling in” forces produced by cytoplasmic dynin act along anti-parallel microtubules and play a major role in the alignment and fusion of two spindles into one. Supported by GM24364 and GM60678.

ICIS Regulates Microtubule Dynamics

W. Lan, T. Stukenberg; Biochemistry and Molecular Genetics, University of Virginia, Charlottesville, VA
A novel microtubule associated protein called ICIS (Inner Centromere Kin I Stimulator), has been found to stimulate the microtubule depolymerase activity of MCAK (Oh et al., 2003). To understand how MCAK regulates microtubule dynamics, we have searched for new interactions of ICIS and studied how ICIS is regulated. We have found that ICIS interacts with Pxl1 and can stimulate its kinase activity about 3 fold in vitro. ICIS has separate domains that interact with the inner centromere regulators MCAK, Aurora B and Pxl1. ICIS is also phosphorylated by Aurora B kinase on S775 both in vitro and in vivo. However, we find that Xenopus extracts that have had 97% of ICIS removed by immunodepletion still produce normal bipolar spindles. Centrosomes in Xenopus extracts give weak asters in the presence of ICIS antibodies, suggesting roles independent of simulating MCAK. Together, our data suggest that ICIS is regulated by the mitotic phosphorylations, and has functions in regulating microtubule dynamics that may be distinct from regulation of MCAK.

The Dam1 Kinetochore Ring Complex Harnesses Microtubule Dynamics to Produce Force and Movement

C. L. Ashbury, 1 T. N. Davis, 1 D. R. Gestaut, 1 A. F. Powers, 1 A. D. Franck 1
1 Physiology and Biophysics, University of Washington, Seattle, WA, 2 Biochemistry, University of Washington, Seattle, WA
Kinetochore microtubules are an essential component of kinetochores in yeast, but can be directly removed from kinetochores. For instance, mutations that disrupt the Dam1 complex have no effect on chromosome movement. We have developed a new method to measure the changes in MT number and distribution, at single MT resolution in living cells. We show for wild-type cells, bipolar spindle symmetry is maintained by the MT assembly and disassembly that occurs under tension. When the spindle breaks down, the astral MTs, the astral MT bundles, and the PAA microtubules in fission yeast are composed primarily of 1 individual MT along their lengths. We measure the cellular concentration of MT plus ends of interphase MTs. As many microtubule (MT) structures such as the mitotic spindle contain MTs that are bundled and stabilized in overlapping arrays. In the fission yeast Schizosaccharomyces pombe, stable overlapping MTs are located in the spindle midzone and interphase MT bundles. CLASPs are well known as MT binding proteins that contribute to the stabilization of MT plus-ends. Here, we show that the fission yeast CLASP, cls1p, localizes to MT bundles at the spindle and kinetochores during mitosis and at perinuclear interphase MTOCs (iMTOCs) during interphase, but not to MT plus ends of interphase MTs. As cls1 is an essential gene, we generated conditional cls1/ alleles that rapidly lose function upon temperature shift. Using these alleles, we found that cls1p was required for both the assembly and maintenance of the spindle. For instance, loss of cls1p in anaphase led to rapid depolymerization of all spindle MTs. Stabilization of interphase MT bundles at iMTOCs was also lost in these mutants. Conversely, overexpression of cls1p led to stabilization of all MT structures, apparently by increasing rescue rates. This stabilization activity was independent of EB1 (mal3p), PRC1 (ase1p), and CLIP170 (tip1p). At endogenous levels, cls1p localization was dependent on the MT bundling protein ase1p, which is also localized to the spindle midzone and interphase MT bundles. We measure the cellular concentration of MT plus end associated with the Dam1 complex to be 4.04 ± 0.24 μM. The Dam1 complex may contribute directly to microtubule-driven chromosome movement. Many microtubule associated protein called ICIS (Inner Centromere Kin I Stimulator), has been found to stimulate the microtubule depolymerase activity of MCAK (Oh et al., 2003). To understand how MCAK regulates microtubule dynamics, we have searched for new interactions of ICIS and studied how ICIS is regulated. We have found that ICIS interacts with Pxl1 and can stimulate its kinase activity about 3 fold in vitro. ICIS has separate domains that interact with the inner centromere regulators MCAK, Aurora B and Pxl1. ICIS is also phosphorylated by Aurora B kinase on S775 both in vitro and in vivo. However, we find that Xenopus extracts that have had 97% of ICIS removed by immunodepletion still produce normal bipolar spindles. Centrosomes in Xenopus extracts give weak asters in the presence of ICIS antibodies, suggesting roles independent of simulating MCAK. Together, our data suggest that ICIS is regulated by the mitotic phosphorylations, and has functions in regulating microtubule dynamics that may be distinct from regulation of MCAK.

The Dam1 Kinetochore Ring Complex Harnesses Microtubule Dynamics to Produce Force and Movement

Kinetochore microtubules are an essential component of kinetochores in yeast, but can be directly removed from kinetochores. For instance, mutations that disrupt the Dam1 complex have no effect on chromosome movement. We have developed a new method to measure the changes in MT number and distribution, at single MT resolution in living cells. We show for wild-type cells, bipolar spindle symmetry is maintained by the MT assembly and disassembly that occurs under tension. When the spindle breaks down, the astral MTs, the astral MT bundles, and the PAA microtubules in fission yeast. Αβ-η tubulin subunits to be 4.04 ± 0.24 μM at interphase $G_1$, $S$, 3.83 ± 0.32 μM at interphase $G_2$, and 5.35 ± 0.55 μM at mitosis M, of the peptide promoted formation of non-microtubule polymers. Dolastatin 15 induced conformational changes in tubulin. Taken together, the results suggest that dolastatin 15 inhibits mitosis and induces cell death by perturbing microtubule dynamics.
Gas7, a Novel Microtubule Polymerization Accelerator Stabilizers Sheet Structure of the Polymerization Intermediate

T. Uchida,1 H. Akiyama,1 M. Sanauda,1 T. Higashi,1 T. J. Ito;2 Enzymology, Department of Molecular Cell Biology, Tohoku University, Sendai, Japan, 2Nagoya, Nagoya, Japan

Although it is well known that protein phosphorylation is a key of intracellular signal transduction systems, the molecular mechanism of the regulation of phosphorylation signal is not elucidated. We have been studying the regulatory molecules for the phosphorylating signal transduction. It has been reported that WW motif in the peptides-prolyl cis/trans isomerase Ptn1 binds phosphoserine...Pro in Tau, a major member of heat-stable MAPs superfamily. Tau enhances microtubule polymerization, but phosphorylation impairs this activity. We searched the proteins containing similar sequence to the Ptn1's WW domain and found growth-arrest specific protein 7 (Gas7). It has been reported that Gas7 is required for actin polymerization but it was not known if it interacts with phosphorylated Tau. We found that Gas7 binds the moderately phosphorylated Tau. We characterized the effect of Gas7 on the polymerization of microtubule in vitro. Light scattering measurement showed that Gas7 increased microtubule polymerization. Dark-field microscopic observation showed the numbers of microtubules were increased by Gas7. Initially, single and more flexible filaments were observed, and the straight microtubules with “fluttering banner structure”, or “PROMISE” (pro-microtubule structure end up) appeared with the elongation of the entire length. "PROMISE" would correspond to the sheet intermediate of polymerization observed by electron microscopy. Gas7 enhances the persistency of the polymerization intermediates. Typical dynamic instability with stochastically occurring catastrophe and rescue was observed in control, but no catastrophe was observed in the presence of Gas7. These results suggest that Gas7 interacts with and stabilizes phosphorylated Tau by keeping “PROMISE” and maintains microtubule polymerization. We also found that Gas7 exists in the normal brains but not in the brains of patients with Alzheimer’s disease. We speculate that Gas7 is required for keeping nervous network system and its degradation may cause dementia.

Microtubule Plus End Protein CLASP Supports Microtubule Formation at the Trans-Golgi Membranes

I. Kavena,1 P. Efremova,1 T. Lomaczek,2 P. Efremov,1 F. G. T. Jones,1 H. Saito,1 A. Krokhin2; 1Cell and Developmental Biology, Vanderbilt University Medical Center, Nashville, TN, 2Wadsworth Center, Albany, NY, 3University of Melbourne, Melbourne, Australia, 4University of Porto, Porto, Portugal

In addition to binding plus ends of growing microtubules CLASP is also reproducibly found in the Golgi complex. However, the specificity and functional significance of this localization are not clear. By using immunofluorescence co-localization and live-cell imaging we localized CLASP to the most external compartment of the Golgi, presumably the trans-Golgi network (TGN) in normal human cells (HEK-293). Further, we found that CLASP is exposed at the cytoplasmic side of Golgi membranes and dissociates into the cytosol upon Brefeldin A treatment similarly to GRIP-domain containing TGN proteins. Mass-spectrometry analyses identified the GRIP-domain protein GCC185 as a CLASP-binding partner. It is likely that GCC185 recruits CLASP to the Golgi membranes. Thus, CLASP associates with the Golgi in a specific and controllable fashion. These data suggest that CLASP is involved in some aspects of microtubule dynamics regulation at the Golgi complex. In this regard, dense arrays of microtubules are consistently found emanating from the Golgi in normal human cells. Live-cell analyses of microtubule growth reveal that significant number of microtubules form at the Golgi stacks both in steady state, and during microtubule re-growth after nocodazole treatment. The role of the Golgi as a major microtubule organizing center becomes particularly evident upon ablation of the centrosome by laser micro-beam. Depletion of CLASP via siRNA in RPE-1 cells abolished microtubule-organizing potentials of the Golgi, indicating that CLASP is essential for this process. Furthermore, microtubules formed at the Golgi stacks after nocodazole washout are enriched with CLASP in contrast to those formed at the centrosome. We suggest that CLASP concentrated at the Golgi membranes selectively stabilizes microtubule seeds at this location and thus supports non-centrosomal microtubule arrays.

Insights into the Regulation of Microtubule Dynamics by EB1: The Role of Its Flexible C-terminus

T. Mamma,1 P. Efremova,2 J. Miller,1 M. O. Stemmle,1 L. Wilson1; 1Molecular, Cellular, and Developmental Biology, University of California at Santa Barbara, Santa Barbara, CA, 2Structural Biology, Paul Scherrer Institut, Villigen PSI, Switzerland

The evolutionary-conserved EB1+TIP protein family is involved in a number of microtubule (MT) dependent cellular processes including polarity and migration. One of EB1’s important functions is to regulate MT dynamics. However, the mechanisms by which EB1 and its binding partners such as P150 glut(s) might regulate MT dynamics are not understood. Here by using a purified recombinant MT system, we analyzed the effects of EB1 on steady-state microtubule dynamic instability by video microscopy and determined the role of its flexible C-terminus in the regulation of dynamics in the presence and absence of P150s. Our results demonstrated that the C-terminus of EB1. Full length EB1 alone significantly suppressed the rate and extent of shortening and the catastrophe frequency at plus ends of individual MTs in the absence of significant effects on the growth rate. Interestingly, depletion of its flexible C-terminal tail (the terminal 19 amino acid residues, EB1-C) increased EB1’s potency — four fold, in concert with a significant increase in MT binding. For example, at an initial EB1: tubulin ratio of 1:3, 1 mol of full-length EB1 bound 3.3 ± 1.1 tubulin dimers in microtubules, while 1 mol of EB1-C bound per 3.1 ± 0.9 mol of tubulin dimers. When analyzed together with full-length EB1, P150s increased the potency of EB1 to that of C-terminally-truncated EB1. Our results demonstrate at a mechanistic level that the flexible C-terminus tail of EB1 negatively regulates EB1’s effects on MT dynamics and that the binding to EB1 one of its binding partners (P150 glued) overcomes the negative regulation. The data are consistent with the previous hypothesis that the C-terminus of EB1 negatively regulates its effects on MTs. TBCE Interacts with EB1 and Modulates Centrosomal Regrowth

M. C. Huang,1 G. Tian,2 R. Parvar,1 N. J. Cowan,3 G. A. Diaz3; 1Human Genetics, Mt Sinai School of Medicine, New York, NY, 2Biochemistry, New York University, New York, NY, 3Ben Gurion University of the Negev, Beer Sheva, Israel

Tubulin-binding cofactor E (TBCE) is a chaperone required for the de novo formation of αβ-tubulin heterodimers, the building blocks of microtubules (MTs). Mutations in TBCE cause a human syndrome characterized by hypohypharyngism, mental retardation, facial dysmoria, and growth failure (HRD), and a murine model for peripheral motor neuropathy. HRD disease carrying a common founder mutation have normal tubulin abundance but disorganized MTs, suggesting that TBCE may have functions beyond its role in heterodimer assembly. We have previously reported the discovery of a repressor interaction between TBCE and EB1, a plus-end tracking protein (+TIP). We have confirmed and extended these findings through co-immunoprecipitation studies of overexpressed and purified proteins. We refined the interaction to the TBCE Ubiquitin-like domain and the EB1 C-terminus, which is known to associate with other +TIPs. Fluorescently-tagged TBCE and EB1 did not colocalize at MT plus ends, suggesting that this interaction occurs in the cytoplasm and may be regulatory in nature. Whereas overexpression of TBCE results in tubulin destruction in vivo, co-expression of EB1 and TBCE rescues α-tubulin, but not MTs, suggesting that EB1 may protect tubulin from TBCE-mediated degradation. Overexpression of EB1 increased MT overlap regions. Finally, cls1p bound to ase1p directly and this interaction is critical for its function. These studies suggest that ase1p recruits CLASP to regions of MT overlap to stabilize these MT structures.

The Role of LIMK1 in Endothelial Barrier Function

T. Vojno-Yanezskaya, M. Gorovoy, F. Neuma; University of Illinois, Chicago, IL

Microtubule (MT) destabilization promotes formation of actin stress fibers and enhances the contractility of cells. LIM kinase 1(LIMK1) regulates actin polymerization by phosphorylating the actin depolymerization factor, cofilin. Here we report that LIMK1 is also involved in the MT destabilization. In endothelial cells endogenous LIMK1 co-localizes with MTs and forms a complex with tubulin via the PDZ domain. MT destabilization induced by thrombin or nocodazole resulted in a decrease of LIMK1 co-localization with MTs. Overexpression of wild type LIMK1 resulted in MT destabilization, whereas the kinase-dead mutant of LIMK1 (KD) did not affect MT stability. Importantly, down-regulation of endogenous LIMK1 by siRNA resulted in abrogation of the thrombin-induced MTs destabilization and the inhibition of actin polymerization in endothelial cell. We examined pulmonary vascular permeability in LIMK1−/− mice. We found that endothelial permeability in the lungs of LIMK1 −/− mice was lower than in wild type mice. Perfusion of the lungs of wild type mice with PAR1 peptide showed significant increase of endothelial permeability. Notably, the endothelial permeability of the lungs of LIMK1 −/− mice after PAR1 peptide
Microtubule Dynamics Stimulated by F11L-dependent Inhibition of Rho Signaling Is Required for Release of Vaccinia Virus from Infected Cells

Microtubules and their dynamics play a critical role during many cellular processes including for example intracellular trafficking and cell migration. Microtubules also play an important role in the transport of viral pathogens during their infection cycles. A role of microtubule dynamics during viral pathogenesis however remains to be established. Using live-cell imaging of GFP-tagged tubulin and EB1, we now show that vaccinia virus infection dramatically stimulates microtubule dynamics. Stimulation of microtubule dynamics was dependent on inhibition of Rho GTPase signaling by F11L, a viral encoded inhibitor of RhoA. Inhibition of microtubule dynamics, while not inhibiting vaccinia virus assembly, did result in a dramatic reduction of the number of virus particles accumulating at the plasma membrane and being released from the infected cell. Based on our observations we suggest that viral stimulated increase of microtubule dynamics in the cell periphery may play an important role in facilitating efficient cell to cell spread of viruses during infection. Phosphorylation of Serine 16 or Serine 63 Strongly Diminishes Stathmin’s Catastrophe-promoting Activity at Microtubule Plus and Minus Ends

T. Manna, S. Honnappa, D. A. Thrower, H. P. Miller, M. O. Steinmetz, L. Wilson; 1Department of Molecular, Cellular, and Developmental Biology and The Neuroscience Research Institute, University of California at Santa Barbara, Santa Barbara, CA, 2Department of Cell Biology, University of Connecticut, Storrs, CT.

Stathmin, an AAA ATPase mutated in the neurodegenerative disease Hereditary Spastic Paraplegia, severs microtubules. AAA ATPases are molecular machines that assemble into ring-shaped oligomers which often drive unfolding of target proteins by translocating them through the central pore during successive rounds of ATP hydrolysis. Loops projecting into the pore are required for target recognition, translocation, and enzyme function. By analytical ultracentrifugation, gel filtration chromatography, and electron microscopy we show that Stathmin assembles into a hexameric ring in an ATP-dependent fashion. Using purified WT and mutant versions of Stathmin in microtubule severing and tubulin binding assays we show that pore loops in hexameric Stathmin recognize the extreme C-terminal amino acids of tubulin and that this interaction is critical for microtubule severing. A disease-associated mutation affects one pore loop. In contrast to the ATP-dependent interaction described above, we found that Stathmin contains a second microtubule binding domain which makes a distinct, ATP-independent interaction with microtubules. This domain is required for engagement of tubulin tail recognition and severing. We propose that Stathmin exerts force on the microtubule in part by engagement of the tubulin tail by Stathmin’s pore. Severing could be achieved by pulling the tail into the pore. Alternatively, since the N-terminal microtubule binding domain (N-MTBD) interacts with a microtubule, Stathmin engages a microtubule in two places. Possibly, molecular motions that result in the reorientation of the N-MTBD with respect to the AAA ring could result in force being applied to the microtubule.

Tubulin Cofactor A (TBCA) Is Required for Cell Viability

S. Nolasco, J. Belillo, J. Gonçalves, J. C. Zahala, H. Soares; 1Instituto Gulbenkian de Ciência, Oeiras, Portugal, 2Departamento de Biologia Molecular-Unidad Asociada al Centro de Investigaciones Biológicas (CSIC), Universidad de Cantabria, Santander, Spain, 3Escuela Superior de Tecnología da Saúde de Lisboa, Lisboa, Portugal.

The folding of tubulin and assembly of αβ-tubulin heterodimers competent to polymerise is a complex multistep process involving several molecular chaperones and cofactors. We hypothesise that the tubulin folding pathway, controlling the synthesis and flux of mature tubulin heterodimers, plays a central role in regulating the assembly, remodelling and dynamics of microtubule structures. In vitro, tubulin cofactor A (TBCA) interacts with β-tubulin in a quasi-native state behaving as a molecular chaperone. In human cell lines, we showed that TBCA is an essential gene since its knockdown, by RNAi, in Hela and MCF-7 cells induced cell death. The essentiality of TBCA in these cell lines may be related with the tubulin gene family complexity since this gene is not essential in yeast. The indirect immunolocalization of tubulin showed subtle alterations in microtubules and the cell cycle analysis (by flow cytometry) showed cellular proliferation inhibition by G1 cell cycle arrest. Furthermore, MCF-7 cells presented also a dramatic change in cell shape resembling differentiation. Our results strongly suggest the involvement of caspase activities in cell death. However, Annexin-V and PI staining indicated that cell death occurs essentially by necrosis/late apoptosis. In both cell lines the knockdown of TBCA also induces a decrease in β-tubulin levels that is accompanied by a decrease in α-tubulin levels indicating a strict regulation between tubulins. This decrease correlates with cell death and could be due to a reduction in the tubulin folding rate or to an increase of the degradation of the improperly folded tubulin. However, the idea that TBCA could play alternative/additional roles in vivo is still an unanswered question.

Phosphorylation of Ser16 or Serine 63 Strongly Diminishes Stathmin’s Catastrophe-promoting Activity at Microtubule Plus and Minus Ends

T. Manna, S. Honnappa, D. A. Thrower, H. P. Miller, M. O. Steinmetz, L. Wilson; 1Department of Molecular, Cellular, and Developmental Biology and The Neuroscience Research Institute, University of California, Santa Barbara, CA, 2Department of Structural Biology, Paul Scherrer Institut, Villigen PSI, Switzerland

Stathmin plays a major role in cell cycle progression by regulating microtubule (MT) dynamics via phosphorylation dependent pathways. Stathmin’s four serine residues (Ser16, Ser25, Ser38 and Ser63) are phosphorylated during mitosis, which is believed to be critically involved in switching off stathmin’s MT-stabilizing activity. Recent studies have indicated that phosphorylation at Ser16 and Ser63 is critical in regulating MT organization and function during mitosis (Larsson et al, Mol. Biol. Cell 17:5530-5539, 1997). However, the mechanisms by which phosphorylation of Ser16 or Ser63 might regulate MT dynamics are largely unknown. Our recent studies have shown that stathmin modulates steady-state MT dynamic instability predominantly by increasing the catastrophe frequency both at plus and minus ends through a direct action on MTs, with the catastrophe promoting activity at minus ends being considerably stronger than at plus ends (Manna et al., J.Biol. Chem 281:2071-2078, 2006). Consistent with its ability to destabilize minus ends, stathmin strongly increases the treadmilling rate of bovine brain MTs in vitro. Here we analyzed the effects of authentically phosphorylated stathmin individually at Ser16 and Ser63 on stathmin’s ability to regulate the catastrophe frequency at plus and minus ends through a direct action on MTs at steady state. Phosphorylation at Ser16 strongly reduced stathmin’s ability to increase the catastrophe frequency at plus ends and it completely abolished stathmin’s ability to increase the catastrophe frequency at minus ends. In contrast, stathmin completely lost its ability to increase the catastrophe frequency at either MT end upon phosphorylation of Ser63. The reduced ability of the phosphorylated proteins to increase the catastrophe frequency correlated well with reduced ability to bind soluble tubulin, to bind intact microtubules, and to inhibit MT polymerization. Supported by NIH NS13560, NSF 0331697, and Swiss National Research Foundation 31-64978.01.
Gsa Activates Tubulin GTPase and Differentially Interacts with Tubulin Isotypes
R. H. Dave\textsuperscript{1}, V. Frasad\textsuperscript{2}, A. Banerjee\textsuperscript{2}, R. F. Ludala\textsuperscript{2}, M. M. Rasenick\textsuperscript{1}\textsuperscript{,}\textsuperscript{3}; \textsuperscript{1}Department of Physiology, Neuroscience Program, and MD/PhD Program, University of Illinois Chicago College of Medicine, Chicago, IL, \textsuperscript{2}Dept. Biobiochemistry, University of Texas Health Science Center at San Antonio, San Antonio, TX, \textsuperscript{3}Department of Physiology, Department of Psychiatry and Neuroscience Program, University of Illinois Chicago College of Medicine, Chicago, IL.

Tubulin is not only a building block of microtubules, but is a participant in G protein signaling. Tubulin binds tightly to the heterotrimeric G proteins, Gs, Giq and Gq, (Kd=100 nM) and activates those G-proteins in a receptor-independent manner, by direct transfer of GTP (transactivation). Under physiologic conditions, Gs only is not capable of transactivating tubulin, but Gs and Gqα increase the steady-state tubulin GTP hydrolysis activity and microtubule dynamicity. Disruption of Gs-tubulin interactions in COS, PC-12 and primary hippocampal neurons decreases process (neurite) outgrowth. Thus, there is a bidirecional physiologic interaction between Gs and tubulin in regulating cellular differentiation. Here, we show that Gsa differentially interacts with tubulin isotypes, preferentially associating with βIII and βII tubulin over the βI and βI tubulin isotypes; this reflects both affinity and isotype prevalence in mammalian brain. Moreover, we demonstrate that Gsa directly increases the intrinsic, single turnover, GTPase rate of βII and βIII tubulin dose-dependently with saturation kinetics. The Hill coefficient obtained was approximately 1.0, consistent with the predicted 1:1 stoichiometry of the tubulin-Gsa interaction. The maximal stimulation observed between the isotypes. The ability of the various tubulin isotypes to transfer GTP to Gsa is currently being determined. In summary, these results suggest a role for Gs in regulating tubulin function, regardless of isotype, thereby providing an interface for G protein-mediated regulation of the cytoskeleton. Moreover, Gs appears to differentially interact with tubulin isotypes. Eventually, this line of investigation could yield insight into the mechanistic significance for modified signal transduction in malignant cells, where tubulin isotype expression is altered. Further, these studies may have implications for the ability of G proteins to modify synaptic outgrowth in response to neurotransmitter.

Analysis of Mutants That Impair Turnaround of the IFT-Machinery in \textit{C. elegans} Sensory Cilia
M. C. Them\textsuperscript{2}, G. Ou\textsuperscript{2}, M. Keggi\textsuperscript{2}, M. Scholey\textsuperscript{1}, Section of Molecular and Cellular Biology, University of California, Davis, Davis, CA, \textsuperscript{2}Department of Biology, Kyushu University Graduate School, Fukuoka, Japan

Kinesin-II and OSM-3 motor proteins work cooperatively to build the sensory cilia in \textit{C. elegans} in a process termed anterograde IFT. Both motors reductantly build the initial segment of the cilium while OSM-3 alone forms the distal segment. Retrograde transport, driven by dynein, is necessary to recycle ciliary components and motors to the basal body. This process requires coordinated motor switching, cargo unloading, reorganization and turnaround of IFT components at the tip of both the initial and distal segments, which are poorly characterized events. We propose to use two ciliary mutants, which were isolated in a screen for dyf mutants, to dissect the process of IFT turnaround during ciliogenesis. Visualization of GFP-tagged IFT components has revealed that these mutants accumulate IFT particles at the tip of the initial segment, suggesting disrupted turnaround and, in addition, one of the mutants also exhibits retarded transport rates along the initial segment. We are using genetic and molecular approaches to identify the corresponding gene products of these mutants in order to improve our understanding of the mechanism of turnaround of the IFT machinery and to learn how mutations in one of the gene products alters both turnaround and rate of IFT.

Molecules Required for Sensory Signal Transduction Regulate Ciliary Structures in \textit{C. elegans}
S. Mukhopadhyay\textsuperscript{2}, P. Sengupta\textsuperscript{1}, Biology, Brandeis University, Waltham, MA.

Cilia and flagella are cellular organelles formed by evolutionarily conserved mechanisms requiring intraflagellar transport (IFT). IFT involves microtubule-based transport of axoneme precursors and membrane proteins via an anterograde and retrograde motors. In addition to mediating motility, cilia and flagella also act in sensory signaling, and some of the signal transduction complexes required for responses to the environment are localized to these organelles. Defects in signaling molecules involved in the phototransduction cascade, including rhodopsin and cyclic nucleotide-gated channels result in degeneration of rhodobes in flies and retinal degeneration in mice, respectively. The role of these signaling proteins and their interplay with IFT in regulating cilia structure and function is unclear. We are studying the role of genes coding for signaling proteins in regulating the structure and function of amphiob cilia in \textit{C. elegans}. It has previously been reported that alteration of the ODR-3 G α alpha protein subunit alters the cilia morphology of the AWA and AWC olfactory neurons (Roayaie et al., 1998). We found that gain-of-function mutations in \textit{odr-3} also result in shortening of the cilia of the AWA neurons. In addition, mutations in genes acting downstream of \textit{ODR-3} in sensory signal transduction such as the guanylyl cyclase \textit{odr-1} and the cyclic-nucleotide gated cation channel subunits \textit{tax-2} and \textit{tax-4} alter the structure of the AWA and AWC olfactory cilia. Eipstasis analyses suggest that similar to their roles in ophthalmic signal transduction, \textit{odr-1} and \textit{tax-2/4} act downstream of \textit{odr-3} to modulate ciliary structure. We also find that overexpression of chemoreceptor genes affects ciliary structure of AWA in a way similar to \textit{odr-1} mutants. The ciliary defects of \textit{odr-1/\textit{tax-2/4}} mutants are suppressed by mutations in the anterograde IFT motor Kinesin-II subunit \textit{klp-11}, suggesting that the alteration in cilia structures may be dependent on IFT.

Neuron-specific Modulation of Intraflagellar Transport in \textit{C. elegans}
S. Mukhopadhyay\textsuperscript{2}, H. Qin\textsuperscript{1}, Y. Lu\textsuperscript{2}, A. Ljuanju\textsuperscript{2}, J. Rosenbaum\textsuperscript{2}, S. Shaham\textsuperscript{1}, P. Sengupta\textsuperscript{1}, Biology, Brandeis University, Waltham, MA, \textsuperscript{2}Biology, Texas A&M University, College Station, TX, \textsuperscript{3}Developmental Genetics, Rockefeller University, New York, NY, \textsuperscript{4}Molecular and Cell Biology, Harvard University, Cambridge, MA, \textsuperscript{5}Molecular, Cellular and Developmental Biology, Yale University, New Haven, CT.

Most metazoan cell types contain primary cilia, which are sensory organelles. Sensory neurons such as photoreceptors and olfactory neurons exhibit distinct cell type-specific sensory ciliary morphologies. Intraflagellar transport (IFT) motors assemble and maintain all cilia by transporting ciliary axonemal precursors and membrane proteins, but it is not known how the IFT process is involved in the formation of neuron-specific ciliary specializations. A subset of \textit{C. elegans} chemosensory neurons exhibit specialized cell-specific sensory cilia, providing an excellent model in which to explore the mechanisms underlying the formation of distinct ciliary structures. In the \textit{C. elegans} channel chemosensory neurons, the anterograde kinesin-II and OSM-3 motors act cooperatively to form the middle segments, whereas OSM-3 alone acts in the distal segments. However, the functions of these motors in the more elaborate olfactory neuron cilia are not characterized. To characterize and compare IFT mechanisms in individual sensory cilia, we visualized IFT specifically in the cilia of two channel chemosensory neuron subtypes, ASH and ASI, and in the cilia of the olfactory AWA neurons. We find that, unlike in the channel cilia, the IFT motors Kinesin-II and OSM-3 function largely independently in each of the AWA cilia. We observe rare IFT events in the distal segments of the AWA cilia, and in contrast to the channel cilia distal segments, which require IFT components to function, the AWA distal segments appear to be formed in the absence of OSM-3. Thus, the distal AWA cilia segments may have mechanisms of formation distinct from IFT. Mutations in the \textit{fkh-2} forkhead domain transcription factor result in AWA-specific defects in dendritic and ciliary morphology, and \textit{fkh-2} mutants are suppressed by mutations in the \textit{odr-1}\textit{tax-2/4} subunit of IFT. Our results suggest that IFT mechanisms are regulated in a neuron-specific manner, and may underlie the generation of specific ciliary specializations.

The Molecular Control of IFT and Cilium Morphogenesis in \textit{C. elegans} Neurons
G. Ou\textsuperscript{2}, M. Keggi\textsuperscript{2}, J. Scholey\textsuperscript{1}, Center for Genetics and Development, Section of Molecular and Cellular Biology, University of California, Davis, Davis, CA, \textsuperscript{2}Department of Biology, Faculty of Sciences, Kyushu University Graduate School, Hakozaki, Higashi-ku, Fukuoka, Japan

Cilium biogenesis depends upon intraflagellar transport (IFT) motors which deliver ciliary precursors associated with IFT particles to the tip of the axoneme. In \textit{C. elegans}, two IFT-motors, kinesin-II and OSM-3 kinesin cooperate to form two sequential anterograde IFT pathways that build distinct parts of cilia. We previously identified three proteins that mediate the functional coordination of these motors. The Bardet-Biedl syndrome (BBS) ciliary disease proteins, BBS-\textit{s} and BBS-\textit{8} stabilize complexes of IFT-particles containing both IFT-motors, and a conserved ciliary protein, \textit{DFY-1}, is specifically required for OSM-3-kinesin to dock onto and move IFT-particles. To understand how the BBS proteins in ciliogenesis and diversity, we introduced markers of IFT and cilium morphology into a comprehensive collection of \textit{dyf}, \textit{che}, \textit{osm}, \textit{daf}, \textit{unc}, and \textit{mec} mutants and monitored IFT and mutant ciliary morphology. Our results suggest that: 1) the IFT-protein machinery is critical for ciliogenesis and its functional modulation leads to ciliary diversity; 2) neuronal ciliogenesis depends on proper transport along dendrites and proper formation and guidance of axons; and 3) proper cilium development relies on signals from environment and neighboring cells.
Mechanism of IFT-Particles in C. elegans Cilia by the Concerted Action of Kinesin-II and OSM-3 Motors

X. Pan,1 G. OU,1 G. Crevello-gak-Schloet,1 O. Blaauw,2 N. Endres,3 L. Yao, A. Mogilner,1 M. Lerous,3 R. Vale,1 J. Scholz,1 Center for Genetics and Development, Department of Molecular and Cell Biology, University of California, Davis, Davis, CA, 2Department of Molecular Biology and Biochemistry, Simon Fraser University, Burnaby, BC, Canada, 3Department of Cellular and Molecular Pharmacology, The Howard Hughes Medical Institute, University of California San Francisco, San Francisco, CA

The assembly and function of cilia on C. elegans neurons depends on the action of two kinesin-2 motors, heterotrimeric kinesin-II and homodimeric OSM-3-kinesin, which cooperate to move the same IFT-particles along microtubule (MT) doublets. Using competitive in vitro MT gliding assays, we show that purified kinesin-II and OSM-3 cooperate to generate movement similar to that seen along the cilium in the absence of any additional regulatory factors. Quantitative modeling suggests that this could reflect an “alternating action” mechanism in which the motors take turns to move along MTs, or “mechanical competition” in which the motors function in a concerted fashion to move along MTs with the slow motor exerting drag on the fast motor and vice versa.

In vivo transport assays performed in Bardet-Biedl syndrome protein and IFT-motor mutants favor a mechanical competition model for motor coordination, in which the IFT-motors exert a BBS protein-dependent tension on IFT-particles which controls the IFT-pathway that builds the cilium foundation. (X. Pan and G. Ou are equal contributors.)

Characterization of a Golgi-associated Intraflagellar Transport (IFT) Complex

J. A. Folliet, J. T. San Agustin, G. J. Pazour, Program in Molecular Medicine, University of Massachusetts Medical School, Worcester, MA

Most vertebrate cells have a primary cilium projecting from their surface. These structures are thought to be sensory organelles that monitor the extracellular environment. Severe defects in primary cilia lead to embryonic lethality while mild defects yield phenotypes ranging from cystic kidney disease to retinal degeneration. The ciliary cytoskeleton is assembled via intraflagellar transport (IFT) in which large particles are moved along ciliary microtubules by kinesin-II and dynein-2. How membrane proteins are delivered to the ciliary compartment is almost completely unknown. We recently showed that the IFT20 subunit of the IFT particle is unique in that it is found associated with the Golgi apparatus in addition to the normal ciliary localization (Folliet et al., Mol. Biol. Cell 2006). Strong reduction of IFT20 by RNAi blocks ciliary assembly while moderate reduction allows for ciliary assembly but reduces the amount of the membrane protein polycystin-2 localized to cilia. This suggests that IFT20 plays a role in directing membrane proteins from the Golgi apparatus to the ciliary compartment. To further understand IFT20 function, we partially purified an IFT complex, termed complex C, that contains IFT20 but is different from the two known IFT complexes. This >2 Mdal complex contains multiple proteins including a Golgi-associated protein called Trip11 or GMAP210. In mammalian cells and yeast, GMAP210 is required for transport of membrane proteins and in yeast and Drosophila, associated proteins play important roles in polarized secretion. We have identified a 226 residue fragment of GMAP210 that displaces IFT20 from the Golgi complex and stabilizes it in the cytoplasm. We are currently investigating the dominant negative properties of this fragment. In addition, we have generated knockout mice for both IFT20 and GMAP210 and are currently characterizing these animals to further our understanding of the role of these proteins in mammalian health and development.

An In Vitro System for Studying Neuronal Primary Cilia Function

N. F. Berber1, J. S. Lewis, C. C. Askwith,1 L. M. Bohm,1 K. Mykytyn1; 1Pharmacology, The Ohio State University, Columbus, OH, 2Neuroscience, The Ohio State University, Columbus, OH

Primary cilia are hair-like cellular appendages that are present on nearly all vertebrate cells and many cells in invertebrates. Primary cilia are now recognized as important sensory and signaling organelles. Although it has been known for more than forty years that neurons throughout the brain possess primary cilia, the function of neuronal cilia is unknown. Recent work has shown that specific G protein-coupled receptors (GPCRs), such as somatostatin receptor 3 (Sstr3) and serotonin receptor 6 (Htr6), localize to neuronal cilia. The finding that certain GPCRs localize to neuronal cilia suggests that cilia-mediated signaling may affect neuronal activity. In order to pursue this question we have developed a culture system for studying neuronal cilia. We show that hippocampal neurons cultured from newborn mice possess cilia upon which known ciliary proteins localize. We further show that GPCRs are functional at the ciliary membrane. These results suggest that neurons possess cilia-mediated GPCR signaling and that this system should be a valuable tool for elucidating the function of cilia in neurons.

Age-related Losses in Neuronal Cilia of Tg37799 Mice

D. Mahato, H. D. Schwarc, J. L. Fuchs, Biological Sciences, University of North Texas, Denton, TX

Primary cilia are characteristic of most vertebrate cell types, including neurons. Recent evidence shows that primary cilia are vital to vertebrate morphogenesis and organ function. The Tg37799 mouse, which was engineered as a model for studying polycystic kidney disease, was shown by Pazour and colleagues (2000) to have shortened primary renal cilia in association with the gene defect in IFT88, an intraflagellar transport protein. Subsequently, ciliary defects were implicated in the development of hydrocephalus and cysts in liver and pancreas. We found that primary cilia in adult Tg37799 mice were missing from neurons in some brain regions and were shortened in others (Fuchs & Schwarc, 2004). The present study found progressive postnatal decreases in the incidence and length of immunostained neuronal cilia in mutant compared with wildtype. In brain regions that retained a substantial number of cilia, wildtype cilia generally grew slightly in length from postnatal day 14 (P14) to P31, while mutant cilia decreased in length. Relative to wildtype, mutant cilia were about 39% shorter on P14 and 49% shorter on P31, while the percentage of neurons with identified cilia declined by 43% on P14 and 72% on P31. The results suggest that intraflagellar transport is critical for maintenance of primary neuronal cilia, and that there are age-related increases in cilia loss which might contribute to the progressive dysfunction typical of ciliary diseases. The regional and developmental differences in cilia loss might reflect differences in IFT88 expression, degree of ciliary defects on IFT88, and unfolding of the consequences of impaired intraflagellar transport.

Dual Regulation of Daam1-mediated Actin Assembly and Ciliogenesis by Dishevelled and RhoA

T. J. Park, S. Matti,1 J. B. Wallingford,1 B. L. Goode,2 Department of Molecular Cell and Developmental Biology, University of Texas, Austin, Austin, TX, 2Biology Department, Brandeis University, Waltham, MA

Dishevelled (Dvl) functions in the Wnt signaling pathway and provides a key point of control in planar cell polarity. Recently, we showed that Dvl-GFP localizes to the apical surface of ciliated epithelial cells, where a dense actin mat governs the orientation of ciliary microtubules. Here, we investigate the role of a downstream target of Dvl, Daam1, which is a formin protein and thereby is predicted to nucleate actin assembly. Daam1-GFP is also enriched apically in ciliated cells. A purified C-terminal fragment of Daam1 directly nucleates actin polymerization, but full-length Daam1 is autoinhibited via interactions of its N- and C-termini. Daam1 autoinhibition is partially relieved by RhoA and by a C-terminal fragment of Dvl containing its PDZ and DEP domains. This suggests that RhoA and Dvl may converge on Daam1 to induce expression. In contrast to the PDZ/DEP fragment of Dvl, a longer fragment that includes its C-terminus fails to activate Daam1, suggesting a novel regulatory role for this sequence. Expression of this conserved C-terminal portion of Dvl (Xdsh-C1), lacking PDZ and DEP domains, led to disrupted assembly of the apical actin mat, decreased ciliary microtubules assembly below and parallel to the apical surface, and a failure of cilia to project apically from the cell surface. Further, ciliogenesis defects caused by expression of Xdsh-C1 were accompanied by a failure of gamma-tubulin to localize tightly at the apical cell surface. Using a fluorescent sensor to assess Rho activation in vivo, we find that Rho is strongly activated apically in ciliated cells in a region corresponding to the apical actin mat. This activation of RhoA is eliminated by expression of Xdsh-C1, though localization of Rho is unaffected. These data support a model in which joint regulation of Daam1-mediated actin assembly by Dvl and RhoA plays an essential role in ciliogenesis.

Primary Cilia: Mechanosensory Organelles in Bone

C. T. Anderson,1 A. M. Malone,1 P. Tummala,2 R. C. Jacobs,2 T. Stearns 1; 1Biological Sciences, Stanford University, Stanford, CA, 2Mechanical Engineering, Stanford University, Stanford, CA

Primary cilia are microtubule-based protrusions that extend from the surface of most mammalian cell types. Primary cilia mediate calcium influx in response to fluid flow in kidney cells, but their function in many other cell types is unknown. Given that bone responds to mechanical loading with increased bone growth and that bone cells display increases in intracellular calcium, prostaglandin E2 release, and expression of osteogenic genes such as osteopontin in response to fluid flow, we asked whether we could detect primary cilia in bone tissue and bone-derived cell lines, and whether loss of primary cilia in cultured bone cells abrogates flow response. By staining mouse tibia cryosections for acetylated alpha-tubulin, we detected primary cilia in both osteoblasts and osteocytes, and we likewise detected primary cilia in 55% and 65% of the MC3T3-E1 osteoblast-like and MLO-Y4 osteocyte-like cell lines, respectively. After removal of...
primary cilia by chloride hydrate treatment or prevention of primary cilia formation by RNAi targeting the ciliary protein polars. MC3T3-E1 cells still exhibited increased intracellular calcium in response to flow, but did not exhibit increased prostaglandin E2 release or osteopontin expression after flow. These results indicate that primary cilia act as mechano sensors in bone cells, but that they may do so by a mechanism that is distinct from that of kidney cells.

Intraflagellar Transport Is Essential for Endochondral Bone Formation

C. J. Haycraft, Q. Zhang, B. Song, R. Serra, B. K. Yoder, Department of Cell Biology, University of Alabama at Birmingham, Birmingham, AL, 2Department of Pediatrics, University of Iowa, Iowa City, IA, 3Department of Pathology, University of Alabama at Birmingham, Birmingham, AL.

Patternning of the mammalian limb requires the complex interaction of at least three signaling centers, the AER, the overlying ectoderm, and the ZPA. Anterior-posterior patterning is regulated by secretion of Shh from cells in the ZPA to inhibit the repressor activities of the transcription factor Gli3. The resulting gradient of Gli3 activator to repressor function imposes a pentadactyl restraint on the developing autopod. Most cells throughout the mesenchyme and ectoderm of the developing limb express a primary cilium which has been shown to be essential for proper Shh signal transduction and Gli3 repressor formation. To bypass the early lethality associated with congenital loss of cilia as well as determine which cell populations in the developing limb require a primary cilium for proper pattern formation, we used mice expressing CRE recombinase under control of the msh2 promoter (msh2Cre), no overt defects in limb patterning or outgrowth are observed. In contrast, deletion of cilia from cells in the mesenchyme using prelcre transgene mice results in extensive polydactyly and loss of Shh signal transduction. Analysis of the role of primary cilia during endochondral bone formation has been hindered by the lethality of congenic ift mutant mice prior to the formation of the skeletal elements. In addition to defects in digit patterning, the limbs of prelcre conditional mutants are severely shortened and endochondral bone formation is altered, possibly through disruption of Ihh signaling. Perichondrial architecture adjacent to the diaphysis of the skeletal elements is altered and bone collar development is disrupted. In agreement with a predicted requirement for cilia in Ihh signaling, both Pthl1 and Gli3 expression are lost in the cartilage and perichondral cells of the developing bones.

Primary Role for Centrosome Proteins in Cilia Formation and Cilia-associated Disorders

B. Delaval, L. Covoss-Barberis, N. Lawson, S. Dossay, Program in Molecular Medicine, UMASS Medical School, Worcester, MA, Program in Gene Function and Expression, UMASS Medical School, Worcester, MA, Program in Molecular Medicine, UMASS Medical School, Worcester, MA, Program in Gene Function and Expression, UMASS Medical School, Worcester, MA.

Cilia are microtubule structures that assemble from the mother centriole of the centrosome. The centrosome contributes to spindle organization, cell cycle progression and cilia assembly. Cilia are microtubule structures that assemble from the mother centriole of the centrosome. Previous studies have shown that the centrosome protein pericentrin plays a role in the assembly/maintenance of centrosomes in human cells. Another study has shown that a Drosophila protein that shares homology with human pericentrin and AKAP450 is also essential for cilia and flagella formation in vivo. To address the role of centrosome proteins in cilia assembly, we have begun a comprehensive analysis of centrosome proteins in human cells and zebrafish embryos. We first examined primary cilia in diploid human epithelial cells (RPE-1). We found that depletion of 10/11 centrosome proteins by RNA interference perturbed primary cilium assembly, demonstrating that primary cilium formation is a common centrosome proteins function. To characterize the role of centrosome proteins in cilia formation in vivo, we used a morpholino-mediated knockdown approach in Zebrafish (Danio rerio). We identified several Zebrafish centrosome genes homologous to vertebrate genes and they are currently being targeted for depletion. Here, we focus on results from centrin 2 (Cetn2) depletion. Essentially all defects observed in Cetn2 depleted embryos phenocopied those observed for cilia genes such as polycystins and intraflagellar transport proteins. For example, loss of Cetn2 prevented formation of cilia in the olfactory placode and induced formation of cysts in the kidney, suggesting polycystic kidney disease. Other cilia-related defects included smaller eyes, hydrocephaly, cardiac oedema and increased body surface. Consistent with these defects, Cetn2 mrnas and mRNAs of other centrosome proteins were localized to organs that were affected by centrin depletion (e.g. promephric duct, olfactory organ, spinal cord). These and other results suggest that centrosome proteins have a primary role in cilia formation and cilia-associated disorders.

EB1 Is Required for Primary Cilia Assembly in Fibroblasts

J. M. Schroder, L. Schneider, S. T. Christensen, L. B. Pedersen, Molecular Biology and Physiology, University of Copenhagen, Copenhagen, Denmark

EB1 is a small, evolutionarily conserved microtubule (MT)-associated protein involved in regulating MT dynamics. EB1 associates preferentially with MT plus ends and appears to play a major role in regulating/tethering of other MT-associates proteins to the MT plus end. EB1 also localizes to centrosomes, is necessary for mitotic spindle elongation and linking of MTs to kinetochores and the cell cortex during mitosis, and has also been implicated in MT stabilization in migrating fibroblasts. We previously showed that EB1 localizes to the flagellar tip and proximal region of the basal bodies in Chlamydomonas, and obtained evidence suggesting a potential role for EB1 in regulating intraflagellar transport (IFT; Pedersen et al., Curr. Biol. 2003). However, the exact function of EB1 in the cilium/flagellum is unknown. To analyze the function of EB1 in the cilium/flagellum we depleted EB1 from NIH3T3 fibroblasts using siRNA, and analyzed the effect of EB1 depletion on primary cilium formation in growth-arrested cells using immunofluorescence microscopy. Strikingly, in three separate experiments, only 37.13±2.30% of EB1-depleted cells (n=293) became ciliated during growth arrest compared to 65.37%±2.15% ciliated cells in mock-transfected controls (n=324). Thus depletion of EB1 causes a ca. 50% reduction in the efficiency of primary cilium assembly in fibroblasts. Since EB1 localizes to the ciliary/flagellar tip as well as to basal bodies, we are currently trying to determine whether the effect of EB1 depletion on primary cilium assembly results from defective assembly of the nascent cilium itself or is due to a defect in basal body assembly. Non-motile (9+0) Primary Cilia in Cell Culture Exhibited Constrained Motion

K. M. Yasatii, T. Ursei, B. Bettencourt-Dias, J. Lippincott-Schwartz, C. M. Ott, Physiology Course 2006, Marine Biological Laboratory, Woods Hole, MA.

The primary cilium is a common structural feature found on many mammalian cells in vivo, shown to be important for mechanosensation, chemosensation, and signaling. This organelle protrudes 5 to 55 μm from the surface of the cell and is composed of a circular bundle of 9 microtubule doublets (9+0) enveloped in plasma membrane. This cilium does not have two internal microtubules in contrast to motile (9+2) cilia and flagella, which contain two additional central microtubules. Hence, primary cilia were long considered non-motile. Recently, movement of primary cilia was observed in the embryonic node (nodal cilia). This rather rapid movement (~50Hz) is thought to be essential for left-right symmetry breaking in early embryonic development. Using live-imaging of fluorescent markers we observe constrained circular motion of primary cilia in cultured cells. We characterized this motion by tracking the distal end of the primary cilium. Strikingly, in three separate experiments, only 37.13±2.30% of the EB1-depleted cells (n=293) became ciliated during growth arrest compared to 65.37%±2.15% ciliated cells in mock-transfected controls (n=324). Thus depletion of EB1 causes a ca. 50% reduction in the efficiency of primary cilium assembly in fibroblasts. Since EB1 localizes to the ciliary/flagellar tip as well as to basal bodies, we are currently trying to determine whether the effect of EB1 depletion on primary cilium assembly results from defective assembly of the nascent cilium itself or is due to a defect in basal body assembly. Supported by grants from the Danish Natural Science Research Council (272-05-0411) and The Novo Nordisk Foundation to LBP.

Imaging Transport Properties of Smoothened in the Membrane of the Primary Cilium

Smoothened is an integral membrane protein essential for the Hedgehog signaling pathway. In the absence of Hedgehog, Smoothened signaling is inhibited by the Hedgehog receptor Patched. Recently, localization of Smoothened to the primary cilium was shown to be essential for Sonic Hedgehog signal transduction to vertebrates. The nature of Smoothened movement within the cilium is unclear; however it will likely be important for signal transduction. Movement of select membrane proteins in the sensory cilium in C. elegans was shown to exhibit bidirectional transport. We utilized oblique laser illumination fluorescence microscopy and fluorescence recovery after photobleaching (FRAP) combined with kinetic modeling to explore the possibility of diffusion versus directed movement of Smoothened within the sensory cilium of the vertebrate. We observed bidirectional transport of Smoothened complexes along the length of the primary cilium. FRAP data were compared to a variety of models and the best agreement was obtained with a model of directed intracilial transport. Additionally, both experimental methods suggest the transport of Smoothened can pause en route to the base or tip of the cilium. Future studies will be required to determine how Smoothened transport within the primary cilium affects hedgehog signal transduction.
Mutations in the NIMA-related Kinase Defective in the jck Model of Polycystic Kidney Disease Cause Altered Ciliary and Centrosomal Localization but Do Not Affect Ciliogenesis

M. L. Trapp, D. K. Manning, D. R. Beier, L. M. Quarmby; Molecular Biology and Biochemistry, Simon Fraser University, Burnaby, BC, Canada; 'Genesics Division, Brigham and Women's Hospital, Harvard Medical School, Boston, MA

Cystic kidney diseases are caused by mutations in a diverse array of genes, including Nek8, a NIMA-related kinase. Originally characterized in the jck (juvenile cystic kidney) mouse model of polycystic kidney disease (Liu S, Lu W, Obara T, Kuida S, Lehoczky J, Dewar K, Drummond IA, and Beier DR. 2002. Development. 129, 5839-5846), Nek8 has been found to localize to the primary cilia of mouse epithelial cells (Mahgoub MR, Trapp ML, and Quarmby LM. 2005. J. Am. Soc. Nephrol. 16, 3485-3489), similar to other cytoplasmic proteins. The cilia on kidney epithelia are key for normal mechano-sensation and signal transduction, as mice that lack cilia develop cystic kidneys. To examine how mutated Nek8 can alter functioning of the cilia and cause intracellular defects, GFP-tagged mouse wild type, kinase-deficient (jck), and jck (G448V) Nek8 were overexpressed in mouse inner medullary collecting duct (IMCD-3) cells. GFP-Nek8 was found to localize to the cytoplasm, cilia, and centrosomes, while GFP-tagged kinase-deficient and jck Nek8 showed different ciliary and centrosomal localization patterns than wild type. Because expression levels also affect localization, we confirmed this difference by analysis of IMCD-3 co-transfected with myc-tagged wild type Nek8 and GFP-mutant Nek8. RNAi knockdown and overexpression of GFP-tagged Nek8 did not affect the percentage of ciliated cells, and neither GFP-K33M nor GFP-jck Nek8 affected overall ciliary assembly. We also analyzed tetracycline-inducible Nek8 knockdown IMCD-3 cells and mutant Nek8 in cells lacking endogenous protein. Our results support the conclusion that polycystic kidney disease caused by the jck mutation of Nek8 is the consequence of a defect in signaling rather than ciliogenesis.

Ciliogenesis and Fibrocytin Expression in the PCK-CCL, a Cholangiocyte Cell Line Derived from an Animal Model of ARPKD, the PCK Rat

T. V. Masyuk, B. Q. Huang, A. I. Masyuk, N. F. Larrusso; Internal Medicine, Mayo Clinic College of Medicine, Rochester, MN

We showed that fibrocytic (FC), the protein product of PKHD1, the gene mutated in Autosomal Recessive Polycystic Kidney Disease (ARPKD), is expressed in normal cholangiocyte cilia but absent from malformed cilia of the PCK rat. We also reported establishment of ciliogenesis model using a normal rat cholangiocyte cell line (NRC) to study FC expression under normal conditions. Our OBJECTIVES here were to develop a ciliogenesis model in PCK-CCL and to examine FC expression under pathological conditions. METHODS: Ciliogenesis was examined by scanning and confocal microscopy and FC expression by confocal microscopy. RESULTS: In sub-confluent and post-confluent day 0 PCK-CCL and NRCs, cilia were absent. At day 3 post-confluence, 35% of NRCs possessed cilia ~1.8um in length. In contrast, in the PCK-CCL, cilia were shorter (1.1um; p<0.05) and present in 10% of cells. At day 7 post-confluence, 86% of NRCs had cilia ~1.8um in length, in the PCK-CCL, cilia were present in 57% of cells and 3.3-fold shorter (2.59+/-0.86um, p<0.05). There were also structural abnormalities with bulbus elongation on the ciliary axoneme. By RT-PCR, an 800bp Pkhd1 product was amplified in NRCs; in the PCK-CCL, the amplicon was ~630bp reflecting the IVS35-2A- T mutation. In NRCs, in the absence of FC, cilia were found in cytoplasm; in NRCs with developed cilia, FC was localized intracellularly, in the basal body and cilia. In PCK-CCL, at all stages of ciliogenesis, FC was expressed in the cytoplasm and nucleus and never in cilia. CONCLUSIONS: We developed a model of ciliogenesis in a cholangiocyte cell line derived from the PCK rat. In PCK-CCL, structural (malformed cilia) and functional (no FC in cilia) abnormalities of cilia are consistent with those seen in vivo in the PCK rat. This model will be useful in elucidating the role of FC in hepatic cyst formation.

Adenyl Cyclases Are Localized to Cholangiocyte Primary Cilia and Are Involved in Chemosensory Ciliary Functions

A. I. Masyuk, B. Q. Huang, A. J. Stroope, P. L. Splinter, N. F. Larrusso; Internal Medicine, Mayo Medical School, Clinic and Foundation, Rochester, MN

We previously reported that cholangiocyte cilia express polycystin-1, polycystin-2, and adenyl cyclase 6 (AC6) which are involved in mechanosensory ciliary functions (Masyuk et al., Gastroenterology, 2006). Given that AC6 is an enzyme whose activity is modulated by different agonists via G protein-coupled receptors, its expression on cholangiocyte cilia suggests possible chemosensory functions for these organelles. The potential agonists present in bile in physiological concentrations that may affect adenyl cyclases (ACs) are ATP and other nucleotides. Since in many cell types nucleotides affect cAMP signaling via the G protein-coupled receptors, P2Y11-14, we tested the hypothesis that biliary ATP induces cAMP signaling in cholangiocytes via P2Y11 and ACs expressed in cilia. Immunofluorescence confocal and immunogold transmission electron microscopy of isolated rat intraphaeric bile duct units (BDUs) were used to assess expression of ACs and P2Y11 in cholangiocyte cilia. A microperfused BDU model was used for functional studies. BDUs were perfused through their lumen with ATP-gammaS (100mM), a specific agonist of P2Y11, and cAMP levels in cholangiocytes measured by a fluorescence assay. P2Y11 and AC6 are both expressed on the microvilli and cilia of the cholangiocyte apical plasma membrane. Luminar perfusion of BDUs with ATP-gammaS resulted in a 2.6-fold increase in cAMP levels in cholangiocytes. The ATP-gammaS-induced cAMP increase was abolished by chlorid hydrate (a compound that removes cilia), by suramin (a specific antagonist of P2Y11) and by siRNAs to AC6. Taken together, these data suggest that cholangiocyte cilia have chemosensory functions in which the key players are nucleotides, P2Y11, and AC6.

Rho Kinase and Cortical Myosin II Control Centriole Migration during Ciliogenesis of Primary Cilia

H. Dawe, K. Gull; Sir William Dunn School of Pathology, University of Oxford, Oxford, United Kingdom

Primary cilia are sensory organelles that function as highly variable cilia type throughout the body. The migration of the mature centriole from a juxtanuclear position to the apical membrane, where it subtends a primary cilium, is a critical early stage in ciliogenesis. However, the molecular mechanisms that control this process remain obscure. We have used a combination of drug studies and siRNA to investigate factors controlling centriole positioning during primary ciliary formation. In this study we show that ROCK I signalling to cortical myosin II is required for centriole migration. Drug- or siRNA-mediated disruption of ROCK I or myosin II prevents centriole migration to the apical membrane and subsequent axoneme extension. Instead, centrioles remain in a pericentriolar position. Inhibition of ROCK I and myosin II had no effect on cilia position in cells with pre-existing cilia. This implies that neither ROCK I nor myosin II is required for maintenance of centriole basal body position once centriole migration is complete. Immobilisation of the cell cortex with tetravalent lectins also prevents centriole migration and ciliation, suggesting that myosin II activity is required within the cortex and that centriole migration can be achieved by cortical contraction.

NHE1 Is Encoded by a Growth Arrest Specific (gas) Gene and Its Activity Is Associated with PDGFrα Signaling in the Primary Cilium During Migration in Quiescent Fibroblasts

L. Schneider, C. M. Stock, E. K. Hoffmann, P. Satir, A. Schwab, S. F. Pedersen, S. T. Christensen; 1Department of Biochemistry, The August Krogh Institute, University of Copenhagen, Copenhagen, Denmark, 2Institute for Physiologie, Muenster, Germany, 3Department of Anatomy and Structural Biology, Albert Einstein College of Medicine Yeshiva University, Bronx, NY

The ubiquitous plasma membrane Na+/H+ exchanger, NHE1, is found in essentially all cell types, and is involved in multiple cellular processes, including the control of cell volume and cellular pH (see Pedersen, SF 2006 Physiog Arch 452(2):249-59). Further, NHE1 has been assigned important roles in the control of cell migration and specifically in the increased migratory and invasive properties of tumor cells (Schwab, A. 2001 Am J Phsiol Renal Physiol. 280:F739-47; Cardone, RA et al. 2005 Nat Rev Cancer 5:786-95). Here we investigated a possible connection between NHE1-mediated effects on cell migration and the growth arrest specific (gas) protein receptor, PDGFR-alpha, which specifically localizes to primary cilia during growth arrest and is uniquely activated in the cilium upon stimulation with PDGF-AA in mouse embryonic fibroblasts (MEFs) (Schneider L. et al. 2005 Curr Biol 25:1861-6). In Tg737"""" mutant MEFs, which show defects in ciliary assembly, PDGFR-alpha is not up-regulated, PDGFR-AA signaling is blocked, and signaling cascades leading to cell cycle entrance are inhibited. We here show that mRNA and protein levels of NHE1 were up-regulated during growth arrest in NIH3T3 cells and primary cultures of both wt and Tg737"""" mutant MEFs, and that these levels decreased upon cell cycle entrance, identifying the exchanger as a gas protein, independent of ciliary formation. Wound healing assays on wt MEFs revealed that inhibition of NHE1 activity by EIPA reduced PDGFR-AA mediated cell migration speed and translocation, and this inhibition was markedly reduced in Tg737"""" mutant MEFs. Our results indicate that NHE1 activity is up-regulated during quiescence and that PDGFR-alpha signaling in the primary cilium is connected to NHE1-dependent mechanisms during cell migration in growth arrested cells. Further, our results support the idea that NHE1 activity may be a critical event in the physiological response to PDGFR-alpha activation.

Contribution of Intraflagellar Transport in Expression and Trafficking of Flagellar Proteins

S. Absalon, G. Trouillas, P. Bastin; 1Pasteur Institute, Paris, France, 2MNHN, Paris, France
Cilia and flagella are present in most eukaryotic organisms and their structure is well conserved throughout evolution. Flagellum biogenesis is a fascinating process by which more than 300 proteins need to be synthesized and assembled in a complex structure at a defined localization and at a precise time of the cell cycle. Trypanosoma brucei, an unflagellated protzoan responsible for sleeping sickness in Africa, is a great model system to study this process, with the particularity to maintain its old flagellum during cell replication. Trypanosomenes can easily be grown and transformed in culture. By genome compation, we have shown that the majority of genes related in construction and function of flagellum are conserved. We have analyzed 12 candidate genes involved in Intraflagellar Transport (IFT), process conserved in ciliated organisms and required for assembly and maintenance of the organelle) using inducible RNAi. After silencing, cells exhibiting a shorter or no flagellum show down regulation of flagellar proteins. We demonstrate that this process depends on a post-transcriptional mechanism (without any influence on RNA stability or processing) whose regulatory elements are present in untranslated regions. This strongly suggests a new function for IFT in control of expression of flagellar genes. To evaluate trafficking of flagellar proteins, we have constructed a fusion with the axonomal component PF16 and a fluorescent tracer called Timer (which is able to change from green to red over time). We have monitored the turn-over and trafficking of this fusion protein in different contexts (wild type cells, IFT or motility mutants). These experiments allowed us to evaluate the importance of flagellum for different stages of the trypanosome cell cycle, in particular the process of basal body migration. Our data show that trypanosomenes use their flagellum to position their basal bodies.

Inositol Hexakisphosphate Production Is Required for Ciliary Function and Maintenance

B. Sarmah, V. P. Winfrey, G. E. Olson, B. Appel, R. S. Wente; 1Cell and Developmental Biology, Vanderbilt University Medical Center, Nashville, TN, 2Biological Sciences, Vanderbilt University, Nashville, TN

Cilia are motile sensory organelles that project from cells as a membranous extension. The microtubule structural core of a cilium is assembled from a basal body by a process called intraflagellar transport (IFT). Here, we report that the enzyme inositol 1,3,4,5,6-pentakisphosphate (IP$_6$) 2-kinase (Ipk1), responsible for conversion of IP$_6$ to inositol hexakisphosphate (IP$_7$), has a conserved ciliary role. Earlier, we reported that Ipk1 activity plays a critical role in the establishment of left-right (LR) asymmetry in zebrafish, mediating a left-biased calcium flux in cells enveloping the Kupffer’s vesicle (KV), a transient ciliated structure essential for the LR asymmetry determination (Sarmah et al., Dev. Cell 9, 133-145, 2005). We now find that reduction in Ipk1 level perturbs ciliary beating in the KV. In contrast to the ventral couterclockwise beating observed in the wild-type embryos, cilia in the Ipk1 depleted embryos quiver in a vibration-like motion devoid of counter-clockwise rotation. In addition, depletion of Ipk1 level shortens cilia length in multiple organs including the KV. Ipk1 depletion also causes distortion of pronephric tubules, a pathology often associated with dysfunctional cilia. Strikingly, Ipk1 is enriched in centrosomes and basal bodies, but not present in the ciliary axoneme. Reducing Ipk1 activity does not alter ciliary axonomal structures. Ipk1 depletion, however, perturbs retrograde melanosome transport in pigment cells indicating that Ipk1 activity might mediate general organelle transport. IP$_6$ may act as a cofactor for motor protein complexes in IFT. Thus, we propose that Ipk1 constitutes a motor component of the basal body facilitating IFT assembly and plays a key role in ciliogenesis. This is the first report of a role for soluble inositol polyphosphate production in ciliary function. This work may facilitate our understanding of the link between ciliary function and cellular signaling, and impact studies of disease and pathology related to dysfunctional cilia.

A Novel Rho Kinase Is Required for Normal Cilia-driven Nodal Flow and Left-Right Polarization in Zebrafish

J. D. Amack, H. J. Yost; Huntsman Cancer Institute, University of Utah, Salt Lake City, UT

A specialized group of ciliated cells--first identified in the mouse embryonic node--generate a directional fluid flow (termed 'nodal flow') that is required for normal left-right (LR) patterning of internal organs. As seen in the mouse node, we have observed cilia-driven nodal flow in zebrafish embryos in a structure called Kupffer’s vesicle (KV). Humans with ciliary defects often have organ laterality defects. This suggests cilia play a conserved role in LR development, but the mechanism(s) by which nodal flow translates into LR signals remain unclear. To better understand nodal flow, we are using zebrafish to identify molecular components that control form and function of ciliated ‘node’ cells. We report a novel Rho kinase gene--likely a paralog of zebrafish rho kinase 2 (rock2)–that is expressed in ciliated KV cells and required for nodal flow and normal organ laterality. Anti-sense morpholinos (MO) that target either translation or splicing of this rock2-related (rock2r) mRNA induce convergent extension defects and perturb LR asymmetries in the heart, gut and brain. MO knockdown of rock2r disrupts left-sided expression of the nodal-related gene southpaw—the earliest marker of LR asymmetry. Nodal flow inside KV is upstream of normal asymmetric southpaw expression. Immunostaining indicated that KV morphology and ciliogenesis are unaffected in rock2r morphants. However, videomicroscopy of fluorescent beads injected into KV revealed nodal flow is severely compromised in morphant embryos, thus providing an explanation for LR polarity defects. These studies link Rho kinase signaling to LR axis determination, specifically at the step of nodal flow. This is the first example of a non-ciliary component that affects nodal flow. Nodal flow may depend on Rho kinase-mediated cytoskeletal arrangements within node cells, or alternatively, node cells may require a particular alignment established by the planar cell polarity pathway, in which Rho kinases have been implicated.

Environmental Cues and G Protein Signaling Regulate Intraflagellar Transport of Ciliary Signaling Molecules

J. Burghoono, M. Dekkers, S. Rademakers, G. Jansen; Cell Biology, Erasmus MC, Rotterdam, The Netherlands

Intraflagellar transport (IFT) plays a critical role in trafficking structural components and signaling molecules in cilia. Recent studies suggest that regulation of IFT allows plasticity of the cilium structure and regulation of the presence of specific signaling molecules in the cilium (Ou et al., 2005; Pan et al., 2004; Wang et al., 2006). However, not much is known about the molecular mechanisms of this regulation. We study the regulation of IFT by G protein signaling in the cilium of the nematode Caenorhabditis elegans. We were intrigued by the fact that expression of a dominant active Gt protein, gpa-3QL, in the sensory neurons affects the uptake of fluorescent dyes into these neurons, a process called dye filling (Zwaal et al., 1997). Dye filling requires intact cilia and mutations in genes that affect IFT often cause dye filling defects. However, gpa-3QL does not affect the localization of IFT particles in the cilia middle or distal segments. Interestingly, we found that gpa-3QL strongly reduces entry into the cilia distal segments of the Go proteins GPA-4 and GPA-15. We show that in wild type animals anterograde transport of GPA-4 and GPA-15 is mediated by both, La Jolla, CA, 1Department of Biological Sciences, Vanderbilt University, Nashville, TN, 2Department of Neurobiology, Yale University, New Haven, CT, 3Interdepartmental Neuroscience Program, Yale University, New Haven, CT

Dynamic rearrangements of the filamentous (F-) actin cytoskeleton power cell migration. Actin polymerization drives leading edge protrusion, while actomyosin contractility generates traction forces required for cell body translocation. The extent to which cell migration is driven by forces derived from actin polymerization versus actomyosin contractility is a major unresolved issue. Abuellion (Abh) family kinases mediate signaling from adhesion and growth factor receptors to coordinate changes in cytoskeleton structure. We showed previously that the Abh-related gene (Arg) nonreceptor tyrosine kinase promotes dynamic F-actin-rich cell edge protrusions in fibroblasts during adhesion to and spreading on fibronectin-coated surfaces. Here we demonstrate a second major cellular role for Arg as an attenuator of cell contractility during fibroblast migration on fibronectin. arg$^-$$^-$ fibroblasts have more prominent F-actin stress fibers and focal adhesions and are more contractile than wild type fibroblasts. Arg re-expression in arg$^-$$^-$ cells reduces stress fibers and focal adhesions through two distinct mechanisms: Arg kinase activity acts through the RhoA inhibitor p190RhoGAP to attenuate stress fiber formation, while Arg inhibits focal adhesions via a kinase-independent mechanism. Using Arg mutants that separate these functions, we show that Arg reduces cell contractility by inhibiting stress fibers, but not by inhibiting focal adhesions. arg$^-$$^-$ cells migrate aberrantly, frequently moving in large steps as they suddenly detach or tear at their trailing edge. Despite these irregular movements, arg$^-$$^-$ cells migrate with faster average speeds than wild type or Arg-re-expressing arg$^+$ cells. Quantitative migration analysis of arg$^-$$^-$ cells reconstituted with Arg and Arg mutants demonstrates that Arg inhibits cell migration by attenuating cell contractility and regulating its coupling to adhesion sites. Our findings reveal that the coupling of actomyosin-based contractility with adhesion is the primary driving force for fibroblast migration on adhesive surfaces.

Leading edge protrusion in the amoeboid sperm of *Ascaris* saum is driven by the localized assembly of the MSP cytoskeleton in the same way that actin assembly powers protrusion in other types of crawling cell. Reconstitution of this process in vitro led to the identification of two accessory proteins required for MSP polymerization: a membrane-associated tyrosine phosphoprotein, MPOP, that orchestrates cytoskeletal assembly and a cytosolic component, MFP2, that governs the rate of protrusion. Here, we identified a 34 kDa cystic protein (p34) that links the activities of MPOP and MFP2 and is also required for motility. MSP polymerization was abolished in sperm extracts immunodepleted of p34 but restored when purified p34 was added back. Amino acid sequence and kinase activity analysis showed that p34 is a member of the casein kinase 1 family of ser/thr protein kinases. MPOP and p34 co-migrate by native gel electrophoresis, co-immunoprecipitate, and co-localize by immunofluorescence indicating that MPOP binds to and recruits p34 to the membrane surface. This process depends on phosphorylation of MPOP. p34, in turn, phosphorylates MFP2 on threonine residues and phosphor-MFP2 incorporates into the cytoskeleton. Beads coated with p34 assembly a surrounding cloud of MSP filaments when incubated in p34-depleted sperm extract. This bead-associated assembly requires MPOP released from membranes by detergent lysis suggesting that MPOP not only recruits but also activated the kinase activity of p34 thereby focusing MSP polymerization at the membrane and minimizing nonproductive filament formation elsewhere in the cell. Supported by NIH Grant R37 GM29994.

**Mechanism of MSP-based Cell Body Retraction in the Amoeboid Sperm of Nematodes**

C. Shimabukuro,1 K. Yi,1 M. Stewart,1 T. M. Roberts;1 Florida State University, Tallahassee, FL, 2MRC Laboratory of Molecular Biology, Cambridge, United Kingdom

Cell body retraction in the amoeboid sperm *Ascaris* saum is generated by disassembly and rearrangement of the MSP cytoskeleton, without the involvement of conventional motors (Miao et al. 2003. Science 302:1405). Reconstitution of retraction in vitro, whereby fibers comprised of columnar meshworks of MSP filaments that assemble behind membrane vesicles derived from the lamelloidal leading edge, can be induced to shorten has enabled us to explore the biochemical and biophysical basis of retraction. We found that fiber retraction triggered by YOP, a protein tyrosine phosphatase requires a cytosolic co-factor. This co-factor requirement can be bypassed by treatment of fibers with PP1ase, a ser/thr phosphatase. Moreover, YOP-induced retraction is blocked by calyculin A, a ser/thr phosphatase inhibitor. Thus, retraction appears to be initiated by sequential protein phosphatase activity in which a tyrosine phosphatase acts upstream of a ser/thr phosphatase. To study the mechanism of phosphatase-induced retraction mechanism, we grew fibers in the presence of Alexa 488-MSP and examined filament dynamics during retraction by fluorescence recovery after photobleaching. However, we were unable to detect large-scale rearrangement of the filaments in shortening fibers by this method. We did find that retraction was significantly reduced in segments of fibers grown with an MSP mutant (D83R). This mutant produces short filaments that pack tightly within fibers but does not affect the rate of filament disassembly. Thus, retraction appears to be modulated by filament length, packaging density, or both. Supported by NIH R37GM29994.

**Endocytosis in Neuronal Migration**

J. C. Shieh,1 B. T. Schaar,2 S. K. McConnell;2 Neurosciences Program, Stanford University, Stanford, CA, 2Biological Sciences, Stanford University, Stanford, CA

Neuronal migration is a crucial aspect of mammalian brain development and its disruption can lead to forms of mental retardation and epilepsy in humans. Unlike other migratory cells, neurons migrate in a saltatory manner. The movement of migrating neurons is characterized by morphologically distinct steps: extension of a single leading process ahead of the stationary cell soma, flattened and exhibit multiple protrusive structures, like lamellipodia and filopodia, all around the cell periphery. Previous studies have shown that human primary schwannoma cells contain a cloud of MSP filaments when incubated in p34-depleted sperm extract. This bead-associated assembly requires MPOP released from membranes by detergent lysis suggesting that MPOP not only recruits but also activated the kinase activity of p34 thereby focusing MSP polymerization at the membrane and minimizing nonproductive filament formation elsewhere in the cell. Supported by NIH Grant R37 GM29994.

**Endocytosis in Neuronal Migration**

C. Bach,1 J. Zhong,1 P. W. Gunning,1 G. M. O'Neill1,2;1Oncology Research Unit, The Children's Hospital at Westmead, NSW, Australia, 2Discipline of Paediatrics and Child Health, The University of Sydney, Sydney, Australia

Two core components in cell migration are the actin cytoskeleton and integrin-based adhesion to the extra-cellular matrix, known as focal adhesions (FAs). FA turnover allows cells to move over the underlying matrix while the actin cytoskeleton directly links to the FAs providing the contractile force that generates movement. Actin filament structure is regulated by distinct isoforms of the tropomyosin (Tm) family of actin-binding proteins. Given the key relationship between adhesion and actin in cell migration, we hypothesized that Tm isoform expression may

**Haphazard Actin Rich Protrusions and GTPase Activation in Merlin Deficient Schwannomas**

C. Flair, C. O. Hanemann; Clinical Neurobiology, Peninsula Medical School, Plymouth, United Kingdom

Schwannomas that occur spontaneously or in patients with the inherited cancer neurofibromatosis type 2 lack both alleles for the tumour suppressor gene Merlin. Merlin binds to the cytoskeleton and has been linked to the Rac-PAK signalling pathway. Rac1, as well as Cdc42, are members of the RhoGTPase family that control the formation of protrusive structures, lamellipodia and filopodia, respectively. Very little is known about actin-rich protrusions that are potentially crucial in schwannoma cell differentiation, and nothing is known about Cdc42 activation in human primary schwannoma cells. Using scanning electron microscopy we show here that normal Schwann cells have a bipolar, spindle shape, whereas schwannoma cells are flattened and exhibit multiple protrusive structures, like lamellipodia and filopodia, all around the cell periphery. Previous studies have shown that human primary schwannoma cells contain more active Rac1. We propose that Rac1 is randomly activated in human primary schwannoma cells, as it colocalises with one its effectors, phospho-PAK1/2, all around the cell periphery thus explaining the multiple lamellipodia. Cdc42 controls filopodia formation and is also activated in schwannomas as shown by pull-down assays and colocalisation with one of its effectors, phospho-PAK. Other effectors of Cdc42, namely phosphorylated ERK proteins (extran, moesin, moesin), characteristically also involved in formation of protrusive structures, similarly localise to the multiple filopodia. Finally, fast and continuous remodeling of the multiple lamellipodia and filopodia can be detected as shown by live cell imaging of actin-EGFP transfected human primary schwannoma cells. Furthermore it would be interesting to find out if the combined Cdc42 and random Rac1 activation also affects the structure and regulation of the actin cytoskeleton and adhesive structures. In summary we suggest that the highly dynamic multiple lamellipodia and filopodia found in merlin-deficient human primary schwannoma cells are caused by a combination of Cdc42 and random Rac1 activation.

**The Tropomyosin Family of Actin-binding Proteins Have Isoform Specific Effects on Adhesion Structure and Signalling**

C. Bach,1 J. Zhong,1 P. W. Gunning,1 G. M. O'Neill1,2;1Oncology Research Unit, The Children's Hospital at Westmead, NSW, Australia, 2Discipline of Paediatrics and Child Health, The University of Sydney, Sydney, Australia

Two core components in cell migration are the actin cytoskeleton and integrin-based adhesion to the extra-cellular matrix, known as focal adhesions (FAs). FA turnover allows cells to move over the underlying matrix while the actin cytoskeleton directly links to the FAs providing the contractile force that generates movement. Actin filament structure is regulated by distinct isoforms of the tropomyosin (Tm) family of actin-binding proteins. Given the key relationship between adhesion and actin in cell migration, we hypothesized that Tm isoform expression may
regulate adhesion structure, in turn determining downstream signalling and migration. Firstly, we find that cells overexpressing the Tm isoform TmBr3 display significantly smaller FAs than control cells. Strikingly, cells overexpressing the Tm isoform Tm5N1 display FAs that are twice the length of control cells and are dispersed across the ventral surface of the cell. In contrast, mouse embryo fibroblasts (MEFs) homozygous null for Tm5N1 display enhanced levels of focal complex formation arrayed at the leading edge of protruding membranes. Using time-lapse microscopy we determined that cells expressing Tm5N1 display reduced random cell movement, while the Tm5N1-/- MEFs travel significantly further than controls. Notably, the velocity of the wild-type and knockout MEFs is identical, therefore suggesting that the Tm5N1-/- MEFs may be more polarized. Current models of cell migration suggest a requirement for cytical activation of Rho GTPases. The FA docking molecule p130Cas can regulate signalling through Rac and Cdc42 thereby regulating cell migration, hence we investigated the phosphorylation status of p130Cas in response to altered Tm isoform expression. We find that p130Cas phosphorylation is reduced in Tm5N1 overexpressing cells when compared with control cells, TmBr3 cells and the Tm5N1 +/- MEFs. Together our data support Tm isoform-specific effects on FA structure, adhesion molecule activation and cell migration.

942 Characterization of an Epidermal Growth Factor-stimulated Acute Lamella Retraction That Temporally Lags Lamellipodial Proliferation
I. Schneider, C. Waterman-Storer; Cell Biology, The Scripps Research Institute, La Jolla, CA
Cell migration involves the spatial and temporal coordination of protrusion, adhesion formation and contraction. These processes are intimately linked to the actin cytoskeleton, but are spatially segregated in different actin networks. Protrusion is mediated by a branched, treadmill actin network in the lamellipodium, while adhesion and contraction is mediated by actomyosin and focal adhesions in the lamella. In physiological settings, protrusion, contraction and adhesion can be altered by signals from growth factor receptors leading to enhanced cell migration. Much work has focused on defining how acute growth factor stimulation regulates actin polymerization and depolymerization, processes that drive lamellipodial protrusion. However, the subsequent temporal regulation of activities in the lamella leading to cell migration after stimulation is less well understood. Using live cell microscopy we have observed a delayed retraction response after epidermal growth factor (EGF) stimulation that pulls the lamellipodium and lamella towards the cell body several minutes after the initial protrusion phase. This retraction can be blocked by blebbistatin indicating a dependence on the ATPase activity of myosin II. Blocking myosin light chain kinase with ML-7 on the other hand does not necessarily block this retraction; however these cells may contain fewer mature peripheral adhesions. We have used traction force microscopy to quantify the retraction response by measuring the force exerted by the cell on the substrate after EGF stimulation of cells pretreated with blebbistatin, ML-7, Y-27632, A Rho kinase inhibitor or vehicle. Cell biochemical techniques support these results and show that myosin regulatory light chain phosphorylation is cotemporal with this lamella retraction. We conclude that this EGF-stimulated retraction phase depends intimately on myosin II-mediated contraction, but also depends on the state of adhesion formation before EGF stimulation, which itself is affected by the basal level of myosin II activity, illustrating the highly connected processes of contraction and adhesion.

943 Focal Adhesion Kinase Is Required for Focal Adhesion Sliding and Trailing Edge Retraction
M. Iwanicki, T. Vomastek, R. W. Tilghman, K. H. Martin, J. K. Slack-Davis, J. T. Parsons; Department of Microbiology, University of Virginia, Charlottesville, VA
In migrating fibroblasts, focal adhesions can be classified as either stationary or sliding. Stationary focal adhesions can be categorized predominantly found at the protruding front, and they are characterized by rapid turnover. On the other hand, sliding focal adhesions are found in the tail and sides of migrating fibroblasts. They are characterized by an elongated phenotype and the capacity to move inward before turnover. During fibroblast migration, trailing adhesions are thought to resist traction forces, leading to increase in tension that is necessary for destabilization of protrusion and detachment. Here we show that Focal Adhesion Kinase (FAK), an integrin-dependent signaling component, is involved in the regulation of focal adhesion sliding and tail retraction. We found that the inhibition of FAK expression using siRNA or FAK activity with a FAK-specific inhibitor in RAT 2 cells results in the loss of adhesion sliding and tail retraction. These results suggest that FAK signaling is required for trailing edge resistance to traction forces and proper protrusion destabilization during tail retraction.

944 Normal Modes of Shape Variation Are Coupled to Cell Behavior in Motile Keratocytes
Z. Pincus, 1, 2 E. L. Barnhart, 2 K. Keren, 2 C. I. Lacayo, 2 J. A. Theriot 2, 3; 1 Program in Biomedical Informatics, Stanford University School of Medicine, Stanford, CA, 2 Department of Biochemistry, Stanford University School of Medicine, Stanford, CA, 3 Department of Microbiology and Immunology, Stanford University School of Medicine, Stanford, CA
We have used a novel application of the principal components analysis to find the major statistically uncorrelated modes of cell shape variation in image datasets representing large populations of cells. Quantitative analysis of the shape of isolated ciliated epithelial keratocytes indicates that there are four principal modes of shape variation that account for ~95% of cell-to-cell shape difference. These modes correspond to (1) the size of the cells, (2) their overall organization into elongated fast-crawling forms (referred to as “canoe” shapes in the literature) vs. less highly organized “D” shapes, 3) the relative fore-and-aft position of the cell body with respect to the trailing edge, and 4) left-right asymmetries, most pronounced at the cell rear. Remarkably, we have found that these statistically uncorrelated modes of shape variation also appear to be biologically independent and tightly coupled to motile behavior, since different treatments that perturb cell movement effect changes along only one shape mode at a time. Keratocytes treated with media of different osmolarities were altered along the cell-size axis (the first shape variation mode), but remained indistinguishable from wild-type along the other three modes. The second shape mode correlated with the amount of anti-activated protein kinase C (PKC) localized to the leading edge, and also with actin filament density distribution, cell speed and directional persistence. Treatment of cells with RGD peptide or manganese ion, which modulate adhesion sliding and PKC activity, respectively, also perturbed the cell's shape along this PKC-sensitive axis. These results suggest that the inhibition of PKC expression using siRNA or PKC activity with a PKC-specific inhibitor in RAT 2 cells results in the loss of adhesion sliding and tail retraction.

945 Discrete Phases of Edge Dynamics during Cell Spreading Dependent on Distinct Mechanoschemical Complexes
B. J. Dabin-Thaler, 1 J. M. Hofman, 2 H. Xenias, 1 H. Débre nner, 1 C. H. Wiggam, 3 M. P. Sheetz 1; 1 Biological Sciences, Columbia University, New York, NY, 2 Physics, Columbia University, New York, NY, 3 Applied Physics and Applied Mathematics, Columbia University, New York, NY
Mouse embryonic fibroblast cells spreading onto fibronectin-coated surfaces commonly exhibit a sequence of three distinct stages of spreading: early, isotropic, and late. Each stage of spreading exhibits a combination of distinct spatiotemporal phases of cystoskeletal organization. Using novel, statistically-based computer algorithms to quantify cell edge movement, we reveal that the cell edge frequently exhibits a phase of pointed cell motility in the early stage. The early stage is followed by a two-minute isotropic stage during which the cell rapidly increases its area via a continuous protrusion phase of the cytoskeleton. The last stage, late spreading, is generally characterized by a periodic contraction phase, though limited regions of the edge can still revert back to the continuous phase. VASP is confined to the leading edge in the continuous phase regardless of the stage. Cytochalasin D, an inhibitor of actin polymerization, disrupts the spatial organization of the isotropic stage while changing the blubbing phase. Based on this and further evidence that the phases respond differently to the
same perturbation, we hypothesize that each dynamic phase reflects a distinct mechanochemical arrangement of cytoskeletal molecules, and the probability of entering a given phase depends on the local signaling environment.

Myosin Activity at the Back of Lamellipodia Activates Adhesion Formation at the Front through the Mechanical Action of Lamellipodial Actin  
G. Giannoni, B. J. Dubin-Thaler; O. Rossier, Y. Caiz, O. Chaga, W. Beaver, H. Döbereiner; Y. Freund, G. Borisy, M. P. Sheetz; Université Bordeaux, Bordeaux, France, biological sciences, Columbia University, New York, NY, Cell and Molecular Biology, Northwestern University, Chicago, IL, computer Science and Engineering, UC San Diego, La Jolla, CA  
Cell motility proceeds by cycles of edge protrusion, adhesion and retraction. Whether these functions are coordinated by complex biochemical or biomechanical processes is unknown. We find that myosin II pulls the rear of the lamellipodial actin network causing upward bending, edge retraction and initiation of new adhesion sites. The network is then released from the edge and condensed over the myosin. Protrusion resumes as lamellipodial actin regenerates from the front and extends rearward until interacting again with new confined myosin, initiating the next cycle. Upward bending, observed by evanescent microscopy and electron microscopy, is consistent with ruffling when adhesion strength is low. Correlative fluorescence and electron microscopy demonstrated that the regenerating lamellipodium forms a cohesive separable layer of actin. Thus, actin polymerization periodically builds a mechanical link, the lamellipodium, connecting myosin motors with the initiation of adhesion sites, suggesting that the major functions driving motility are coordinated through a biomechanical process.

Myosin Contraction, Adhesion, and Retraction of the Trailing Edge in Locomoting Fish Keratocytes  
E. Bartzhart, J. Theriot; Stanford University, Stanford, CA  
Myosin contraction has been shown to promote focal adhesion assembly and stability in stationary cells. However, in migrating cells, myosin is localized primarily in the cell rear, where adhesions must disassemble in order for retraction of the trailing edge to occur. To investigate the relationship between myosin contraction, focal adhesion size, and retraction of the trailing edge, we examined the effect of myosin inhibition on focal adhesion size in rapidly locomoting fish keratocytes. To visualize focal adhesions, cells were either transfected with a vinculin-GFP transgene or fixed and stained with a vinculin antibody. In both live and fixed cells, vinculin accumulated in focal adhesions on either side of the cell body in the cell rear. Inhibiting myosin contraction with blebbistatin resulted in a dramatic reduction in focal adhesion size, but did not have a consistent effect on cell speed. To determine how increasing adhesion strength affects the relationship between myosin contraction and adhesion size, we treated cells with Mn2+, which promotes adhesion by activating integrins. Treating cells with Mn2+ resulted in a reduction in cell speed and impeded translocation of the cell body, but had no effect on vinculin accumulation. Cells treated with both Mn2+ and blebbistatin had significantly smaller focal adhesions than either control or Mn2+-treated cells, indicating that intact actin network is not sufficient for maintenance of focal adhesion size in the absence of myosin contraction. Moreover, treatment with both Mn2+ and blebbistatin resulted in rapid forward motion of the trailing edge without concomitant disassociation of focal adhesions, generating long branched retraction fibers at the rear of the cell, followed by arrest of cell movement. These results suggest that at high adhesion strength, myosin dependent retraction of the connection between the cytoskeleton and focal adhesions is required for proper retraction of the trailing edge and cell locomotion.

Regulation of Cytoskeletal Dynamics and Cell Migration in Colon Carcinoma Cell Lines by Plectin  
L. McIntyre, A. Matta; School of Biological and Biomedical Sciences, Integrative Cell Biology Laboratory, Centre for Stem Cell Biology and Regenerative Medicine, Durham, United Kingdom  
Plectin is a large cytoskeletal linker protein that can connect different cytoskeletal networks to each other and to cell-cell and cell-matrix junctions. Mutations in plectin disrupt tissue integrity in skin, skeletal and heart muscle. The versatility of plectin as a linker protein is further enhanced by complex alternative splicing that results in a large number of plectin isoforms. We are investigating the role of plectin in the cytoskeletal organisation and invasiveness of epithelial carcinomas. We have cloned eight alternative first exons of the human plectin gene including a novel exon, 1K. Real-time PCR shows that there are isoform specific changes between invasive and non invasive colon carcinoma cells. We have also raised polyclonal antibodies to four of the isoforms including the novel 1K. Furthermore, alternative plectin N-terminal domains comprising of the first exon and the following calponin-homology actin binding domain target EGFP constructs to different subcellular localisations. Thus, the first exon appears to determine where in the cell plectin can form actin - intermediate filament cross-bridges. We have shown that exon 1K localises to podosome like structures on the lower surface and vinculin positive circular ruffles on the dorsal surface. Vimentin, which forms the major intermediate filament network in mesenchymal cells, is involved in the formation of focal adhesion points and podosomal structures. Knocking down of plectin and vimentin by siRNA in SW480 cells causes a significant decrease in attachment to collagen and impairs migration and invasion. We propose that a change in plectin isoform expression can lead to altered cytoskeletal and functional organisation and can contribute to invasive properties of carcinoma cells.

Diaphanous-related Formin-6dia2 Is Required for Cellular Movements during Gastrulation in Zebrafish  
S. Lai, S. Lee; Institute of Zoology, National Taiwan University, Taipei, Taiwan  
Intensive cellular movement occurs during gastrulation in embryogenesis that relies heavily on dynamic actin assembly. Various factors have been implicated in the regulation of actin assembly in cellular protrusion and migration, including Rho-activated formin, Diaphanous. However, the function of Diaphanous in cellular migration during gastrulation is unclear. To study the role of Diaphanous in embryogenesis, we have identified a Diaphanous-related formin 2 (zdia2) in zebrafish by in silico cloning; zdia2 was found to be ubiquitously expressed during early development as revealed by RT-PCR and whole-mount in situ hybridization. Knockdown of 6dia2 by translational or splicing blocking morpholino oligos (MO) resulted in incomplete epiboly formation with a yolk plug and failure in involution. Whole-mount in situ hybridization analysis of no tail gene revealed a shortened embryo axis and a less-converged notochord and primordial somites at the bud stage in the zdia2 MO-injected embryos. Time lapse recording further demonstrated that the defects were due to the lack of protractive activities of forerunner cells during epiboly. Moreover, actin filament accumulation in the forerunner cells as shown in normal embryos was decreased in those zdia2 MO-injected embryos. Lastly, co-injection of zdia2 MO and profilin 1, a formin-dependent actin binding protein, but not the other isoform, profilin II, resulted a synergistic effect on all described defects. These results suggest that zdia2 is required for cell movements during gastrulation via the cooperation with profilin 1 in zebrafish development.

An In Vivo Requirement for mDia1 in Cytoskeletal Remodeling Following T Cell Activation  
K. M. Eisenmann, D. Hildebrand, S. M. Kitchen, R. A. West, A. S. Alberts; Cell Structure and Signal Integration, Van Andel Research Institute, Grand Rapids, MI  
The mammalian Diaphanous-related (mDia) formins are important Rho GTase effectors proteins that nucleate and elongate nonbranched actin filaments during directed cell migration and cytokinesis. In order to understand its role in vivo, the gene encoding the canonical marine formin mDia1 was knocked out by conventional methods. While viable, mice either heterozygous or homozygous null for mDia1 have numerous hematopoietic defects – notably, diminished immune cell populations within peripheral lymphoid organs, including the spleen and lymph nodes, suggesting a defect in immune cell proliferation and/or migration. Detailed examination showed that splenic T cell populations were significantly diminished. As it was unclear if the lack of T cells infiltrating the spleen was due to a migratory defect in either mDia1 hetero- or homozygous null mice, isolated splenic T cells were assessed for their ability to adhere and/or migrate upon fibronectin in a transwell assay in response to growth factors or chemokines. Both T cells from both genotypes were defective in fibronectin adhesion and failed to migrate in response to SDF1 stimulation. Polarization in response to activation of the T cell receptor by CD3/CD28 costimulation (TCR) ligation was also affected by mDia1 knockout; cells failed both in the assembly of an actin cap following stimulation and in their ability to orient their microtubule organizing center. Fluorescent resonance energy transfer (FRET)-based microscopy revealed a polarized interaction between mDia1 and RhoA at the leading edge of activated Jurkat T cells. Taken together, these results show a central role for RhoA activated mDia1 in both microtubule and actin dynamics required for normal T cell function.

Regulation of Cell Migration and Matrix Remodeling by Tissue Mobility  
M. Miron-Mendoza, J. Seemann, F. Grinnell; Cell Biology, UT Southwestern Medical Center, Dallas, TX
Nestled collagen matrices provide a unique 3D physical environment to study matrix remodeling and cell migration. In this two stage model, cells contract floating collagen matrices overnight in the first stage. Subsequently, these “dermal equivalents” are embedded and incubated inside cell-free collagen matrices (1.5 mg/ml) in the second stage. During the second stage, nested matrices can be immobile (attached to culture dishes) or mobile (floating in culture medium). In the presence of platelet derived growth factor (PDGF) but not lysophosphatidic acid or basal medium, collagen matrix remodeling begins within hours as shown by collagen migration into the outer matrix at speeds of up to 20μm/hr towards the interface between outer and inner matrices. Subsequently, if the nested matrices are immobile, then a wave of cells begins to migrate into the outer matrix at speeds of up to 60μm/hr beginning after 4-8 hr. The density of migrating cells is highest on the edge of the dermal equivalent nearest the culture dish surface. Also, with 4.0 mg/ml collagen outer matrices, cell migration can occur even if nested matrices are mobile, but there is no matrix remodeling under these conditions. Experiments also were carried out using nested collagen matrices containing two dermal equivalents. In mobile, dual nested matrices, cell migration occurs only in between the two dermal equivalents, and matrix remodeling brings the dermal equivalents together. In immobile, dual nested matrices, cell migration occurs in between and around the outer surfaces of both dermal equivalents, and the dermal equivalents remain apart. Our findings demonstrate a new mechanism of collagen matrix remodeling that requires PDGF-stimulated fibroblast migration. We suggest that the balance between cell migration and matrix remodeling depends on tissue mobility and explains how fibroblast migration at the wound margin has the potential to cause wound closure.

The Exocyst Interacts with the Arp2/3 Complex and Regulates Cell Migration
X. Zuo, J. Zhang, W. Guo, Biology, University of Pennsylvania, Philadelphia, PA

Cells migrate by protrusions, which are mediated by the assembly of a branched actin network that grows beneath the leading edge of the plasma membrane. The Arp2/3 complex is the core machinery that regulates actin for the filamentous actin network. In addition to actin polymerization, cell migration also requires polarized exocytosis for the supply/recycling of lipids and proteins to the leading edge for membrane expansion. Actin dynamics and membrane traffic must be tightly coordinated, both temporally and spatially, for efficient cell migration. The exocyst is a multiprotein complex essential for tethering secretory vesicles to specific domains of the plasma membrane for exocytosis. Here we report that the exocyst component Exo70 directly interacts with the Arp2/3 complex, a key regulator of actin polymerization. We further show that the exocyst-Arp2/3 interaction is regulated by epidermal growth factor (EGF) signaling. Immunofluorescence microscopy shows that components of the exocyst complex are localized to the leading edges of migrating cells. Inhibition of Exo70 by RNA interference or antibody microinjection blocks the formation of actin-based membrane protrusions and affects various aspects of cell motility. We propose that Exo70, in addition to functioning in exocytosis, also regulates actin at the leading edges of migrating cells, therefore coordinating cytoskeleton and membrane traffic during cell migration.

Calcium Is Required in Pigment Granule Dispersion in Bluegill RPE
M. Nagayaama, T. Uchida, T. Taira, K. Shimmura, M. Sakai, K. Gohara; 1Applied Physics, Hokkaido University Graduate School of Engineering, Sapporo, Japan, 2Primary Cell Co., Ltd., Sapporo, Japan

Adipocyte proliferation and differentiation have been widely investigated because hypertrophy and hyperplasia of adipocytes in adipose tissue are associated with obesity, a major risk factor for lifestyle-related diseases. Molecular processes concerning adipocyte differentiation have rapidly been identified, but how these molecular processes lead to morphological and functional changes at the cellular level is still controversial. Thus, we focus on spatial and temporal dynamics of macroscopic structures during adipocyte differentiation (~ several 10 μm, several days). In the present study, we captured time-lapse images of primary stromal-vascular cells (SVCs) derived from rat mesenteric adipose tissue. The time-lapse observations for 5 days showed that the adipocyte differentiation proceeds through the following two steps: (i) Numerous small lipid droplets (LDs), which are a few μm in diameter, appeared in the perinuclear region at an early stage of differentiation, and then (ii) several LDs grew to more than 10 μm in diameter and occupied the cytoplasm, and the other LDs disappear. The temporal and spatial variations of LDs were accompanied by the morphological changes as SVCs converted fibroblastic to spherical shape. Observations at a higher magnification showed that nascent LDs (~ several 100 nm in diameter) grew into small LDs by fusion with adjacent nascent LDs while moving from lamellipodia to the perinuclear region. We also found that SVCs proliferate by distributing LDs evenly between two daughter cells, although the SVCs which started to accumulate nascent LDs were considered to lack proliferative activity. Immunofluorescence observations revealed that cell division of SVCs occurred even after LDs had been coated with perilipin. The findings suggest that SVCs can proliferate and accumulate LDs simultaneously rather than in sequence. In summary, our time-lapse observations would provide an exact description of adipocyte differentiation.

Calcium Is Required in Pigment Granule Dispersion in Bluegill RPE
A. S. Johnson, D. M. Garcia; Biology, Texas State University, San Marcos, TX

The retinal pigment epithelium (RPE) is a single layer of cuboidal cells found between the retina and choroid of the vertebrate eye. Among other functions, it provides bluegill (Lepomis macrochirus) with an anti-photobleaching mechanism known as pigment granule dispersion. The dispersion process can be induced by acetylcholine (or its analog carbachol) which activates M1 muscarinic receptors on the RPE. Once activated, a cascade of messengers ultimately causes pigment granules to move inside long processes that are oriented toward the photoreceptors. With granules in place, the amount of light intensity reaching the photoreceptors is greatly reduced allowing bluegill a defense from excessive photobleaching. Using isolated RPE, the focus of this study is to test whether Ca2+ is required for carbachol-induced dispersion by depleting intracellular calcium and by using BAFTA-AM (10-50μM) to prevent calcium transients. Both treatments blocked carbachol-induced dispersion. To determine whether extracellular Ca2+ is required, we tested to see if pigment granule dispersion is blocked by removing Ca2+ and by treatment with verapamil (10 μM). Neither of these treatments affected pigment granule dispersion. Finally, to test which Ca2+ effectors may be involved, we tested the ability of the PKC inhibitor staurosporine (100μM) as well as the calcium-inhibitor cymperthrin (100μM). Staurosporine had no effect on pigment granule dispersion, whereas cymperthrin significantly inhibited dispersion. The contradiction between these results and those published by King-Smith et al. (1996) will be discussed.
Modeling and Analysis of Receptor-mediated Signal Transduction, Spatial Gradient Sensing, and Wound Invasion
J. Haugh, Chemici & Biomolecular Engineering, North Carolina State University, Raleigh, NC
One of the current challenges in biology is to bridge the scales of molecular-, cellular-, and tissue-level complexity. Mathematical modeling can be useful for testing how a signaling module, carefully and quantitatively characterized with cultured cells, might operate in the context of a dynamically changing environment in vivo; appropriate coarse-graining of the molecular details is needed for proper analysis of higher-level models, however. In the context of dermal wound healing, we have studied the spatial pattern of platelet-derived growth factor (PDGF) receptor-mediated activation of PI 3-kinase, and its influence on fibroblast chemotaxis, at multiple scales. First, at the molecular scale, we have used Brownian dynamics simulations to analyze the co-localized crosstalk of activated Ras and PI 3-kinase in the vicinity of a receptor, their interactions limited by the rate of lateral diffusion in the plasma membrane. Second, at the cellular scale, we have fully characterized through quantitative live-cell imaging experiments and modeled the PI 3-kinase-mediated sensing of PDGF gradients. We find that PDGF gradient sensing in fibroblasts is governed by a relatively simple mechanism that, compared with other chemotactic cells (e.g., neutrophils, D. discoideum), requires steep PDGF gradients with midpoint concentrations spanning a narrow range. Finally, at the tissue level, with our gradient sensing model embedded within a coarse model of wound invasion, we show how a suitable PDGF gradient with the proper steepness and midpoint concentration for chemotaxis can be maintained over millimeter length scales for efficient wound invasion.

Sinai Virus 40 Protein Small Tumor-antigen Causes Centrosome Amplification in Drosophila melanogaster Embryos
S. Kotadia, 1 S. A. Comerford, 2 R. E. Hammer, 1 T. L. Megraw, 1 Pharmacology, Green Center for Reproductive Biology, University of Wisconsin Madison, Madison, WI, 2Biochemistry, Green Center for Reproductive Biology, University of Wisconsin Madison, Madison, WI
Centrosomes are the major microtubule-organizing centers (MTOCs) in animal cells and their duplication is an important yet poorly understood process. To investigate this process, we are using genetic interactions, live-imaging, and biochemical assays utilizing the simian virus-40 (SV-40) protein small tumor-antigen (ST). ST binds to Hsc70 and increases its ATPase activity. Upon binding to the PP2A phosphatase, ST displaces the PP2A B subunit resulting in reduced phosphatase activity towards known substrates. ST causes centrosomes to overduplicate in vertebrate cell lines and in Drosophila embryos. In Drosophila, high levels of maternal ST result in embryonic lethality, while high levels of yzgotic ST cause late larval death. Interestingly, ST expression in embryos results in a marked decrease in the level of phosphorylated centrosomin. Using two ST mutants, we are examining if the PP2A-binding domain or the Hsc70-binding domain are necessary or sufficient to cause centrosome overduplication. Crosses are underway to assess the role of candidate genes in ST-mediated centrosome amplification. In addition, we are assessing for other interacting partners of ST using biochemical approaches. Through these combined genetic and biochemical experiments, we will determine the mechanisms by which ST deregulates centrosome duplication.

Protein Kinase Nek2 Prevents Centrosomal Clustering in Cancer Cells
S. E. Hileman, 1 L. F. Petersen, 2 N. J. Quintyne, 2 W. S. Saunders, 2 Department of Biological Sciences, University of Pittsburgh, Pittsburgh, PA, 3School of Medicine, Wayne State University, Detroit, MI, 4Harlery L. Wilkes Honors College of Florida Atlantic University, Jupiter, FL
Cancer cells are known to display many distinct characteristics in mitosis, including anaphase bridges, lagging chromosomes, and multipolar spindles. Multipolar spindles form following amplification of the microtubule organizing center or centrosome of the cell. In some cases, the amplified centrosomes are clustered to form bipolar rather than multipolar spindles, protecting the cell from this genomic destabilizing event. We describe the action of the centrosomal protein kinase, Nek2, on centrosomal clustering. Nek2 is known to be overexpressed in some tumor cells. We show that Nek2 overexpression prevents centrosomal clustering in cancer cells and it can lead to multipolar spindles when associated with amplification of centrosomes. We also show that inactivation of Nek2 can cause reclustering of the centrosomes in cancer cells. Thus, Nek2 overexpression is proposed to be a mechanism to disrupt normal chromosome segregation in tumor cells.

Beta-catenin Functions in Nek2-mediated Centrosome Cohesion
S. Bahmanyar, 1 D. D. Kaplan, 2 W. J. Nelson, 3 P. J. Casey, 4 A. I. M. Barth 1; 1Molecular and Cellular Physiology, Stanford School of Medicine, Stanford, CA, 2Department of Developmental Biology, Stanford School of Medicine, Stanford, CA, 3Biological Sciences, Stanford University, Stanford, CA, 4Department of Pharmacology, Duke University Medical Center, Durham, NC
Beta-catenin plays important roles in cell adhesion and regulation of gene expression, and mutations in beta-catenin commonly contribute to cancer. It has been shown that beta-catenin localizes to mitotic spindle poles and that depletion of beta-catenin results in monoastral spindles with duplicated, but not separated, centrosomes. Here, we show that beta-catenin is an integral component of interphase centrosomes. Accumulation of a stabilized form of beta-catenin is found in cancers increases centrosome distance in interphase cells, in a manner analogous, but opposite to depletion of beta-catenin. These results indicate that beta-catenin plays a role in centrosome cohesion. Centrosome cohesion is regulated by the NIMA-related kinase Nek2. We identified Nek2 as a binding partner of beta-catenin in isolated centrosome preparations. Nek2 binds directly to and phosphorylates beta-catenin in vitro. Nek2 phosphorylates beta-catenin’s armadillo domain, which is necessary and sufficient for localization of beta-catenin to centrosomes. We suggest that a threshold level of beta-catenin is required for centrosome normal function. Increasing this level results in decreased centrosome cohesion, extra centrosomes, and mitotic defects. Decreasing this level inhibits centrosome separation and results in a prometaphase arrest. Nek2 could regulate beta-catenin levels at centrosomes, allowing for proper centrosome cohesion and progression through mitosis.

An In Silico Screen for Centriole Duplication Genes
W. Marshall; Biochemistry & Biophysics, UCSF, San Francisco, CA
Centrioles are unique among organelles in that they undergo a discrete duplication process, with each mother centriole producing a single daughter. How does a mother produce a daughter? To begin answer this question, we sought mutants incapable of duplication. However, we are not interested in simply obtaining structural building blocks of the centriole (such as the previously well-characterized SAS-6 or BLD10 genes), but rather genes specifically required by the mother to make a daughter. We can distinguish the type of mutant we want (duplication specific from the type we do not want (simple building blocks such as sas6)) because the latter type will not only fail duplication, but also will lack de novo assembly. We therefore developed a mathematical model to describe centriole inheritance and used it to predict the phenotype of a mutant that could not perform standard centriole duplication but could still perform de novo assembly at the wild-type rate. This model takes into account experimental data on the homeostatic regulation of centriole abundance. Comparing the model predictions to data obtained from a collection of centriole copy-number mutants, we identified the FLV3 gene of Chlamydomonas as a candidate gene required for duplication but not for de novo assembly. Imaging studies support this role for FLV3.

Centrosome Replication in Hydroxyurea (HU)-arrested CHO Cells Expressing GFP-tagged Centrin
R. Kuriyama, 1 Y. Terada, 1 J. Pines, 2 K. Lee, 3 C. Wang 1; 1Genetics, Cell Biology, and Development, University of Minnesota, Minneapolis, MN, 2Wellcome/Cancer Research UK Gurdon Institute, Cambridge, United Kingdom, 3National Cancer Institute, NIH, Bethesda, MD
Centrosome duplication is tightly coupled with the cell cycle and neither too many nor too few centrosomes are induced in a normal cell. To study how centrosome formation is regulated, we analyzed the process of abnormal centrosome replication in CHO cells induced by HU treatment (Balczon et al., 1995). GFP-tagged centrin2 constitutively expressed in CHO cells labeled both centrioles and the pericentriolar material of the centrosome. Time-lapse fluorescence microscopy revealed the presence of one or two dots next to each nucleus. During HU treatment, small centrin aggregates of various sizes and numbers appeared inside the cytoplasm: they were frequently embedded in the cloud surrounding the existing centrosomes. The aggregates were highly mobile, continuously changing their position in a microtubule-/microtubule dynamics-dependent manner. The centrosome number increased as small aggregates grew in size and resolved into countable centrosomes. Time course analysis of synchronized cell populations showed that the vast majority of cells did not initiate centrosome replication until 10h after incubation of harvested M phase cells with HU. Although new centrosomes were assembled by 16-18h, their number generally did not exceed more than two. Thereafter the cells underwent multiple
replication cycles to produce various numbers of centrosomes that were frequently abnormal in size and length. These results suggest that: 1) initially new centrosome formation in HU-arrested cells is under the control of preexisting centrosomes, and 2) HU treatment overrides suppression of excess centrosome formation in cells where the full number of centrosomes already exists.

963 The Duplication of the Centrosome Does Not Require Cell Cycle Progression into S-phase in Mammalian Cells
T. Duran, E. Halpin, E. H. Hinchecliffe; Biological Sciences, University of Notre Dame, Notre Dame, IN

In animal cells, centrosome duplication occurs once per cell cycle, and is commonly thought to initiate near the G1/S phase transition or during S phase. We examined whether centrosome duplication requires cell cycle transition into S phase using Chinese Hamster Ovary (CHO) cells stably transfected with GFP-centrin 2. Live-cell imaging in cycling cells revealed that centrosome duplication occurs somewhere between 6 and 8 hrs following the end of mitosis, coordinate with the onset of S-phase as determined by BrdU incorporation. When synchronized 60 cells are released in media containing serum and the well-characterized G1 inhibitor mimosine we observe centrosome duplication beginning around 14 hrs post-release. After 48hrs in G1, 97% of cells had undergone centrosome duplication: 46% possessed 4 centrioles, whilst 51% possessed 5 or more centrioles. Centriole number in G1 arrested cells was confirmed by immunostaining cells with anti-centrin 2 antibody, and by serial section electron microscopy. This is in contrast to CHO cells arrested in S phase with hydroxyurea ~90% of S-phase cells contained greater than 5 centrioles, with many cells having greater than 14 centrioles. The mechanism of centrosome duplication in mammalian cells is not dependent upon cell cycle progression per se, but rather, normally serves to coordinate this process with entry into S-phase.

964 Loss of Centrosome Integrity Induces G1/S Arrest
B. Delaval,1 K. Miki,2 P. Kaldin,3 A. Jerczyk,1 A. Khodjakov,4 S. Dossey5; 1Program in Molecular Medicine, UMASS Medical School, Worcester, MA, 2ArQule Biomedical Institute, Inc., Norwood, MA, 3National Cancer Institute, Frederick, MD, 4Wadsworth Center, Albany, NY

Centrosomes contribute to spindle organization, cytokinesis and primary cilia assembly. They are implicated in cell cycle progression but the mechanism has not been determined. Here we show that siRNA mediated depletion of 14/15 centrosome proteins arrested diploid human cells in the cell cycle as demonstrated by BrdU incorporation and flow cytometry. G1 arrest occurred in late G0 with p21-bound cyclinA/Cdc2 complexes and could be suppressed by re-expression of the relevant centrosome protein. The arrest was induced within G0, ruling out contributions from mitosis and cytokinesis. Proteins that affected cell cycling also perturbed centrosome structure and centrosome functions known to occur in G1, namely centrosome duplication and centrosome-dependent primary cilia assembly. We identified a signal transduction pathway required for centrosome-associated G1 arrest that included p38, p53 and p21. Functional abrogation of any one of these proteins suppressed G1 arrest. Elements of this pathway were present at the centrosome (p38, p53) and a form of p53 activated by p38 (p53-phospho-serine33) was specifically recruited to the centrosome in centrosome protein depleted cells prior to cell cycle arrest. G1 arrest was also observed following heat-induced centrosome disassembly demonstrated the physiological relevance of this cell cycle withdrawal mechanism. G1 arrest was also demonstrated in previous studies by anti-centrosome antibody injection in multicellular organisms demonstrating the conserved nature of this pathway. We propose that mammalian cells have a centrosome damage checkpoint that monitors changes in centrosome integrity and prevents aberrant centrosome duplication, spindle dysfunction and aneuploidy by inducing cell cycle arrest. This checkpoint has strong parallels with the DNA damage checkpoint (occurs at the same time, similar molecular control) and satisfies the definition of checkpoint in having three elements: a perturbation of centrosome structure/function that is sensed, a transducing element (p53) and a receiving element (p21).

965 The Centrosome in G1 Progression: Important, but Not Essential
Y. Uetake,1 J. Lokcěrk3 J. Nordberg,3 G. English,1 A. Khodjakov;4 G. Sluder1; 1Cell Biology, University of Massachusetts Medical School, Worcester, MA, 2Wadsworth Center, New York State Department of Health, Albany, NY

How centrosome removal or perturbations of centrosomal proteins arrest untransformed cells in G1 has been a mystery. We investigated this phenomenon using microsurgery and laser ablation to remove centrosomes from RPE1 and HMEC cells. Surprisingly, we find that these normal human cells progress through G1 in its entirety without centrioles and start to assemble centrioles de novo in S phase. How then can centrosome disruption cause a G1 arrest even though the centrosome is not needed for G1 progression? We test if centrosome loss per se stresses the cell thereby predisposing it to a G1 arrest. In individual microscope fields we microsurgically remove or laser ablate/damage the centrosome from some cells, perform control microsurgery/laser ablations on others, and use the untouched cells as controls. Shortly after experimental intervention we expose the fields to varying doses of 488nm blue light to provide controlled exogenous stress. We find that neither centrosome removal nor blue light exposure acting singly block G1 progression but together they can cause a G1 arrest. Cells without centrosomes are most sensitive to exogenous stress and the control operated cells slightly less so. Both are substantially more sensitive than untouched controls. Inhibition of the p38 stress activated kinase allows cells with removed/damaged centrosomes to progress through G1 despite blue light exposures that otherwise arrest them in G1. Thus, centrosome removal/damage is a stress that can act additively with other stresses to arrest cells in G1. This may explain how a wide variety of centrosomal perturbations can have a profound impact on G1 progression even though the centrosome is not a necessary, integral part of the mechanisms that drive the cell cycle through G1 into S phase.

966 Mechanism Limiting Centrosome Duplication to Once per Cell Cycle
M. Tsou, T. Stearns; Biological Sciences, Stanford University, Stanford, CA

The centrosome organizes the microtubule cytoskeleton and consists of a pair of centrioles surrounded by pericentriolar material. Cells begin the cell cycle with a single centrosome, which duplicates once per cell cycle. During duplication, new centrioles grow orthogonally to existing ones and remain engaged (tightly opposed) with those centrioles until late mitosis or early G1 phase, when they become disengaged. The relationship between centriole engagement/disengagement and centriole duplication potential is not understood, and the mechanisms that control these processes are not known. Here we show that centrosome disengagement requires the protease separase, and that this disengagement licences centrosome duplication in the next cell cycle. We describe an in vitro system using Xenopus egg extract and purified centrioles in which both centriole disengagement and centriole growth occur. Centriole disengagement at anaphase is independent of mitotic exit and Cdc2/cyclin E activity, but requires the anaphase-promoting complex and separase. In contrast to disengagement, new centriole growth occurs in interphase, is dependent on mitotic exit and Cdc2/cyclin E activity, and requires previously disengaged centrioles. This suggests that re-duplication of centrioles within a cell cycle is prevented by centriole engagement itself. We propose that the 'once-only' control of centrosome duplication is achieved by temporally separating licensing in anaphase from growth of new centrioles during S phase. The involvement of separase in both centriole disengagement and sister chromatid separation would prevent premature centrosome disengagement before anaphase onset, which can lead to multipoles and genomic instability.

967 Mechanism of Centriole Amplification in S-arrested Cells
J. Loncarek, V. Magadson, P. Hergert, A. Khodjakov; Molecular Medicine, Wadsworth Center, Albany, NY

Centrioles normally replicate once per cell cycle and this event occurs near G1/S transition. Even when cells are arrested during S, in most cell types (e.g., HeLa) centrioles replicate once and then the cell remains with 4 centrioles indefinitely. However, the number of centrioles in S-arrested CHO cells increases continuously. We use time-lapse microscopy, laser microablation, and same-cell correlative LM/EM analyses in cells expressing centrin-GFP to determine the mechanism(s) responsible for centriole amplification in S-arrested cells. We find that in HeLa cells daughter centrioles remain directly attached to their mothers (i.e., in diplosomes) for as long as cells are arrested in S. However, in S-arrested CHO cells diplosomes break down ~15 hr after G0 replication. Upon disengagement from the diplosome, daughter centrioles become motile which normally occurs during G1. Then, ~10 hr later, both mother and daughter centrioles replicate. Thus, the centriole cycle continues independent of the cell cycle in S arrested CHO cells. Further, daughter centrioles in these cells become fully mature (~25 hr after their formation). Precision of our laser microsurgery allows us to selectively destroy just one of the two centrioles within a diplosome with no detectable damage to the other centriole. Whether a new, newly formed daughter centriole in either CHO cells or HeLa cells capable of forming more than one daughter during a single S period if the original daughter disengages from the diplosome. These data reveal that preserving the functional connection between the daughter and mother centrioles is essential for preventing mother centriole disengagement during prolonged S. We are currently investigating molecular pathways responsible for the disengagement of the daughter centriole from the diplosome and its maturation in S-arrested CHO cells.
Drosophila Spd-2 Is Required for Efficient Centrosome Maturation, but Is Not Essential for Centriole Replication

C. I. De, J. W. Raff; The Department of Genetics, The Gurdon Institute, Cambridge, United Kingdom

As the major microtubule organizing center (MTOC) in animal cells, the centrosome has an important role in driving the efficient formation of a bipolar spindle during cell division. The centrosome comprises an orthogonally arranged centriole pair, surrounded by amorphous pericentriolar material (PCM). To carry out its role as a MTOC, the centrosome must, in accordance with the cell cycle, replicate its centrioles during S-phase and, undergo centrosome maturation prior to and during mitosis. The latter involves the recruitment of extra PCM proteins to the centrosome, promoting microtubule outgrowth. Spindle Depletion 2 (SPD-2) is essential for both processes in the first division of the C. elegans embryo (Kent et al. 2004; Pelletier et al. 2004), and is one of a small number of proteins identified that are essential for centriole replication in worms. To investigate whether these roles of SPD-2 are conserved in the fly, we investigated the function of DSpd-2, the predicted Drosophila orthologue. Like SPD-2, DSpd-2 localises to the centrioles throughout the cell cycle and to the PCM in mitosis. In larval brain cells DSpd-2 is essential for the efficient recruitment of the mitotic PCM proteins γ-tubulin and Centrosomin (CNN), reflecting the conserved role of SPD-2 related proteins in centrosome maturation. However, centriole number is almost unperturbed in the Dspd-2 null mutant. Therefore, we conclude that the SPD-2 family proteins are not components of centriole replication machinery operating in all organisms/cell types, and the mechanisms utilised may differ depending on the cellular context. DSpd-2 mutant flies are viable but sterile. Mutant males exhibit severe defects in spermatogenesis, and the number of centrioles per spermatocyte is highly variable. Surprisingly, Dspd-2 is also maternal effect lethal, and mutant embryos do not develop beyond the first mitotic division. We are currently investigating the specific nature of these defects.

The Xenopus TACC Protein Maskin Is Required for Centrosome Maturation

A. J. Albee, L. Liu, C. Wise; Biochemistry, University of Wisconsin-Madison, Madison, WI

The centrosome is the major microtubule organizing center of metazoan cells. It is composed of a pair of centrioles surrounded by the amorphous pericentriolar material (PCM). The composition and structure of the PCM changes throughout the cell cycle. The mitotic kinase, Aurora A, is an essential kinase required for increasing the microtubule nucleation capacity of the centrosome at the onset of mitosis. The phosphorylation of the Xenopus TACC protein, maskin, by Aurora A is required for its association with the mitotic centrosome (Peset et al. 2005. J. Cell Biol. 171 1057-1056; Kinoshita et al. 2005. J. Cell Biol. 174 1047-1055 ). Using centrosome assembly assays based on Xenopus egg extracts, we found that in addition to its role in stabilizing microtubules, maskin is required for the assembly of a functional centrosome. We further found that maskin binds to the regulator of spindle assembly, importin β. Importin β binding prevents phosphorylation of maskin by Aurora A. These findings suggest a role for maskin in centrosome assembly, and a role for importin β in regulating maskin at the centrosome.

The Role of NUD-1 in Centrosome Maturation and Organization

R. Thomas, L. Faircloth, G. A. Caldwell, K. A. Caldwell; Biological Sciences, The University of Alabama, Tuscaloosa, AL

Despite the essential role of centrosomes for accurate cell division, a detailed understanding of the factors that contribute to the proper assembly and maturation of these cytoskeletal structures is lacking. The C. elegans one-celled embryo represents an excellent system by which cellular components involved in this process can be elucidated. A hallmark of centrosome maturation is the accumulation of gamma-tubulin at the centrosome. Several proteins have been identified that are required for maturation and gamma-tubulin recruitment at the centrosome in C. elegans, including SPD-5 (a pericentriolar scaffold protein), AIB-1 (the worm aurora-A kinase homolog), and ZYG-9 (a centrosomal microtubule-stabilizing protein related to XMAP-215 in Xenopus). Here, we report that NUD-1, the C. elegans ortholog of the Aspergillus nidulans nuclear distribution protein, NudC, is localized to centrosomes during cell division. The level of NUD-1 protein accumulation is commensurate with centrosome maturation. Furthermore, we have determined that C. elegans NUD-1 is required for the recruitment of gamma-tubulin to centrosomes as there is a marked decrease in gamma-tubulin at the centrosome when nud-1 mRNA is depleted via RNAi. Since the centrosome is composed of a large number of components, we have investigated the possibility that centrosome maturation requires only one of the centrosomal protein components, and that the centrosome in nud-1 mutant flies is defective due to the loss of a centrosomal component. This possibility is unlikely, as we have found that NUD-1 is required for recruitment of the centrosome in C. elegans embryos when other PCM components, such as SPD-5, AIB-1, and ZYG-9, are depleted. Current efforts are focused on determining if nud-1 is required for the recruitment of these PCM components to the centrosome during cell division.

Flies without Centrioles, Centrosomes, Cilia, or Flagella

J. W. Raff, R. Basto, J. Lau; The Gurdon Institute, Cambridge, United Kingdom

Centrosomes and centrioles have an important role in many aspects of animal cell organisation, but it is uncertain to what extent they are essential for animal development. The Drosophila protein DSpd-2, a homologue of the C. elegans centriolar protein Sas-4. We show that DSas-4 is essential for centriole replication in flies. DSas-4 mutants start to lose centrioles during embryonic development, and, by 3rd instar larval stages, no centrioles or centrosomes are detectable. Mitotic spindle assembly is slow in mutant cells, and ~30% of the asymmetric divisions of larval neuroblasts are abnormal. Nevertheless, mutant flies develop with near normal timing into morphologically normal adults. These flies, however, are uncoordinated and fail to feed, move or mate due to the lack of basal bodies in their sensory neurons. Live analysis of dsas-4 mutant third instar larval neuroblasts revealed however, that a proportion (~20%) of the asymmetric cell divisions of the larval nervous system are impaired. We would like understand which might contribute to the establishment of cell polarity in the absence of centrioles in ~80% of dsas-4 mutant cells. To do so, using a live imaging approach in larval brain cells, we are dissecting the cellular consequences of combining the dsas-4 mutation with other mutations in various other cell cycle and polarity genes. We are also investigating how the acentrosomal spindles of dsas-4 mutants can be aligned along the polarity axis. Using time-lapse video microscopy to follow MTs together with either polarity proteins or cell fate determinants suggest that cortical protein distribution is highly dynamic and can change to match the spindle axis.

Establishing Cell Polarity without Centrioles

R. Basto, J. Lau, J. W. Raff. Wellcome Cancer Research Institute, Cambridge, United Kingdom

Centrosomes are the major microtubule (MT) organising centers in many animal cells and contribute to a variety of processes such as PCM recruitment during mitosis, cell migration and the establishment of cell polarity. We have recently identified and characterised a new drosophila mutation, das-4, where centriole replication is abolished. DAs-4 is related to the C. elegans Sas-4 (a protein required for centriole replication) and with the human CENP-J, a gene mutated in the neuro disorder, Microcephaly. Like SPD-2, DSpd-2 localises to the centrosomes throughout the cell cycle and to the PCM in mitosis. In larval brain cells DSpd-2 is essential for the efficient recruitment of the mitotic PCM proteins γ-tubulin and Centrosomin (CNN), reflecting the conserved role of SPD-2 related proteins in centrosome maturation. However, centriole number is almost unperturbed in the Dspd-2 null mutant. Therefore, we conclude that the SPD-2 family proteins are not components of centriole replication machinery operating in all organisms/cell types, and the mechanisms utilised may differ depending on the cellular context. DSpd-2 mutant flies are viable but sterile. Mutant males exhibit severe defects in spermatogenesis, and the number of centrioles per spermatocyte is highly variable. Surprisingly, Dspd-2 is also maternal effect lethal, and mutant embryos do not develop beyond the first mitotic division. We are currently investigating the specific nature of these defects.

Dissecting SAK/PLK4 Function in Templated and De Novo Formation of Centrioles

M. Bettencourt-Dias,1 A. Rodrigues-Martins,1 M. Riparbelle,2 M. Gatt,1 L. Carpenter,3 C. Ferreira,2 G. Callaini,2 D. M. Glover;1 1Instituto Gulbenkian de Ciencia, Lisbon, Portugal, 2Department of Evolutionary Biology, University of Siena, Siena, Italy, 3Department of Genetics, University of Cambridge, Cambridge, United Kingdom

Sak/Plk4 (Drosophila) is a distinct member of the polo-like kinase family. We have recently reported that Drosophila cells progressively lose centrioles, the core structure of centrosomes, following downregulation of SAK by mutation or RNAi. SAK mutants lose their centrioles during the mitotic divisions preceding male meiosis but still produce cysts of 16 primary spermatocytes as in wild-type. Mathematical modelling of the stochyted cell divisions of spermatogenesis can account for such loss by defective centriole duplication. Depletion of SAK in human cells prevents centriole duplication and gives rise to mitotic abnormalities, pointing to a conserved role of this protein in centrosome biogenesis. To further dissect the function of SAK in centriole biogenesis we have overexpressed this kinase in both S2 cells and in Drosophila embryos. Overexpression of SAK leads to centrosome amplification. SAK overexpression during oogenesis leads to amplification of centrosomes in the embryo with developmental arrest. Both oogenesis and early embryogenesis are normal with centrosome amplification occurring at the end of first mitosis. Interestingly, fertilization is not needed for centrosome amplification to occur, indicating that redundant expression of SAK can lead to de novo centrosome formation. Here we explore this result to
further understand the role of SAK in templated and de novo centrosome formation. Differences in the pattern and timing of centrosome appearance in embryos and unfertilized eggs are consistent with their different origins. Hence, we show that SAK is a master regulator of centrosome biogenesis, being involved in both templated and de novo centrosome formation.

974  The Role of SYZ-5 in *C. elegans* Centrosome Duplication
N. B. Miliaras, M. K. Addappali, K. F. O'Connell; Laboratory of Biochemistry and Genetics, NIDDK/NIH, Bethesda, MD

The kinase ZYG-1 is essential for centriole duplication in the early embryonic cells of the nematode *Caenorhabditis elegans*. It is thought to function by recruiting a series of coiled-coil domain containing proteins that help assemble a new centriole adjacent to the parent one. However, in embryos that lack maternal ZYG-1 activity, this fails to occur, leaving the original centriole pair, provided by the sperm, as the sole microtubule-organizing center (MTOC) in the one-cell stage embryo. While the centrioles can separate (the first step required for centrosome duplication) and form a bipolar spindle, they cannot duplicate to form a new centrosome during the second mitotic division. This results in each blastomere in the two-cell stage embryo forming a monopolar spindle. To dissect the mechanism through which ZYG-1 functions in initiating centrosome duplication, a genetic screen for suppressors of zyg-1 (zyz) has been carried out. The suppressors rescue the complete temperature-sensitive lethality of the zyg-1(zyz) allele at 24°C. One such suppressor, zyz-5 (bos7) exhibits an aggregation of tubulin and other centrosomal proteins in the gonad of adult hermaphrodites and cytoplasts of early embryos at restrictive temperature. Furthermore, a majority of embryos display phenotypes consistent with cytokinetic failure, such as multiple centrosomes and over-replicated DNA at the one-and-two-cell stages. These phenotypes, are unaffected by the absence of ZYG-1, thus SYZ-5 is most likely a downstream target of ZYG-1 in the centrosome replication pathway. The main goals of this project are to understand how ZYG-1 acts through SYZ-5 to initiate centrosome duplication and how ZYG-1 itself might function as a regulator of centrosome duplication. We have identified an open reading frame that is mutated in the zyz-5 strain and are in the process of confirming the molecular identity of this gene.

975  Pcp89 Links Multiple Proteins, Including the Septation Initiation Network, to the Core of the Fission Yeast Spindle-Pole Body
J. A. Rosenberg,1 G. C. Tomlin,1 W. H. McDonald,1 B. E. Snyderman,1 E. G. Muller,1 J. R. Yates,1 K. L. Gould,1 Howard Hughes Medical Institute and Cell and Developmental Biology, Vanderbilt University, Nashville, TN, 1The Scripps Research Institute, La Jolla, CA, 2Department of Biochemistry, University of Washington, Seattle, WA

The spindle-pole body (SPB), the yeast analog of the centrosome, serves as the major microtubule (MT) organizing center in the yeast cell. In addition to this central function, the SPB organizes and concentrates proteins required for proper coordination between the nuclear-division cycle and cytokinesis. For example, the Schizosaccharomyces pombe septation-initiation network (SIN), which is responsible for initiating asymmetric cell division and cytokinesis, is assembled at the SPB through its two scaffolding components, Sid4 and Cdc11. In an effort to identify novel SIN interactors, we purified Cdc1 and identified by mass spectrometry a previously uncharacterized protein associated with it, Pcp89. Pcp89 localizes constitutively to the SPB and interacts directly with Sid4. pcp89A cells are inviable and exhibit defects in SPB integrity, and hence spindle formation, chromosome segregation, and SIN and γTuC localization. Pcp89 overproduction is lethal, resulting primarily in a G2 arrest accompanied by massive enlargement of the SPB and increased SPB MT nucleation. These results suggest a fundamental role for Pcp89 in organizing the SIN, γTuC, and structural elements of the *S. pombe* SPB. Currently we are investigating the role of phosphorylation of γTuC members Sid1 and Mto2.

976  A Functional Genomic Analysis of SCF Ubiquitin Ligases and Their Roles in Centrosome Duplication and Cell Cycle Progression
G. Rogers, S. Rogers, Biology, University of North Carolina at Chapel Hill, Chapel Hill, NC

During mitosis in eukaryotic cells, centrosomes organize the poles of the mitotic spindle in order to guide segregating chromosomes to each daughter cell. However, in cells that have either too many or too few centrosomes, chromosome segregation may occur asymmetrically (on a multipolar spindle) or may not occur at all (on a monopolar spindle), resulting in aneuploid cell divisions and genomic instability. In order to ensure proper chromosomal inheritance, cells must duplicate the centrosome only once per cell cycle. A centrosome "licensing factor" may exist to regulate duplication only once itself, or by signaling ubiquitin-dependent degradation. Allen has shown that the regulatory subunit of the anaphase-promoting complex regulates centrosome duplication and that its license is essential for centrosome cell cycle progression, the molecular components involved remain largely unknown. Genetic analyses of centrosome duplication in *Drosophila* have implicated ubiquitin-mediated protein degradation as mutations in subunits of the SCF E3 ubiquitin ligase (SkpA and the F-box protein, Slmb) result in the production of supernumerary centrosomes. To expand upon these initial findings, we have conducted a functional genomic analysis of all Roc, Cullin, Skp and F-box family members using RNAi in cultured *Drosophila* cells. Measurements of centrosome number within the context of the cell cycle allowed us to identify a putative SCF complex containing SkpB and Slmb that is required to prevent centriole amplification. In addition, slmb-GFP expressed in living S2 cells localizes asymmetrically to centrosome tips in a cell cycle-dependent manner where it may work to ubiquitinate a centrosome licensing factor.

977  The Essential Function of CylA in Centrosome Re-duplication Is to Prevent the Degradation of Mps1 at Centrosomes
H. A. Fisk,1 C. Kasbek,1 C. Yang,1 S. Tae,1 M. Winney1;1 Molecular Genetics, The Ohio State University, Columbus, OH, 2MBCD Biology, University of Colorado, Boulder, CO

Centrosomes are microtubule organizing structures that orchestrate assembly of the mitotic spindle apparatus, and their duplication must be tightly controlled to ensure spindle bipolarity. Many human tumors possess extra centrosomes that produce anisometric and abnormally large mitotic spindles and lead to aneuploidy. One possible mechanism to explain their occurrence is the overproduction of centrosomes during S-phase. Called centrosome re-duplication, this requires Cdk2 and in human cells has been shown by others to require overexpression of the Cdc2 partner cyclin A. We previously demonstrated that one function of Cdk2 is to prevent the degradation of one of its substrates, the Mps1 protein kinase. We have now found that Cdk2 modulates a centrosome-specific Mps1 degradation mechanism, and that cyclin A-dependent centrosome re-duplication is mediated by Mps1. Overexpression of cyclin A increases the levels of Mps1 at centrosomes, and Mps1 siRNAs prevent cyclin A-dependent centrosome re-duplication. In contrast, cyclin A siRNAs reduce the centrosomal levels of Mps1 without affecting other Mps1 pools. We have identified the Mps1 degradation signal and shown that its phosphorylation by Cdk2 is required for the function of Mps1 in centrosome re-duplication. Furthermore, when the Mps1 degradation signal is removed Mps1 accumulates at centrosomes and causes centrosome re-duplication even in the presence of cyclin A siRNAs. Therefore, our data supports a model whereby the essential function of cyclin A in centrosome re-duplication is to prevent the degradation of Mps1 at centrosomes, and preventing Mps1 degradation by other means completely bypasses the requirement for cyclin A. Cyclin A is overexpressed in a variety of human tumors, and these results suggest a simple mechanism for genomic instability in such tumors.

978  Heat Shock Protein 27 Plays a Role in Neurite Growth Independent of Its Chaperone Like Activity and Role in Thermoprotection
K. L. Williams, M. Rahimtula, K. M. Mearow; Basic Medical Sciences, Memorial University of Newfoundland, St. John's, NF, Canada

We have previously shown that heat shock protein 27 (Hsp27) is involved in neurite extension and branching in adult rat dorsal root ganglion neurons (DRGs) in vitro. Specifically, downregulation of endogenous Hsp27 by small interfering RNA (siRNA) resulted in decreased neurite tree length and complexity, while an increase in exogenous Hsp27 resulted in an increase in neurite tree length and complexity. In this series of experiments we have tried to further elucidate the role of Hsp27 in neurite growth by simultaneously knocking down Hsp27 protein levels by siRNA and overexpressing either wild type Hamster Hsp27 or a mutant form of Hamster Hsp27. This mutant form of Hsp27 has a deletion between amino acids 5 and 23 which removes the thermal shock protein like activity of Hsp27. This mutant form of Hsp27 has a deletion between amino acids 5 and 23 which renders the protein with no thermoprotection or chaperone like activity. Results show that expression of Hsp27 Δ5-23 rescues the decrease in neuritic tree length and complexity of neurons the increased endogenous Hsp27 is depleted by siRNA. The neurite growth resulting from rescue with the Hsp27 Δ5-23 construct is equivalent to growth observed via rescue with exogenous wild type Hsp27. Additionally expression of Hsp27 Δ5-23 results in increased branching compared to expression of exogenous wild type Hsp27. The ability of Hsp27 Δ5-23 to rescue growth indicates that Hsp27 plays a role in neurite growth and branching independent of its role in thermoprotection and its chaperone like activity. Supporting our hypothesis that Hsp27 may play a role in neurite growth via modulation of the actin cytoskeleton, rather than through its activity as a chaperone.

979  Live Cell Imaging of Sce Tyrosine Kinase in Neuronal Growth Cones
B. Wu, B. Decourt, M. A. Zahbidi, L. T. Wuetrich, K. MacIsaac, W. H. Kim, D. M. Suter; Department of Biological Sciences, Purdue University, West Lafayette, IN

Sce tyrosine kinases have recently been implicated in signal transduction pathways downstream of various membrane receptors controlling neurite outgrowth and axon guidance. However, surprisingly little is known about the detailed temporal and spatial distribution of these key signaling proteins in the neuronal growth cone. To address this problem we took advantage of the
Aplysia growth cone system which is well suited for high-resolution live imaging of protein dynamics. We have identified two novel members of the Src family of protein tyrosine kinases in Aplysia, termed Src1 and Src2, using a homology-based PCR approach. Amino acid sequence alignments suggest that these two kinases belong to two distinct subfamilies of invertebrate Src tyrosine kinases. We produced Aplysia Src1- and Src2-specific antibodies and C-terminal EGFP-fusion proteins to study the distribution of these two kinases in both fixed and live growth cones of cultured Aplysia bag cell neurons. Expression of wildtype Src1- and Src2-EGFP by microinjection of in vitro transcribed mRNA revealed a homogenous plasma membrane-associated distribution of these two kinases. The EGFP construct design do not interfere with the regulation of expressed Src. Time lapse imaging of Src-EGFP fusion proteins revealed Src-positive organelles undergoing dynamic movements particularly in the transition zone and central domain, potentially by F-actin and microtubule association. Immunocytochemistry with peptide antibodies revealed a punctate distribution of Src1 and Src2 throughout the growth cone. Src1 is enriched in the central domain, while active Src2 accumulates in filopodia tips, which is consistent with the localization of constitutively active mutant of Src2-EGFP. Double immunofluorescence labeling and biochemical cell fractionation data indicate a partial association of active Src2 with microtubules. Our findings suggest that distribution of Src is partially regulated by cytoskeletal structures in neuronal growth cones.

980 Biochemical and Cell Biological Analyses of a Developmentally Regulated Septin, Sept8, Enriched in Presynaptic Nerve Terminals
H. Ito,1 I. Iwamoto,2 K. Sado,2 R. Morishita,1 K. Mizutani,2 Y. Nozawa,1 T. Asano,1 K. Nagata1; 1Department of Molecular Neurobiology, Institute for Developmental Research, Aichi Human Service Center, Aichi, Japan, 2Gifu Graduate School of Medicine, Gifu, Japan, 3Gifu International Institute of Biotechnology, Gifu, Japan

The septins are members of a conserved family of cytoskeletal GTPases present in organisms as diverse as yeast and mammals. Thirteen septin genes have so far been identified in mammalian cells. We analyzed the distribution of five septins, Sept6, Sept7, Sept8, Sept9 and Sept11, in various rat tissues by western blot analysis using specific antibodies, and found all septins to be expressed in brain. Especially, Sept6 and Sept8 were preferentially expressed in brain. Further analyses revealed that they were expressed in distinct manners in thirteen brain regions. We also examined the developmental changes of the expression of the five septins in the rat brain and found that levels of several isoforms of Sept8 differentially increased during developmental stage. Immunofluorescence studies revealed that Sept8 is well co-localized with a presynaptic marker, synaptophysin, in matured rat hippocampal neurons, strongly suggesting enrichment at synapses. Using yeast two-hybrid screening and immunoprecipitation assay, we identified the soluble N-ethylmaleimide-sensitive factor attachment protein receptor protein, synaptobrevin, as a binding partner for Sept8. These results suggest that Sept8 may participate in the regulation and/or maintenance of synapse function(s) such as neurotransmitter release.

981 Identifying Genes Involved in Transport of Mitochondria in C. elegans Neurons
S. Mohan,1 G. Reddy,1 S. Johri,1 M. Nouni,3 S. Koushika1; 1NCBS-TIFR, Bangalore, India, 2School of Medicine, Washington University, St. Louis, MO

The growth, maintenance, and survival of neurons rely critically on transport between the cell body and the synapse. Mitochondria participate in many functions which include ATP production, calcium homeostasis and apoptosis. The failures of mitochondrial function and distribution are thought to underlie excitotoxic injury and diverse neuropathological disorders such as Alzheimer’s and Parkinson’s disease. Mitochondria, unlike other organelles are transported bi-directionally and remain stationary for 75% of the time. To address this question we take a classical genetic approach using a transgenic strain jsIs609 in which GFP is targeted to the mitochondrial matrix. This is under the control of a cell-specific promoter which specifically expresses in the six mechanosensory neurons of C. elegans. We have performed EMS mutagenesis and screened approximately 3000 genomes for abnormal mitochondrial distribution and localization. We have isolated 16 mutants that fall into 4 classes. We are currently performing complementation analyses with these mutants. 50-100% increase in number of mitochondria in the axons. •50 - 100% decrease in number of mitochondria in the axons. •Accumulation of globular mitochondria in the cell body. •Accumulation of mitochondria in the minor neurite. We have also analyzed the distribution of mitochondria in mutants with known roles in axonal transport and mitochondrial dynamics viz: unc-1, rab-7, unc-116, unc-16. In unc-116 Kinesin-1 mutants there are fewer mitochondria, however in unc-16 JIP3/JASP1 there more mitochondria. To analyze the mitochondrial dynamics due to metabolism, starvation analyses was done and distribution with different food sources. We find that the cell bodies of the neurons are fragmented during starvation and takes more than one generation to regain their normal phenotype but the axons was spared and is normal. There was no change in mitochondrial distribution and localization with different food sources. We are currently imaging mitochondrial motility and dynamics in vivo.

982 Large-scale Purification of Neurites and Quantitative Proteomics Reveals Spatial Organization of Protein Networks and Novel Proteins Involved in Neuronal Polarization
O. Pertz,1 Y. Wang,1 F. Yang,1 J. M. Jacobs,1 D. G. C. Camp,2 R. D. Smith,2 R. L. Klenke1; 1Department of Pathology and Moores Cancer Center, University of California San Diego, La Jolla, CA, 2Biological Sciences Division, Environmental Molecular Sciences Laboratory, Pacific Northwest National Laboratory, Richland, WA

Neurons morphologically polarize by extending neurites directionally in response to soluble chemokine gradients and adhesive cues present in the extracellular environment. However, while spatial regulation of neuritogenesis is critical for axon and dendrite formation during brain development, the molecular mechanisms that initiate neuronal polarity and guide neurite extension are poorly defined. This is largely due to the inability to differentially isolate the neurite and soma for large-scale biochemical analysis of protein networks. Here we utilize a novel microporous filter system that facilitates large-scale neurite purification and quantitative proteomics to characterize the spatial organization of protein isolated from polarized neurons. Using this system, we identified 5073 proteins of which 2074 were found to be significantly increased in the neurite compartment. Bioinformatic and functional cluster analysis of neurite enriched proteins revealed signaling networks largely involved in the regulation of the actin/myosin cytoskeleton, whereas analysis of the cell soma compartment revealed protein networks involved in nuclear function and metabolism. Importantly, we also uncovered several novel proteins important for neuritogenesis. Currently, we are functionally testing these proteins to determine their role in neuritogenesis and cell polarization. Together our findings provide valuable insight into mechanisms of neuronal polarization by revealing spatially regulated protein networks that control neuritogenesis. These findings are important for understanding mechanisms of brain development as well as neurodevelopmental conditions associated with neurodevelopmental diseases and spinal cord injury.

983 Neurite Purification Using Microporous Technology Reveals Spatio-temporal Dynamics of Erk Activation during Neurite Outgrowth and Collapse
O. Pertz,1 M. M. Holcomb, R. L. Klenke; Department of Pathology and Moores Cancer Center, University of California San Diego, La Jolla, CA

Neuritogenesis and axonal guidance are key cellular processes necessary for proper development of the adult nervous system. In both processes, directional neurite extension depends on precise cytoskeletal and adhesion dynamics induced by sensing of attractive and repulsive extracellular cues. However, the inability to biochemically purify significant amounts of neurites has precluded large-scale spatial analysis of this structure. This has limited our ability to understand mechanisms of neuronal polarity and neuritogenesis. Here, we examine the temporal and spatial role of ERK signaling in neuritogenesis using a novel microporous filter system that allows large-scale biochemical purification of extending or collapsing neurites from neurons polarized towards a laminar gradient. We found that Erk activity is dramatically and spatially enriched in the extending neurite relative to the cell soma. Inhibition of ERK activity with PD98059 prevented neurite formation indicating that ERK kinase activity and phosphorylation of downstream substrates are necessary for this process. Interestingly, exposure of neurites to the collapsing agent lysophosphatidic acid (LPA) facilitated inactivation of ERK leading to growth cone and neurite collapse. Finally, neurite extension and retraction processes are regulated by integrin dependent Rac/PAK signals that converge on MEK, the upstream regulator of ERK. These data point to Erk as an important signaling switch that facilitates neurite outgrowth and collapse in response to neuronal cues provided by the extracellular matrix. These findings are important for understanding spatial signaling mechanisms that contribute to brain development as well as neurodevelopmental conditions associated with neurodevelopmental diseases and spinal cord injury.

984 Novel Membrane Targeting Compounds Promoting Axon Regeneration
J. Wong,1 H. Brastianos,2 R. Andersen,2 T. P. O’Connor1; 1Cellular and Physiological Sciences, University of British Columbia, Vancouver, BC, Canada, 2Earth and Ocean Sciences, University of British Columbia, Vancouver, BC, Canada

During axon development, a delicate interplay between lipid microdomains, signaling molecules and the downstream cytoskeletal components is necessary to regulate axon outgrowth and pathfinding. Following axotomy, axons regeneration typically fails to occur in the adult central nervous system due to the presence of extrinsic inhibitors, as well as the reduced regenerative capacity of the damaged axons. Given the role of lipid microdomains in axon development, we are currently screening for membrane targeting amphiphilic small molecules that promote regeneration of CNS axons on inhibitory myelin and CSPG substrates. We have recently identified a lipopophil extract in marine sponge that promotes neurite outgrowth on inhibitory
substrates. Further characterization of this extract may provide insight into how lipid microdomains influence axon outgrowth and pathfinding, and how lipid raft manipulation can promote axon regeneration in the adult CNS.

985
Analysis of the Microtubule-associated Proteome during Neuronal Morphogenesis
E. Hwang,1 J. Tipton,2 J. Busby,2 S. Halpain1; 1Department of Cell Biology, The Scripps Research Institute, La Jolla, CA, 2Department of Proteomics, Scripps Florida, Jupiter, FL
During nerve cell development, newly postmitotic neurons transform from seemingly unpolarized cells into highly polarized ones. These highly polarized neurons contain long cellular processes termed neurites that are filled with the microtubule (MT) cytoskeleton, and will later mature into axons or dendrites. It has been shown that the morphological change during neuronal development depends on the organization of the MT cytoskeleton. Although many of the later stages of neuronal development (e.g., axon outgrowth, axon guidance, and synaptogenesis) have been extensively studied, little is known about the very first step, the initial sprouting of a neurite, termed "neuritogenesis" or "neurite initiation". Although a handful of MT-associated proteins are known to play important roles during neurite initiation, a comprehensive proteomic analysis focusing on the MT cytoskeleton during this process is lacking. To better understand the mechanisms controlling neuritogenesis, it is of great advantage to perform a proteomic analysis focusing on the MT-associated proteome involved in this process. We have conducted mass spectrometry and gel-based methods to analyze MT-associated proteins before and shortly after neurite initiation. We have found 10 MT-associated proteins to be specifically enriched during the neuronal differentiation; more than 2 dozens to be present in both undifferentiated and differentiated cells. These results provide the basic compositional change of the MT cytoskeleton during neuronal differentiation and will help us identify specific MT-associated proteins that are key mediators of neurite initiation.

986
Distinct Roles of Doublecortin Modulating the Microtubule Cytoskeleton
C. A. Moores,1 M. Perderiset,2 C. Kappeler,1 S. Kain,1 D. Drummond,3 S. J. Perkins,4 J. Chelly,5 R. Cross,6 A. Houdusse,2 F. Francis1; 1Department of Crystallography, Birkbeck College, London, United Kingdom, 2Centre d'Etudes des Structures Chimiques et Biologiques (CIESC), Paris, France, 3Department of Pathology, Columbia University, New York, NY, 4Department of Radiology, Columbia University, New York, NY, 5Department of Neurology, Columbia University, New York, NY
Doublecortin is a neuronal microtubule stabilising protein, mutations of which cause mental retardation and epilepsy in humans. How doublecortin influences microtubule dynamics, and thereby brain development, is unclear. We show by video microscopy that purified doublecortin has no effect on the growth rate of microtubules. However, it is a potent anti-catastrophe factor that stabilises microtubules by linking adjacent protofilaments and counteracting their outward bending in depolymerising microtubules. Using an in vitro motility assay, we found that doublecortin-stabilised microtubules are substrates for kinesin translocate motors and for depolymerase kinesins. Doublecortin does not itself oligomerise, as judged by analytical ultracentrifugation. It does not bind to tubulin heterodimers but does nucleate microtubules. In cells, doublecortin localises to the distal ends of neuronal processes and our data raise the possibility that the function of doublecortin in neurons is to drive assembly and stabilisation of non-centrosomal microtubules in these doublecortin-enriched distal zones. These distinct properties combine to give doublecortin a unique function in microtubule regulation, a role that cannot be compensated for by other microtubule stabilising proteins and nucleating factors.

987
MARK2/Par-1 Mediated Neuronal Migration
O. Reiner,1 T. Sapir,2 S. Saposnik,1 E. Mandelkow,2 T. Timm,1; 1Molecular Genetics, Weizmann Institute, Rehovot, Israel, 2Max-Planck-Unit for Structural Molecular Biology, Hamburg, Germany
Our results depict a novel role for microtubule affinity-regulating kinase (MARK2/Par1) in neuronal migration. Using in utero electroporation, we have been able to dissect the two tasks of MARK2/Par1 during cortical development: neuronal polarity and neuronal migration. Neuronal migration retardation, which is observed following introduction of MARK2/Par1 RNAi, is associated with MARK2 kinase activity. This was demonstrated by either overexpression of kinase active and kinase dead versions of MARK2/Par1, or by overexpression of MARK2/Par1 specific inhibitor PAK5. A kinase dead version of PAK5 has no affect on the actin cytoskeleton yet was able to partially inhibit neuronal migration via its suppressive activity on MARK2/Par1. Furthermore, we identified novel MARK2/Par1 substrates, which include LIS1 and interacting proteins. Reduction in MARK2/Par1 levels results in centrosomal - nuclear uncoupling, a known LIS1 mediated function. These results suggest that MARK/Par1 is a key regulator of neuronal migration by its affect on multiple MAPs some of which have pivotal roles during the development of the cortex. In addition our results suggest a link between LIS1 and the MARK2/Par1 cascade, thus placing LIS1 downstream of the polarity pathway. These observations are synergistic to a previous study situating LIS1 upstream to Rho GTPases. Combining the position of LIS1 as a target of the polarity kinase as well as a small GTPase regulator suggests an exciting feedback regulatory role for LIS1.

988
A Role for Dynnein, Dynactin, and LIS1 in Growth Cone Remodeling and Rapid Axonal Growth
G. E. Seale,1 J. P. W. Grabham,1 M. Bennech,1 D. J. Goldberg,2 R. B. Vallee1; 1Dept. of Pathology, Columbia University, New York, NY, 2Center for Neurobiology and Behavior, Columbia University, New York, NY
Mechanisms in Neurite Initiation: Dynein-dependent Induction of Cell Protrusions
L. Dehmelt,1 P. Nalbant,2 W. Steffen,3 S. Halpain1; 1Department of Cell Biology, The Scripps Research Institute, La Jolla, CA, 2Department of Molecular and Cellular Physiology, University Hannover, Hannover, Germany
A key event in neurite initiation is the accumulation of microtubule bundles at the neuron periphery, which subsequently form thin protrusions that extend from the cell body. We hypothesized that such bundled microtubules may generate a force at the plasma membrane that induces local protrusions, which then become the focal point for neurite outgrowth. To test this idea we observed the behavior of microtubule bundles that were induced by the microtubule-associated protein MAP2c. Endogenous MAP2c contributes to neurite initiation in primary neurons, and exogenous MAP2c is sufficient to induce neurites in Neuro2a cells. During nocodazole washout in Neuro-2a and COS7 cells, small bundles formed rapidly throughout the cytoplasm and immediately began to move toward the cell periphery in a unidirectional manner. Spindle microscopy indicated that such movement was due to bundle transport, not treadmilling. At the periphery bundles remained under a unidirectional force and induced local cell protrusions that were further enhanced by suppression of Rho kinase activity. Surprisingly, this bundle motility was independent of classical actin- or microtubule-based tracks. It was, however, reversed by function-blocking antibodies against dynnein. Suppression of dynnein expression in primary neurons by RNA interference severely inhibited the generation of new neurites, but not the elongation of existing neurites formed prior to dynnein knockdown. These data suggest that neuronal microtubule-associated proteins induce microtubule bundles that are pushed outward by dynnein and locally override inward contraction to initiate a neurite.

The Mitotic Motor, Eg5: Functions as a “Brake” on Short Microtubule Transport to Regulate the Rate of Axonal Outgrowth  
K. A. Myers, P. W. Basas; Neurobiology and Anatomy, Drexel University College of Medicine, Philadelphia, PA  
Eg5 is a plus-end-directed motor protein that is required for the formation and proper segregation of the bipolar mitotic spindle. Four molecules of Eg5 form a homotetramer with the motor domains projected outward; the homotetramer can drive oppositely oriented microtubules apart or can zipper and crosslink microtubules of the same orientation. We have previously shown that Eg5 is expressed in terminally postmitotic neurons, and that pharmacologic inhibition of its activity results in enhanced rates of axonal growth. Here, we used either monostable treatment or siRNA-based depletion of Eg5 to investigate the mechanism underlying this observation. Similar to monostable treatment, siRNA-based depletion of Eg5 resulted in a sharp and statistically significant increase in the rates of axonal growth to levels approximately five times greater than displayed by control neurons. Enhanced axonal growth rates were accompanied by augmented axonal length, increases in axonal branching frequency, and heightened numbers of growth cones. To explore how this might occur, we evaluated the behavior of vesicular cargo and short microtubules, both of which are transported bi-directionally in the axon during its growth. There was no change in the rates or distances of vesicle movement. However, inhibition of the Eg5 motor did result in a significant and bi-directional increase in the frequency of short microtubule transport, to levels approximately 45% greater than controls. Taken together, these data suggest a model in which neuronal Eg5 functions not as a classical vesicle-associated kinesin, but rather as a brake against the other motor-driven forces utilized to transport short microtubules within the axon. This conclusion is consistent with the expected properties of the Eg5 homotetramer, given that axons contain uniformly oriented microtubules. We propose that there exists a direct relationship between the frequency of short microtubule transport, as regulated by the Eg5 motor, and the rate of axonal growth.

Filopodial Actin Bundles Help Neuronal Growth Cone Generate Assembly Dependent Push  
D. T. Burnett,1 A. W. Schaefer,1 L. J.;2 D. Gaudenz,1; P. Forscher1; 1MCDB, Yale University, New Haven, CT, 2Department of Cell Biology, Scripps Research Institute, La Jolla, CA  
Two actin filament components normally assemble at the leading edge of growth cones: polarized actin bundles that create the cores of filopodia and intervening isotropic actin networks. Both of these actin structures move at the same rate by retrograde actin flow under control conditions; however, their movement slows by about 50% after Myosin II inhibition with Blebbistatin. Evidence suggests that the “push” driving this residual retrograde flow is provided by actin assembly at the leading edge. Acute treatment with low doses (350 nM) of Cytocalasin B (CB) resulted in immediate retraction of non-polarized growing actin bundles but had essentially no effect on retrograde flow rates or peripheral isotropic actin network structure. This resulted in growth cones depleted of filopodia as judged by fluorescent speckle microscopy and ultrastructural analysis. Interestingly, in growth cones without filopodia, retrograde flow rates were now much more sensitive to myosin II inhibition. Our previous studies provided evidence that actin assembly alone could drive the retrograde flow at surprisingly fast rates. Our current results further suggest that filopodial actin bundles allow network assembly dependent pushing forces to develop more efficiently.

Myosin II Mediates Actin/Microtubule Interactions during Inhibition of Growth Cone Advance  
M. L. Koeppel, E. A. Hogan; Biology, Canisius College, Buffalo, NY  
Our previous experiments suggest a role for actin/microtubule interactions during inhibition of growth cone advance in the absence of growth cone collapse. Treatment with jasplakinolide (jasp), a toxin that inhibits actin turnover, triggers an organelle withdrawal response (OWR), characterized by the removal of organelles from the central domain into the axon, concomitant with increased microtubule(MT) invasion of the growth cone peripheral domain. We have proposed that MTs serve as a substrate for the centripetal movement of F-actin and organelles out of the growth cone. Here, we tested the role of myosin in mediating the interactions between MTs and F-actin during the OWR by treating neurons simultaneously with blebbistatin, a specific myosin II ATPase inhibitor, and jasp (bleb/jasp). Time-lapse microscopy showed that treatment with bleb/jasp counteracted the effects of jasp treatment in 60% of the growth cones, resulting in an expansion of the central domain region into the peripheral domain. In the remaining 40% of jasp treated growth cones, the organelle withdrawal distance was reduced 2.5 x compared to jasp treated growth cones. To determine if jasp inhibition of the OWR was due to its effects on myosin II or to inhibition of MT invasion into the peripheral domain, we used tubulin immunofluorescence/DIC microscopy to determine the position of MT ends from the leading edge of the growth cone. Inhibition of myosin II activity did not affect MT invasion into the growth cone, as there was no significant difference (T test, 0.05) in MT end position between jasp and bleb/jasp treated neurons, while there was a significant decrease (2 fold) in MT end position in bleb/jasp growth cones compared to untreated growth cones. These results suggest a role for myosin II in mediating the MT-dependent OWR response.

The Role of Tropomyosin Isoforms in Neurite Outgrowth  
T. Fath, 1 H. Clarke,1 G. Schevoy,1 P. Gunning2; 1Oncology Research Unit, Children’s Hospital at Westmead, Westmead, Australia, 2Department of Pathology, University of Sydney, Sydney, Australia  
Alpha-tubulin is subject to various post-translational modifications among which a cycle of detyrosination-tyrosination. TTL is the enzyme responsible for the re-addition of the C-terminal residue after its removal by an unknown carboxypeptidase. Tyrosinated-tubulin is found distally, at the dynamic end of microtubules whereas detyrosinated-tubulin is enriched in stable microtubules. Although the physiological role of this cycle is poorly understood, TTL has been shown to be involved in the control of neurite outgrowth. We have further investigated its role by analyzing the hindbrain development in TTL null mice. In particular, we have characterized the migration of Inferior Oliveary Neurons (ION) that consists in the emission of a leading process and further translocation of the nucleus inside it (nucleokinesis). Despite an overall normal cyto-architecture of the ION nucleus, TTL null mice showed an abnormal inter-olivary commissure after Dil retrograde tracing at birth. Consistent with this observation, we showed that growth cones were more spiny and enlarged in organotypic cultures when they met the floor-plate, an intermediate target that synthesizes various tropic molecules that guide ION migration. When migration was assayed in collagen matrix, axons poorly grew outside the hindbrain explant but nucleokinesis was not affected. Furthermore, interaction between actin and microtubules cytoskeletons in the growth cone was perturbed since microtubules bundles invaded the actin domain (peripheral domain) of the growth cone. These results led us to propose that tubulin tyrosinase is required for growth cone dynamic and response to guidance signals, especially at decision points. We are currently investigating the molecular cause(s) of the mis-regulation of the cross-talk between actin and microtubule cytoskeletons in growth cones.
Our aim is to reveal the mechanism by which Tms define these actin-filament populations. To address this aim we have generated mice deficient for specific Tm isoforms. The effect of eliminating products of the γTm gene which lack exon 9d (and thus isoforms TmSNM1/2) on neurons was analyzed in cortical cultures from 16.5 day old wild-type (wt), hemizygous or homozygous 9d-Tm knockout mouse embryos. The reduction of exon 9d-containing isoforms is compensated by an upregulation of exon 9c-containing isoforms. Preliminary experiments show that the loss of TmSNM1/2 leads to altered growth cone size and that the altered morphology is dependent on the relative levels of exon 9d and 9c containing isoforms. These results are consistent with earlier observations of altered growth cone size upon overexpression of exogenous TmSNM1 protein in cortical neurons and support the hypothesis that the composition of Tms can locally affect specific compartments of a cell. Further studies on alterations in the molecular composition of actin-filament populations upon manipulation of Tm protein levels will give us a better understanding of actin-cytoskeleton related processes which underlie neuronal morphogenesis and function.

**C. elegans Neural Ankyrin Interaction with CLASP2, PP2A, and Calcium**

A. J. Otsuka, P. Gong; Department of Biological Sciences, Illinois State University, Normal, IL

UNC-44 A031 ankyrin is found in the nervous system and is required for proper axon guidance (Otsuka et al., J. Cell. Biol., 129:1081-1092, 1995; Boontrakulpoontawee and Otsuka, Moloc. Genet. Genom., 267:291-302, 2002; Otsuka et al., J Neurobiol., 50:333-349, 2002). We recently found that AO13 ankyrin interacts with CLASP2, PP2A B’ subunits, and calcium ions (Gong and Otsuka, Moloc. Biol Cell (suppl.), 16:365a Abst. #1349, 2005). It is known from work by others that CLASP2 binds to the plus ends of microtubules at the leading edge of migrating cells, is under the control of the PI3-kinase and GSK-3β pathways, and is inhibited by phosphorylation. The carboxyl terminus of CLASP2 is required for cortical association in vertebrates, although the plasma membrane docking sites are unknown. We have found that the carboxyl end of CLASP2 binds to AO13 ankyrin which may serve as the cortical adapter molecule in neurons. Affinity-purified CLASP2 antibodies labeled the cytoplasm and, in some cases, labeled the cell periphery. In our previous work, we found that a 141-aa region of AO13 ankyrin was required for calcium binding. We have now narrowed the calcium-binding site to a two EF-hand structure within that region. Further, CLASP2 binds to the same two-EF-hand structure. The entire 141-aa region is needed for efficient binding of the two nematode PP2A B’ subunits. In addition to yeast two-hybrid and pull-down experiments demonstrating the PP2A-ankyrin interaction, we have now shown PP2A and AO13 ankyrin co-localize in neurons by antibody staining. The UNC-44 and CLASP2 interaction suggests that UNC-44 may act to capture CLASP2-tipped microtubules that are pioneering the growth cone filopodia. Further, it is possible that UNC-44 is a calcium sensor that affects microtubule and cortical interactions depending on the UNC-44 phosphorylation state.

**Developmental Regulation of Myosin II Expression and Function in Sensory Neurons**

A. R. Keshet, S. L. Jones, R. Puri, G. Gallo; Neurobiology & Anatomy, Drexel University College of Medicine, Philadelphia, PA

During development cultured sensory neurons switch from extending a single axon to extending multiple axons suggesting fundamental changes in the cytoskeletal mechanisms of axon extension. Myosin II is a mechanoenzyme that generates cellular contractile forces though interactions with actin filaments and is involved in axon extension and guidance. We report that in cultured chicken sensory axons the levels of myosin II undergo developmental down regulation between embryonic day (E) 7 and E14. Decreases in myosin II expression were observed in axons growing on laminin or polylysine coated substrata. Inhibition of myosin II using blebbistatin reduced the axon extension rate of E7, but not E14, neurons cultured on laminin. On polylysine, blebbistatin increased axon extension rate at both E7 and E14. The ability of axons to remain on laminin when encountering a laminin-polylysine border has previously been shown to require myosin II activity. We found that E7 axons remained on laminin with a greater frequency than E14 axons. Treatment with blebbistatin resulted in border crossing by both E7 and E14 axons, indicating that at both ages axon guidance is still dependent on myosin II. Axon retraction in response to pharmacological stabilization of the actin cytoskeleton using jasplakinolide results in myosin II dependent axon retraction. We found that E14 axons retracted at approximately half the rate of E7 axons in response to jasplakinolide, although the retraction at both ages was dependent on myosin II. Collectively these data indicate that the developmental decrease in the expression of myosin II in sensory neurons has functional consequences for axon extension and guidance. In future experiments, we will address whether re-expressing myosin II in E14 axons restores the dependence of axon extension and guidance on myosin II activity characteristic of E7 axons.

**Axonal Transport of Actin in Monomeric Form**

G. Gallo; Neurobiology and Anatomy, Drexel University College of Medicine, Philadelphia, PA

Cytoskeletal proteins are synthesized in the cell bodies of neurons and undergo slow axonal transport to the tips of axons. Whether cytoskeletal proteins are transported as monomers/dimers or as polymers is not clear. Previous evidence indicates that tubulin can be transported in polymeric form or as tubulin subunits. We tested whether actin can undergo transport in monomeric or filamentous form. Embryonic sensory neurons were transfected with photoactivatable GFP-actin and the movement of photoactivated actin was tracked in single axons. Photoactivated actin underwent net anterograde transport. In addition, we performed FRAP (Fluorescence Recovery After Photobleach) analysis in the distal axons of EGFP-actin expressing neurons. Pharmacological manipulation of the actin monomer/filament equilibrium in neurons revealed that if actin was driven into filamentous form by treatment with jasplakinolide FRAP failed to occur, and photoactivated actin filaments did not undergo transport. Conversely, depolymerization of filaments using latrunculinA or wiskinolideA did not prevent FRAP. Rather, when actin was driven into monomeric form the net FRAP increased relative to controls. Manipulating the equilibrium between actin monomers/filaments did not affect FRAP of EGFP-tubulin, indicating the effects are specific for the transport of actin. These data are interpreted to indicate that actin undergoes axonal transport in the form of monomers, and that incorporation of actin into filaments en route decreases the net flux of transported actin.

**Neurofilaments Spend More Time Pausing in Axons Lacking Myosin Va**

N. Alam, A. Brown; Center for Molecular Neurobiology, The Ohio State University, Columbus, OH

Neurofilaments move rapidly along axons but their overall rate is slow because they spend most of the time pausing. The motors for neurofilament transport are thought to be dynein and kinesin, which move along microtubules, but neurofilaments also interact with myosin Va, which moves along microfilaments. Interestingly, neurofilament number is increased in axons of dilute lethal mice, which lack myosin Va. To investigate whether myosin Va is a neurofilament motor, we previously compared the velocity and short-term pausing behavior of GFP-tagged neurofilaments moving through gaps in the axonal neurofilament array of cultured SCG neurons from wild type and dilute lethal mice and found no significant difference. Now we have extended that study by comparing the long-term pausing behavior of GFP-tagged neurofilaments in cultured wild type and dilute lethal DRG neurons using a fluorescence photoactivation pulse-escape technique. Neurons were transfected with a photoactivatable green fluorescent neurofilament fusion protein and then neurofilaments were photoactivated in a short segment of axon. The fluorescent neurofilaments departed from the activated region with exponential kinetics at a rate dictated by their pause durations. Statistical comparison of the log-transformed kinetics using an autoregressive linear mixed model revealed a significant difference (p<0.001), with an average half life of 3.0 hours in wild type neurons (n=27) and 4.4 hours in dilute lethal neurons (n=25). Since the velocity was unchanged, these data indicate that neurofilaments spend approximately 50% more time pausing in dilute lethal DRG neurons than in wild type. We propose that myosin Va is a short-range neurofilament motor and functions to deliver neurofilaments to their microtubule tracks, thereby increasing the efficiency of neurofilament transport. In the absence of myosin Va, neurofilaments that are not close to microtubules can become stranded and therefore pause for more time, which can explain their accumulation in axons of dilute lethal mice.

**Microtubule-induced Focal Adhesion Disassembly Requires Clathrin**

E. J. Erzatty, 1 G. E. Marcantoni, 2 G. G. Gundersen, 1; 1Anatomy and Cell Biology, Columbia University, New York, NY, 2Pathology, Columbia University, New York, NY

Focal adhesion disassembly is an important aspect of cell migration that is not well understood. We recently developed a new approach to study focal adhesion disassembly, based on the observation that microtubule (MT) regrowth following nocodazole washout induced disassembly of focal adhesions in NIH3T3 fibroblasts, a process that was dependent on focal adhesion kinase (FAK) and dynamin (Erzatty, et al., Nature Cell Biology, 2005). These results suggested that a rate limiting step during focal adhesion disassembly may involve endocytosis. To test this hypothesis we examined the effects of heavy chain transferrin-loaded carriers, as well as transferrin uptake in Clathrin heavy chain, but not light chain, localized to a subset of focal adhesions when visualized using total internal reflection fluorescence microscopy. We screened clathrin adapter proteins for co-localization with FAK, and found that the adapter protein disabled-2 co-localized with focal adhesions, whereas AP2 and mum were excluded from these structures. Disabled-2 may directly inhibit endocytosis at focal adhesions during focal adhesion disassembly, since the phosphotyrosine binding domain of disabled-2 binds the cytoplasmic tail of integrins (Calderwood et al., PNAS 2003). To test if...
integrins are internalized during focal adhesion disassembly, we used antibody labeling and flow cytometry to monitor the surface expression of α5 integrin during MT-induced focal adhesion disassembly. Levels of surface α5 integrin decreased by over 50% during MT-regrowth following nocodazole washout. The loss of surface integrin was specific for extracellular matrix bound integrin as the surface levels of the collagen receptor α1 integrin in fibroblasts adhering to fibronectin remained unchanged during disassembly. In these same cells, α5 integrin levels were significantly diminished. These data suggest that extracellular matrix-bound integrin is specifically internalized from focal adhesions. We propose that MT-induced focal adhesion disassembly occurs via clathrin-dependent endocytosis of α5β1 integrin from focal adhesions.

A Live Cell Assay to Visualize the Activation of Integrin Adhesion Receptors
J. A. Galbraith, C. G. Galbraith, NINDS, National Institutes of Health, Bethesda, MD, NIDCR, National Institutes of Health, Bethesda, MD
Migrating cells continually extend protrusions to probe the surrounding matrix in search of new sites to form adhesions with the extracellular matrix. The adhesions are initiated at the front of the cell; however, the precursor events in adhesion formation such as the spatial regulation of initial integrin activation are largely unknown. Using a new assay, we can temporally and spatially visualize and track the conformational state of integrins in living cells. We have seen the previous appearance of actin-unlinked unligated integrin adhesion receptors at the leading edge of migrating cells. When we incubate a fluorescently labeled antibody targeted against conformationally activated integrin adhesion receptors rapidly labels all high-affinity receptors on the surface of a cell, including the ligated adhesion receptors in established adhesions. Any subsequent labeling of the cell surface during a live cell experiment indicates where high-affinity integrins appear on the cell surface. This version of an antibody capture assay produces a fluorescently “speckled” cell surface where the speckles indicate conformationally activated integrin adhesion receptors. The movement of the activated integrins can then be tracked using single particle tracking analysis routines. We see the newly activated integrins appear at the leading edge before moving rearward on the treading cell membrane. These data are consistent with laser trap experiments demonstrating an increased avidity of integrin adhesion receptors at the leading edge of migratory cells. Thus, this new live cell antibody capture assay allows us to visualize changes in integrin activation state during the initial development of adhesion complexes, and track the movement of these newly activated integrins on the cell surface.

Talin-Actin Binding and Focal Adhesion Turnover Is Regulated by pH
Focal adhesion (FA) turnover, a major determinant in tissue remodeling and cell movement, is in part regulated by talin, which tethers the actin cytoskeleton to integrin adhesion complexes through its binding to integrins and F-actin. We previously reported that FA turnover is dependent on H+ efflux by the Na-H exchanger NHE1 and an increase in intracellular pH (pHi). We now present a predicted mechanism for how increased pH disrupts actin binding by the C-terminal I/LWEQ domain of talin to allow FA turnover. Computational pKa prediction of a homology model based on the structure of the Hip1R I/LWEQ domain and upstream α helix (USH) revealed that 5 amino acids (3 Asp, Glu, His) with pKas near physiological cluster at one end of a 5-helix bundle. Computer-aided molecular dynamics simulations suggest that protonation of the pH sensor causes a dramatic conformational change in the packing of the helical bundle in the vicinity of the actin binding site, which is remote from the pH sensor. NMR titrations identified histidine has an up-shifted pKa >7 in the C-terminus. Two-dimensional 1H, 15N correlation spectra of USH (+)/I/LWEQ show significant pH-driven conformational changes within the physiological range for ~20 residues associated with changes in overall dynamics and an increase in structure at lower pH. This model was supported by actin co-sedimentation assays. Talin USH (+)/I/LWEQ had high affinity actin binding at pH 6.5 and low affinity binding pH 7.5, however actin binding by the I/LWEQ domain lacking the USH segment was pH-insensitive. Furthermore, pH-sensitivity of actin binding by USH (+)/I/LWEQ was markedly reduced by an HAF mutation in the pH sensor. These data suggest a mechanism whereby changes in pHi can affect talin-actin binding to promote normal dynamic FA remodeling, and impaired remodeling with disease-associated aberrant pH.

Rack1 Associates with Na+/H+ Exchanger NHE5 in Focal Adhesions and Positively Regulates the Transporter Activity
I. Onishi, P. J. C. Lin, G. H. Dieringer, W. P. Williams, M. Numata; Biochemistry and Molecular Biology, University of British Columbia, Vancouver, BC, Canada
Na+/H+ exchanger isoform 5 (NHE5) is a brain-enriched NHE that may play important roles in ion and pH homeostasis, and cell-volume regulation in neurons. However, the regulation mechanism of NHE5 activity has not been fully elucidated. In order to identify potential NHE5 regulating proteins we screened a human brain embryonic cDNA library using yeast two-hybrid methodology. Here, we show that the signaling scaffold protein Receptor for Activated C Kinase 1 (RACK1) directly binds to NHE5 and positively regulates the transporter functionality. NHE5 co-localized with RACK1 as well as the markers for focal adhesions β1 integrin, paxillin and vinculin, suggesting that NHE5 associates with these structures and may play a specialized role during cell-matrix adhesion. By using RACK1 dominant-negative mutants and siRNA, we further show that RACK1 regulates NHE5 both directly and through an integrin-dependent pathway. The NHE5-RACK1 interaction, but not the RACK1-β1 integrin interaction, was reinforced when cells were spread on an integrin-substrate fibronectin. We propose that RACK1 activates NHE5 both by integrin-dependent and independent pathways, which may coordinate cellular ion and pH homeostasis during cell-matrix adhesion.

RACK1-Src Complex Regulates Adhesion Dynamics and Cell Migration
A. T. Doan; Pharmacology, University of Wisconsin, Madison, WI
Receptor for Activated C Kinase, RACK1, is an adaptor protein that binds to and regulates signaling via Src and PKC-dependent pathways. Elevated levels of rack1 mRNA has been demonstrated in non-small cell lung, colon, and breast carcinoma cells compared to normal tissue. Thus identification of the function of RACK1 and its regulation in normal and tumor cells appears to be essential to evaluate oncogenic or tumor suppressor potential. In this study, we show that RACK1 regulates adhesion complex dynamics through its direct interaction with Src and paxillin. RACK1-deficient cells are generated using siRNA and show increased number and size of paxillin-containing focal adhesions at the cell periphery. Quantification of focal adhesion duration and dynamics demonstrates that RACK1 is required for the efficient assembly/disassembly of paxillin from focal adhesions. We find this to be unique, since RACK1-deficient cells do not affect other focal adhesion protein dynamics. Phosphorylation of focal adhesion proteins, paxillin and FAK, were augmented in RACK1-deficient cells compared to control. The use of a Src inhibitor, PP2, or co-transfecting full length RACK1 in the deficient cells rescued the adhesion defects. Cell migration was reduced in RACK1-deficient cells. This reduction in cell migration may be due to the stabilized focal adhesions observed in the RACK1-deficient cells. To investigate the role of the RACK1-Src interaction in FA dynamics, we used RACK1 in which the Src binding site has been mutated (RACK1 Y246F). Expression of RACK1 Y246F was unable to rescue the adhesion and migration defects observed in the RACK1-deficient cells. Together, our findings suggest that RACK1 play a role in adhesion complex dynamics and cell migration by modulating Src-mediated phosphorylation of the adhesion protein, paxillin.

Vinexin Promotes the Association of Vinculin with Cytoskeleton at Focal Adhesions
H. Takahashi, K. Ueda, N. Kioka; Agriculture, Kyoto University, Kyoto, Japan
Adhesion sites between cultured cells and extracellular matrix are termed focal adhesions (FAs) and play pivotal roles in cell behaviour. We have reported that the expression of one of FA proteins, vinexin α, accumulates F-actin at FAs in NIH 3T3 cells, while vinexin β, a shorter variant, has only a weaker effect on actin cytoskeleton although both vinexin α and β localise at FAs and bind to vinculin. We assume that vinexin α changes the assembly of proteins at focal adhesions or changes the status of proteins at focal adhesions leading to the accumulation of F-actin. In this study, to examine these possibilities, we used modified cytoskeleton stabilizing buffer (CSK), which removes protein from cytoplasm and leaves cytoskeletal components. This method can determine the affinity of FA proteins to cytoskeleton. We found that vinexin α still remained at the FAs after the treatment with the CSK, while vinexin β did not. Actin stress fibres were partly washed out by the CSK in the vinexin β-expressing cells, leaving thin and weak phalloidin staining. In contrast, significant actin remained at the FAs containing vinexin α. Importantly, we also observed similar results in vinculin staining: a considerable amount of vinculin was left as a CSK resistant component at the FAs in the cells expressing vinexin α, but not β. Different from vinexin, paxillin and FAK were washed out even in the cells expressing vinexin α. Consistent with the overexpression experiments, knockdown of endogenous vinexin expression by siRNA in NIH 3T3 cells resulted in attenuated staining of vinculin after the CSK treatment. These findings suggest that vinexin α promotes the association of vinculin with cytoskeleton and also raise the possibility that this association results in the accumulation of F-actin at FAs.
Conformational Restriction Decreases Lipid Binding of the Vinculin C-Terminal
C. K. Voss, L. E. C. McDonald, E. H. Ball, Biochemistry, The University of Western Ontario, London, ON, Canada

The C-terminal tail domain of vinculin is responsible for the interactions of the protein with actin and lipid in cell-cell and cell-matrix adhesions. Drastic conformational changes, including the separation of the fibronectin and the β integrin binding domains, that are associated with vinculin function, have been suggested to occur during binding to lipid. To examine the need for such large conortions, we constructed three mutants with inserted pairs of cysteine residues to form disulfide bonds that would hold parts of the protein together. Cysteines at positions 951 and 999 held helices 3 and 4 together; at 958 and 1037 held helices 4 and 5; and at 878 and 1066 held the C-terminal arm in place (‘armlock’ mutation). The purified mutant domains were oxidized to create disulfide linkages, and their binding properties compared with those of wild type. All of the mutants showed normal binding to the head domain in gel filtration or fluorescence assays, whether oxidized or reduced, indicating that they were in a native, active conformation. The disulfide bonded mutants with locked helices were still able to bind lipid and actin in cosedimentation assays; however, the ‘armlock’ mutant showed a drastic decrease in lipid binding (75% decrease) and some decrease in actin binding (50%). Upon reduction with DTT, these differences were abolished, indicating that the disulfide bond itself, and not the inserted cysteines, was responsible. These results point to an important role for conformational flexibility in the C-terminal arm of vinculin function: it is needed for at least one step in lipid binding whereas large scale helix separation is not (but may still occur at later stages).

Zyxin (zyx102) Function Is Required for Viability in Drosophila melanogaster
P. J. Renfranz, E. Blankman, M. C. Beckerle; Huntsman Cancer Institute, University of Utah, Salt Lake City, UT

Zyxin family proteins function in actin assembly, cell motility and adhesion. In vertebrate tissue culture cells, zyxin family members localize to focal adhesions, adherens junctions, actin stress fibers, and nuclei. Zyxin null fibroblasts show striking defects in motility and response to stretch. To study the role of zyxin during development, we have focused on the single homologue in Drosophila, zyx102. The predicted protein contains three C-terminal LIM domains, at least one potential nuclear export signal, and at least one poly-proline motif that interacts with members of the Ena/VASP protein family. Drosophila zyxin is localized at adhesions similar to its vertebrate counterparts. We have generated germline zyx102 RNAi transformatants to knockdown Zyx102 protein using the GAL4/UAS expression system. Flies carrying the transgene have been crossed to a number of fly lines that express GALA under the control of specific enhancers/promoters. Protein immunoblot analysis shows that Zyx102 protein levels are significantly reduced in these flies, indicating that targeted RNAi occurs. We observe a lethal effect when UAS-zyx102-dsRNAi expression is driven ubiquitously by Actin5C-GAL4, indicating that in Drosophila, zyxin protein is required for viability. The lethal period is the pharate adult stage, a narrow developmental window during which the fly must molt, resorb molting fluid, fill adult trachea with air and execute a behavioral program to eclose. While knockdown animals make feebly active larvae, the adult trachea are abnormally branched and nerves near the neuropil are either not present or not air filled in knockdown animals. Knockdown individuals dissected from the pupal case, while morphologically normal, are still inviable. Similar phenotypes have been observed in wishful thinking mutants involved in BMP signaling, raising the possibility of a functional link between zyxin and the BMP pathway.

Differential Activities of the Urochordate Ciona intestinalis Talin-a/b Splice Variant
R. H. Singiser, R. O. McCann; Molecular and Cellular Biochemistry, University of Kentucky, Lexington, KY

Talin, a cytoskeletal linker-protein, is alternatively spliced in Ciona intestinalis. The alternative splice generates two distinct isoforms that contain non-identical I/LWEQ regions, which are important for actin binding and subcellular targeting. The talin splice variant found in Ciona mimic the two isoforms of talin, Taln1/2, found in vertebrates. Taln2 is found in cardiac and skeletal muscle in vertebrates. Ciona intestinalis is a model organism for studies of chordate development of heart and muscle tissues. The use of Ciona intestinalis to study the development of both Ciona muscle and cardiac tissue will provide insight in a chordate model system that is applicable to a vertebrate system. An NCBI database analysis revealed predominant expression of Ciona talin-b in blood cells while Ciona talin-a was variably expressed throughout development. Actin co-sedimentation assays demonstrate that both splice variants have the capability to bind actin: however, the talin-a splice variant found in the chordate model system mimics the characteristics of Taln1/2 binding in a vertebrate model system. These data suggest the usefulness of Ciona intestinalis as a model system for studying talin function in development. Future studies will clarify isoform specific roles of talin splice variants in Ciona development.

Vimentin Filament Interaction with Focal Contacts Is Mediated by Specific Residues within the β3 Integrin Cytoplasmic Tail: Functional Implications
R. Bhattacharya, J. C. Jones; Cell and Molecular Biology, Northwestern University, Chicago, IL

Angiogenesis, the growth of blood vessels, is essential for tumor survival and is central to pathogenesis of certain diseases including neovascular macular degeneration. Angiogenesis involves endothelial cell migration from preexisting blood vessels, formation of adhesive sites between migrating cells and ECM and assembly of endothelial cells into vessels. Focal contacts (FCs) play a role in each of these processes. Previously, we have demonstrated that vimentin associates with avß3 integrin-rich FCs in endothelial cells. This association depends on integrin activation since IF-Fc interaction is dramatically decreased in endothelial cells plated onto poly-L-lysine but is restored upon addition of Mn2+. Knockdown β3 integrin expression in endothelial cells results in a 70% decrease in the numbers of FCs exhibiting IF association. To provide further support for β3 integrin-mediated vimentin-FC interaction, we transfected GFP-ß3 integrin into CHO cells which lack β3 integrin but contain vimentin. In “parental” CHO cells vimentin IF are collapsed in the perinuclear zone. In CHO cells expressing wild-type β3 integrin (CHOwß3), vimentin extends to FCs. However, in CHO cells (CHOß3Y759F; CHOß3Y747F) expressing mutated β3 integrin, in which either tyrosine residue at position 759 or 747 is replaced by glycine, a non-phosphorylatable mimetic, there is a significant decrease in vimentin-FC interaction compared to CHOwß3 cells. ß3Y759F and ß3Y747F integrin, nonetheless, target to FCs and their expression has no impact on actin organization. We assessed the functional consequences of IF-FC interactions in CHO cells. Using trypsinization and shear stress assays, our results indicate that CHOwß3 cells exhibit significantly greater angiogenic activity compared to CHOß3 cells. Moreover, cultures of CHOwß3 cells close in vitro wounds significantly faster than parental CHO, CHOß3Y759F and CHOß3Y747F cells. In summary, our data reveal that β3 integrin mediates vimentin-FC association and that vimentin-FC interactions regulate the adhesive function of these proteins and their role in migration.

The Phosphotyrosine-independent Interaction of DLC-1 and the SH2 Domain of Cten Regulates Focal Adhesion Localization and Growth Suppression Activity of DLC-1
Y. Liao, L. Si, S. Lo; Center for Tissue Regeneration and Repair, Department of Orthopaedic Surgery and Cancer Center, University of California, Davis, Sacramento, CA

DLC-1 was further confirmed by immunoprecipitation and mammalian two-hybrid assay. By yeast two-hybrid analyses with truncated constructs, we demonstrated that the regions responsible for the binding are the SH2 domain on cten and 1-535 amino acids on DLC-1. The interaction is independent of tyrosine phosphorylation of DLC-1, which is a new binding feature of tensins.

CaMK-II Promotes Focal Complex Disassembly to Influence Cell Motility
C. A. Easley, R. M. Tombs; Biochemistry, Virginia Commonwealth School of Medicine, Richmond, VA

We also report a novel role for CaMK-II in focal complex dynamics, cell spreading and motility. Cells expressing constitutively

2006 ASCB Annual Meeting Abstracts
active CaMK-II exhibit decreased cell adhesion and fail to migrate on FN. In contrast to cells expressing wild type CaMK-II, cells expressing constitutively active CaMK-II lack focal complexes as determined by GFP-paxillin and GFP-FAK. Focal complexes can be recovered within 1 hour using a membrane permeant, CaMK-II specific, catalytic inhibitor. Using this inhibitor alone, cell spreading is enhanced and focal complexes are enlarged as determined using Total Internal Reflection Fluorescence microscopy (TIRFM). Inhibition of CaMK-II activity also blocks cell motility. Thus, full inhibition and full activation of CaMK-II disrupt cell motility. Taken together, these results indicate that CaMK-II is activated by FN to promote focal complex disassembly to enable cell motility.

1012 Zyxin-dependent Regulation of Actin Stress Fiber Reinforcement
L. M. Hoffman, C. C. Jensen, A. Chaturvedi, M. Yoshigi, M. C. Beckerle; Huntsman Cancer Institute, University of Utah, Salt Lake City, UT
Control of actin filament assembly and dynamics is critical for cell motility, and mechanical stability of cells. The focal adhesion protein, zyxin, interacts with p130Cas, alpha-actinin and Ena/VASP family members and has been shown to promote actin assembly when targeted to the inner leaflet of the plasma membrane or to mitochondria. Here we describe efforts to characterize the contribution of zyxin to the assembly of stress fibers, large bundles of actin filaments that are prominent architectural features in cultured fibroblasts. Exposure of cells to the actin stabilizing agent, jasplakinolide, promotes the formation of robust actin stress fibers in fibroblasts. Comparison of the response of wild-type and zyxin-null cells to jasplakinolide reveals that zyxin is required for robust assembly of stress fibers. Likewise, zyxin is required for reinforcement of actin stress fibers in cells exposed to uniaxial mechanical stress. The reinforcement of actin stress fibers in response to mechanical stress is not dependent on the presence of p130Cas, though p130Cas binds zyxin and has, itself, been implicated in mechanotransduction. Upon either jasplakinolide treatment or mechanical stimulation, zyxin is mobilized from focal adhesions to actin stress fibers while many other focal adhesion components, including vinculin, remain at substratum adhesion sites. Thus zyxin appears to be actively trafficked to the actin stress fibers during the reinforcement process. Stress fiber development is stimulated by activation of Rho-kinase. Interestingly, the zyxin-dependent reinforcement of actin stress fibers in response to mechanical stimulation is not completely blocked by the Rho-kinase inhibitor, Y27632. Moreover, zyxin-null cells display a heightened sensitivity to Rho-kinase inhibitor compared to wild-type cells, suggesting that zyxin and Rho-kinase act in parallel to influence actin stress fiber assembly.

1013 Genomic Analysis of the Cas Family Identifies a Novel Cas-related Protein, HEF1-Efs-p130cas-Like (HEPL), and a Complex Family Splice Structure
M. K. Singh,1 D. Dadic,2 E. Nicolás,3 S. Apostolou,1 A. Canutescu,1 I. Serebriskii,1 E. A. Golemis,1 Basic Sciences, Fox Chase Cancer Center, Philadelphia, PA, 2Cancer Research Program, Stem Cell Research Center, Manipal Hospital, Bangalore, India
Members of the Cas protein family of multi-domain scaffolding proteins are important mediators of cell attachment, motility, and survival, and have also been implicated in other processes including cell cycle control and vascular trafficking. To better understand the function of the known Cas proteins (p130Cas, HEF1/NEOD9/Cas-L, and Efs/Sin), we performed a coupled genomic, expression, and functional analysis of the Cas protein group. By this means, we have identified a completely novel member of the Cas protein family, termed HEPL, which is conserved through lower vertebrates. We have used quantitative real time reverse transcriptase-polymerase chain reaction (RT-PCR) to determine that the human HEPL is expressed in many cell lines and tumors, and may influence Cas family function. In functional analyses, we have compared HEPL protein localization, association, and action with that of other family members. We have also mined through genomic resources to better define the splice structure of the Cas gene family. This has led to the identification of both evolutionarily conserved and recent splice variants, many of which are not detectable with standard tools for study of Cas proteins, but which are abundant at the mRNA level in many cell types. In functional studies of HEF1 splice variants, we have demonstrated specific variants oppose the activity of canonical HEF1, inhibiting cell spreading and FAK activation. The identification of HEPL and the Cas family splice variants, the majority of which are not distinguishable by currently available antibodies to the Cas family proteins, provides an important context for further studies of this protein group.

1014 Hypermobility Induces Reorganization of Actin Stress Fiber Assembly in Osteoblastic MC3T3-E1 Cells
Y. Miyamoto, Y. Ishikawa, E. Shimura, Y. Mogami; Department of Biology, Ochanomizu University, Tokyo, Japan
Actin stress fibers, which are linked to integrin in focal adhesions, play a central role in cell movement and cell adhesion. Recently, the network of stress fibers and focal adhesions has been reported to be responsible for mechano-sensing. Based on the hypothesis that the network also senses mechanical loading due to gravity, we examined the effect of hypermobility on the reorganization of stress fiber assembly in osteoblastic MC3T3-E1 cells by fluorescence microscopy. Under hypermobility generated by centrifugation, we observed that the hypermobility (60G, 2h) enhanced the assembly of the stress fiber in MC3T3-E1 cells. Hypermobility also enhanced recovery of the partially disrupted stress fiber network induced by adding 1.25 μg/ml cytochalasin B. However, there was no apparent recovery when hypermobility was applied to cells with a substantially disrupted network. In addition, after cessation of hypermobility, the recovery effect was reversed to a point midway between the 60G-loaded state and the non-loaded state (1G) with cytochalasin B, suggesting that the hypermobility response is reversible and induces reorganization of the stress fiber assembly. Next, we examine the roles of integrin in the hypermobility response, an inhibitory peptide (RGD), which interferes with the RGD-dependent integrin binding to extracellular matrix, was added to the cells. The RGD peptide induced the partial disruption of the network of the stress fiber. However, there was no disruption of the network by RGD peptides under hypermobility and, no hypermobility-induced rescue of the disruption by RGD peptide in the presence of an inhibitor of Rho kinase, Y-27632, indicating that Rho kinase plays an essential role in the rescue. These findings suggest that mechanical load due to gravity may be sensed via a network of stress fibers in which non-RGD dependent integrins may play some complementary roles in the reorganization of the fiber assembly.

1015 Mutations in the Conserved WDF Motif of the Integrin beta 1 Tail: Effects on Integrin-Talin Interactions, Cell Adhesion, and Adhesion Signaling
B. L. Nieve,1 C. H. Reverter,1 A. Benware,2 S. E. LaFlamme; Center for Cell Biology and Cancer Research, Albany Medical Center, Albany, NY
Integrin-mediated cell adhesion is essential for tissue homeostasis as well as for many biological processes including development, wound healing, tumor metastasis and angiogenesis. The highly conserved integrin beta subunit cytoplasmic domain is thought to play a central role in these processes by regulating the formation of signaling complexes that promote integrin activation, cell adhesion and adhesion-dependent processes. Talin, a major cytoskeletal linker protein, has been implicated in mediating the inside-out activation of integrins through the binding of its IT-domains to the central portion of the integrin beta tail (WDTANNPLYK in the case of the beta1 tail). Using HIS-tagged fusion proteins containing wild-type and mutant beta tails, we demonstrated that alanine substitutions for the WD or WT residues within the corresponding WDTGENPIYK region of the beta1 tail impaired talin-binding in vitro. The WDTANNPLYK sequence is highly conserved among integrins and is thought to mediate receptor-ligand interactions in the extracellular domain. Recently, it has been shown that talin-binding to extracellular matrix, was added to the cells. The RGD peptide induced the partial disruption of the network of the stress fiber. However, there was no apparent recovery when hypermobility was applied to cells with a substantially disrupted network. In addition, after cessation of hypermobility, the recovery effect was reversed to a point midway between the 60G-loaded state and the non-loaded state (1G) with cytochalasin B, suggesting that the hypermobility response is reversible and induces reorganization of the stress fiber assembly. Next, we examine the roles of integrin in the hypermobility response, an inhibitory peptide (RGD), which interferes with the RGD-dependent integrin binding to extracellular matrix, was added to the cells. The RGD peptide induced the partial disruption of the network of the stress fiber. However, there was no disruption of the network by RGD peptides under hypermobility and, no hypermobility-induced rescue of the disruption by RGD peptide in the presence of an inhibitor of Rho kinase, Y-27632, indicating that Rho kinase plays an essential role in the rescue. These findings suggest that mechanical load due to gravity may be sensed via a network of stress fibers in which non-RGD dependent integrins may play some complementary roles in the reorganization of the fiber assembly.

1016 TRPM7 Regulates Cell Adhesion and Membrane Protrusion by Controlling the Calcium Dependent Protease Calpain
L. Su,1 M. Agapito,1 M. Li,2 A. Sato,2 W. Simonson,4 A. Huttenlocher,4 R. Habas,3 L. Yue,2 L. Runnels1; 1Pharmacology, University of Medicine & Dentistry of NJ-Robert Wood Johnson Medical School, Graduate School of Biomedical Sciences, Piscataway, NJ, 2Cell Biology, University of Connecticut Health Center, Farmington, CT, 3Biochemistry, University of Medicine & Dentistry of NJ-Robert Wood Johnson Medical School, Piscataway, NJ, 4Cell Biology, University of Medicine & Dentistry of NJ-Robert Wood Johnson Medical School, Piscataway, NJ, 5Pharmacology, University of Wisconsin, Madison, WI
TRPM7 is a bifunctional protein with ion channel and kinase activities that is a member of the transient receptor potential (TRP) ion channel family. M-calpain is a protease implicated in the control of cell shape, cell locomotion, and focal adhesion dynamics. Tenase complex, a membrane component with m-calpain in spatially and temporally controlled is not well understood, particularly because calpain’s dependence on calcium exceeds the sub-micromolar concentrations normally observed in cells. Here we show that the channel-kinase TRPM7 localizes to peripheral adhesion complexes with m-calpain, where it regulates cell adhesion by controlling the activity of the protease. Our research revealed that overexpression of TRPM7 in HEK-293 cells caused cell rounding with a concomitant loss of cell adhesion that is dependent upon the protein’s channel but not its kinase activities. Knockdown of m-calpain blocked TRPM7-induced cell rounding and cell detachment. Silencing of TRPM7 by RNA interference, however, strengthened cell adhesion and increased the number of peripheral adhesion complexes in cells. Together, our results suggest that TRPM7 regulates cell adhesion through m-calpain by mediating local influx of calcium into peripheral adhesion complexes. To verify TRPM7’s impact on cell adhesion and cell spreading, we created a Swiss 3T3 fibroblast cell line in which the protein’s channel has been knocked-down by RNA interference. TRPM7 knockdown fibroblasts attached and spread more rapidly to the substrate, as well as increased the frequency of membrane protrusion and retraction, indicating that the channel may play a role in regulating lamellipodia stability. Finally, to confirm
that TRPM7 is regulating cell motility we investigated the role of TRPM7 during Xenopus development. Depletion or overexpression of TRPM7 blocked gastrulation cell movements and neural fold closure, making TRPM7 the first channel required for early development. Together, our findings support a novel role of TRPM7 in regulating cell adhesion and membrane protrusions in migrating cells.

Deficiency of Tenascin-C Attenuates Liver Fibrosis in Immune-mediated Chronic Hepatitis in Mice

Tenascin-C (TNC), an extracellular matrix glycoprotein, is upregulated in chronic liver disease. Here, we investigated the contribution of TNC to liver fibrogenesis by comparing immune-mediated hepatitis in wild-type (WT) and TNC-null (TNKO) mice. Eight-week-old BALB/c mice received weekly intravenous injections of Concanavalin A to induce hepatitis, and were sacrificed one week after the 3rd, 6th, 9th and 12th injections. In WT livers, TNC expression in both protein and mRNA levels gradually increased, and peaked after the 9th injection. Collagen deposition stained with picrosirius red was significantly less intense in TNKO mice than in WT mice, and procollagen I and III transcripts were significantly upregulated in WT mice compared with TNKO mice. Inflammatory infiltrates were more prominent after the 3rd-6th injections in both groups and were less intense in TNKO mice than in WT mice. Levels of Interferon-γ and interleukin-1β mRNA were significantly higher in WT mice than in TNKO mice, while desmin-positive hepatic stellate cells (HSCs) and myofibroblasts, a cellular source of TNC and procollagens, were more common in WT livers. Transforming growth factor (TGF)-β1 mRNA expression was significantly upregulated in WT mice, but not in TNKO mice. TNC can promote liver fibrogenesis through enhancement of inflammatory response along with cytokine upregulation, HSC recruitment and TGF-β expression during progression of hepatitis to liver fibrosis.

Deficiency of Tenascin C Attenuates Allergen-induced Bronchial Asthma in the Mouse

H. Nakahara, E. C. Gabazza, T. Fujimoto, K. Imanaka-Yoshida, T. Yoshida, O. Taguchi; Department of Pulmonary and Critical Care Medicine, Mie University School of Medicine, Tsu, Japan

Tenascin C is a phosphatide matrix glycoprotein whose expression is increased in several inflammatory diseases of the lung including bronchial asthma. However, the exact function of tenascin C in the pathogenesis of lung inflammation remains unclear. In the present study, we compared the degree of allergic airway inflammation between wild type and tenascin C-deficient (-/-) Balb/c mice. Bronchial asthma was induced by sensitization and challenged with ovalbumin. Littermates treated with saline were used as controls. Cytokines in bronchoalveolar lavage fluid and proteins produced by lung specific epithelial cells were measured. The number of epithelial cells in the lung was significantly increased in the wild type compared with tenascin-C knockout mice. Airway hyperreactivity, NF-kappaB activation and the bronchoalveolar lavage fluid concentrations of monocyte chemoattractant protein-1, interleukin-5, interleukin-13, metalloproteinase-9 and immunoglobulin-E were significantly higher in ovalbumin sensitized/challenged tenascin-C knockout mice compared with their wild type counterparts. In vitro experiments disclosed that tenascin-C significantly stimulated the secretion of interleukin-5, interleukin-13, interferon-gamma and immunoglobulin-E from spleen lymphocytes. These observations suggest that tenascin C is involved in the pathogenesis of bronchial asthma.

UV-Modulatable Substrates for Spatio-Temporal Mechanotransduction Studies

M. T. Frey, N. Burnham, Y. Wang; Physiology, University of Massachusetts Medical School, Worcester, MA

Polyacrylamide gels have been used widely for cell culture studies as substrata for their favorable optical properties and the ability to tailor their mechanical properties. Understanding cell response to substrate stiffness is important in the fields of developmental biology, regenerative medicine, wound healing, and tissue engineering. Similar to surface biochemistry, the mechanical properties of substrata provide a biological cue that affects cell behavior, such as spreading and migration speed. However, these studies are done in parallel fashion and yield no information regarding the transition dynamics of cell behavior during changes in substrate stiffness. We have created a model system for such a study by modifying polyacrylamide with a photo-activatable crosslinking agent. Cells readily adhere to this substrate after addition of fibrinogen. Based on atomic force microscopy measurements, ultraviolet light exposure reduces the substrate stiffness. Cells on the substrate before and after exposure behave in a similar fashion to cells on stiff and soft substrata respectively, while cells on glass appear to be unaffected by the same intensity of exposure. This novel substrate allows for transition dynamics of cells to be studied as a function of changing stiffness.

Agrin as a Cell Adhesion Molecule on Nanopatterned Substrates

T. Wolfram,1 T. Schoen,2 J. P. Spatz;3 Institute for Molecular Biophysics, The Jackson Laboratory, Bar Harbor, ME, 1New Materials and Biosystems, Max-Planck Institute for Metals Research, Stuttgart, Germany, 2New Materials and Biosystems, Biophysical Chemistry, Max-Planck Institute and University of Heidelberg, Stuttgart, Heidelberg, Germany

Agrin is a heparane sulfate proteoglycan known predominantly for its inductive role during the formation of the neuromuscular junction. Agrin is also expressed in several other tissues including those of the central nervous system (CNS). To investigate the role of agrin in the CNS we designed a sophisticated cellular adhesion assay using nanostuctured surfaces. Our assay system allows us to address the hypothesis that the c-terminal domains of agrin can facilitate adhesion of neural and neuronal cells. Additionally we were able to investigate the amount of proteins necessary for cell adhesion. We generated substrates with a defined chemical environment, controlling the amount of agrin and the orientation of the agrin molecules in a side directed manner by binding single molecules to gold nanodots. The area around the gold dots was coated with a cell repellent polyethylene glycol (PEG) layer. Functionality of the substrates was confirmed by immunofluorescence (IF) microscopy and atomic force microscopy (AFM). Single molecules were detected by immuno-gold labelling. Agrin is functional as a cell adhesion molecule for a variety of neural cell lines such as neuroblastoma cells SH-SY5Y, mouse neuroblastoma cells N2a and rat neuroblastoma cells B153 as well as primary cortical neurons from C57/B16 wild type mice. In contrast, agrin was a less sufficient substrate for the adhesion of primary mouse embryonic fibroblasts. We also were able to show that agrin has to be offered at a certain density (~300 molecules/μm) on the substrate to facilitate cell adhesion. Furthermore with peptide-inhibition assays we identify possible molecular mediators of the cell adhesion function of agrin. The key regulators for this function could be laminin dependent integrins via modulation of actin cytoskeleton elements. Our results indicate that agrin is a potentially important component of the cell adhesion process in the central nervous system.
Collagen deposition and epithelial-mesenchymal transdifferentiation (EMT) play very important role in pathophysiology of chronic kidney failure. Collagen contains two receptors, integrin and discoidin domain receptor (DDR1). We previously demonstrated that DDR1 served to counteract TGFβ1 integrin mediated cell migration induced by collagen. In this study, we wished to study the function of DDR1 in cell differentiation and EMT in renal epithelial cells by employing MDCK cells stably transfected with DDR1, or dominant negative (DN)-DDR1. We found that collagen markedly inhibited microvilli formation in MDCK cells. Overexpression of DDR1 prevented, whereas DN-DDR1 augmented collagen-induced reduction of microvilli. In addition, we showed that DDR1 overexpression prevented TGFβ1-induced mesenchymal morphological changes upon collagen stimulation, whereas DN-DDR1 promoted mesenchymal morphology even without TGFβ1 stimulation. Immunofluorescence studies showed DDR1 overexpression prevented TGFβ1-induced E-cadherin mislocalization from cell-cell junction to cytosol, whereas DN-DDR1 promotes this phenomenon even without TGFβ1 stimulation. Interestingly, we found that cells overexpressing constitutive active β1-integrin exhibited E-cadherin mislocalization and mesenchymal morphology. Taken together, these results indicate that DDR1 promotes cell differentiation upon collagen stimulation and inhibits TGFβ1-induced EMT.

Prox1 and Podoplanin Are Required for Lymphatic Endothelial Capillary Tube Formation

A. Navarro, M. Rezaee chalkagh, S. Mabry, D. Xu, W. E. Tsou, J. I. Ekekeze; Pediatrics/Neonatology, Children's Mercy Hospitals and Clinics/University of Missouri-Kansas City School of Medicine, Kansas City, MO

Vascular networks derive from endothelial cells through vasculogenesis - nascent vessel formation, or via angiogenesis - sprouting from existing vessels. An important step in both processes is tubulogenesis, whereby endothelial cells align themselves to form vessels. Factors orchestrating tubulogenesis remain poorly understood. Prospero-related homeobox 1 (Prox1) is a transcription factor selectively expressed in endothelial cells of lymphatic nature. Because it is known that Prox1 is required for the development of the murine lymphatic system, our objective was to investigate the role of the Prox1 protein in the process of capillary tube formation in lymphatic endothelial cells derived from human lung. Culture in matrigel is a well-established method of studying endothelial cell tubular network formation in vitro. When using siRNA to block the expression of Prox1 in lung lymphatic endothelial cells, we could observe no effect on either cell morphology or viability when cultured under normal conditions, but the arrangement of the lymphatic endothelial cells into capillary tubes in vitro (on Matrigel) was severely compromised. This effect was specific to the lack of Prox1 protein, since it did not occur in cells treated with a comparable siRNA (scrambled sequence) or if the cells used were blood vascular endothelial cells derived from human lung. Similar results were obtained when using siRNA specific for Podoplanin, a type 1 membrane protein and specific marker for lymphatic endothelial cells. These results identify a critical role for Prox1 and Podoplanin in the endothelial cell cytoskeletal dynamic changes associated with the process of tubulation formation.

Urokolinase-derived Peptide Inhibitor of the uPA/uPAR System Inhibits Microvascular Permeability

D. Navarrate, A. Das, G. Memucci, P. G. McGuire; 1Cell Biology, Cell Biology, School of Medicine, University of New Mexico, Albuquerque, NM, 2Surgery & Ophthalmology, School of Medicine, University of New Mexico, Albuquerque, NM

Breakdown of the blood-retinal barrier (BRB) is a central event in early diabetic retinopathy. The progressive activation of extracellular proteases in later diabetic events like retinal neovascularization has been well-documented. However, their role in early retinal permeability changes remains unexplored. In an animal model of diabetes, mRNA levels of both urokinase plasminogen activator (uPA) and its receptor (uPAR) were upregulated in the retinal vasculature after 2 weeks of diabetes. The aim of this study was to determine the role of the uPA/uPAR system in mechanisms affecting retinal permeability. A peptide inhibitor derived from the non-receptor-binding region of urokinase which blocks the interaction of uPA with uPAR (Å6) was used in these studies. Diabetic rats received intraperitoneal injections of Å6 (100mg/kg) daily for 2-weeks after induction of diabetes. Retinal permeability was assayed using the Evans blue technique. Diabetic rats treated with Å6 showed a significant decrease in permeability levels as compared to 100 fold higher basal levels. To elucidate how inhibition by Å6 affects cell junctions, human umbilical vein endothelial cells were treated with AGE-BSA, which induced increases in monolayer permeability, the loss of cell surface VE-cadherin expression and decreased cell-cell contact. All of these effects were reversed by the addition of Å6. These data support a role for uPA and uPAR in the breakdown of the blood-retinal barrier during diabetes and also suggest that inhibition of this interaction might be a promising target for early therapeutic intervention in diabetic retinopathy.

Recreating Adipogenesis In Vitro: A New Approach Exploiting the Biological Properties of Human Adipose-derived Stromal Cells in Tissue Engineering

J. Fradette, M. Vernette, V. Trottier, L. Saint-Pierre; Surgery, Laval University, Quebec, PQ, Canada

Adipogenesis, the differentiation of stromal precursor cells into lipid-filled adipocytes, contributes to the expansion of adipose tissue depots. The lack of adequate in vitro models to study adipogenesis and key aspects of human adipocyte metabolism in a tridimensional (3D) environment prompted us to reconstruct adipose tissue using tissue-engineering approaches. We extracted stromal cells from liposorbed (LA) and excised fat (LP, lpectomy) to assess their capacity to generate 3D adipose tissues using a « self-assembly » culture technique. This method is based on seeding cells to produce their own extracellular matrix following ascorbic acid (AA) stimulation in vitro, avoiding the usual requirement for exogenous biomaterials. Compared to excised fat, stromal cells from liposorptions featured a higher adipogenic potential in vitro (1.6x to 2.0x) at passages 3, 6 and 11 in presence of AA, as quantified after Oil Red O stainings. When cultured for 28 days in presence of AA, both LA and LP-derived stromal cells produced manipulable sheets rich in extracellular matrix components. By inducing adipogenic differentiation at different stages of matrix formation (namely at day 7 or 21 of culture), adipose sheets were produced (3.5 cm² surface area), featuring human adipocytes at early or late stages of differentiation. These adipose sheets were then layered and assembled into thicker tissues (146± 8.7 µm, 3 layers, n=6). This tissue-engineered adipose tissues secreted leptin and adiponectin in culture. Treatment with the β-adrenergic agonist isoproterenol (0.25 µM) stimulated lipolysis 2.0 fold over basal levels, as determined by glyceral release. Taken together, these results establish the functionality of the reconstructed adipose tissues. In conclusion, this new tissue-engineered model of adipose tissue will allow us to study not only the regulation of adipogenesis in a 3D context in vitro, but also the metabolism of human adipocytes at defined stages of differentiation under various pharmacological treatments.

A Specific Immunocapture Activity Assay for Matrix Metalloproteinases Using 5-FAM/QXL 520™ FRET Peptide

Y. Tang, X. Li, X. Zhu, X. Han, Z. Diwu; AnaSpec, Inc., San Jose, CA

Matrix metalloproteinases (MMPs) belong to a family of secreted or membrane-associated zinc endopeptidases capable of digesting extracellular matrix components. MMPs play roles in the multiple stages of tumor development and metastasis, rheumatoid arthritis, wound healing, angiogenesis, as well as in other pathological and physiological events. Many assays, such as zymography, ELISA, and assay-based activity assays, have been developed to facilitate the research and drug discovery for MMPs; however, zymography is a relatively low-throughput method, and ELISA does not provide MMP activity information. In contrast, FRET-based activity assay has gained popularity because of its simple and fast format — a feature ideal for large scale drug compound screening. When a FRET-peptide based assay is applied to biological samples, it measures non-specific cleavages of the different MMPs and even from other non-selective proteases, which maybe simultaneously present in biological fluids. To solve this problem of non-specific cleavages, an anti-MMP is first used to capture a specific MMP from the mixture, and then the activity of this particular MMP is measured by a FRET-peptide substrate. In previous studies, we have developed highly sensitive FRET-peptide substrates for MMPs using the strongly-fluorescent 5-FAM as the FRET donor and QXL™520 as the quencher. In this current study, we incorporate the 5-FAM/QXL™520 FRET-peptide substrate to the above specific immunocapture assay. This results in a highly sensitive, specific detection of MMP-1, MMP-9 or MMP-13 activity in mixed biological samples.

Lycopene Inhibits Tumor Cell Invasion and MMP-2 Activity in a Frog Renal Adenocarcinoma Cell Line

P. Dalvi, P. Leggett-Robinson, M. Martinez, R. M. Troy; 1Biology, Tuskegee University, Tuskegee, AL, 2Chemistry, Tuskegee University, Tuskegee, AL, 3Biology/RCMI, Tuskegee University, Tuskegee, AL

One of the steps in the pathway leading to invasion and metastasis in cancer involves the over-expression of the matrix metalloproteinases (MMPs) by tumor cells. These enzymes, involved in the degradation of the extracellular matrix (ECM), can thus be identified as one of the determinants of whether the cancer cell undergoes metastasis. Therapeutic regimes that inhibit the activation of the MMPs might prove to reverse the poor prognosis associated with metastatic cancers. In recent years, dietary natural products have been shown to exhibit anti-cancer activity and might be utilized not only as chemopreventive agents but might be efficacious in a chemotherapeutic manner. In this study, lycopene, extracted from commercially available tomato paste, was examined for its ability to inhibit tumor cell invasion and MMP-2 activity in the PNKT-4B frog renal adenocarcinoma cell line that exhibits temperature-dependent invasion. Cells incubated at a low temperature (18°C) had an invasive capacity of approximately 18% as determined by the matrigel assay. However, at a higher temperature (28°C), invasion was approximately 89%. Inhibition of the highly invasive temperature was examined by incubating cells with 2.5, 5.0, and 10 µM of lycopene. The lycopene was extracted from 15 g of commercial tomato paste, resolved on TLC plates, and further characterized by UV-VIS spectrometry to determine purity. Lycopene displayed a maximum inhibition of invasion (72%) at a concentration

of 5 μM. To determine the mechanism of lycopene inhibition, MMP-2 activity at 28°C (the invasive-permissive temperature) was analyzed since this MMP has a strong correlation to invasion and metastasis. Activity was only inhibited by 29% as determined by gelatin zymography. These data show that the mechanism of lycopene inhibition may in part be due to inhibition of active MMP-2 and that other MMPs or other proteins may be involved in the inhibition of tumor cell invasion.

1033 Vibrio Vulnificus Secretes a Broad Specificity Metalloprotease with Blood Clotting Modulating and Cell Death Inducing Properties

N. H. Lee, A. K. Chang, J. E. Park, J. S. Lee; Chosun University, Gwangju, Republic of Korea
Vibrio vulnificus is a marine bacterium and a human pathogen capable of causing wound infection and sepsis. In this study we show that a metalloprotease (vEP) secreted by V. vulnificus ATCC 29207 could activate prothrombin and cleave fibrinogen as well as cross-linked fibrin. Furthermore, it is capable of activating a mutant prothrombin-3 (D3A) in vitro. D3A lacks the specific aspartate residues that form the cleavage sites in wild-type prothrombin-3, and activation occurred through cleavage of the zymogen at a site close to the native cleavage site. Since vEP is likely to be secreted into the blood stream during infection the ability of other virulence factors within the host tissue is of major interest to our investigation. We examined the cytotoxicity exerted by vEP on two mammalian cultured cell lines, NIH3T3 and HeLa cells. vEP exhibited cytotoxic activity on both cell lines, but the effect was stronger for NIH3T3 cells, with less than 50% cell viability remaining at 5 μg/ml compared with about 70% for HeLa cells. However, vEP did not induce apoptosis as cells treated with vEP appeared to show no typical apoptotic markers, such as DNA fragmentation and caspase-3 activation, although the enzyme appeared to enter the cells as revealed by confocal microscopy images of cells treated with a fluorescein-labeled recombinant vEP. Activation of caspase-3 was not observed despite the presence of cell death. It appears that cell death (and hence possible host tissue damage in vivo) could be caused by direct degradation of extracellular matrix proteins (ECM) of the cells, since vEP could degrade proteins such as collagen and elastin, which are components of the ECM although the exact mode of cell death induction evoked by vEP and the response of cell toward vEP have yet to be elucidated.

1034 CB1 Cannabinoid Receptor-mediated Activation of Endothelial Nitric Oxide Synthase Regulates MMP Activity in Endothelial Cells

I. Johnson, S. Mukhopadhyay; Program in Neuroscience, Biomedical Biotech Research Institute, North Carolina Central University, Durham, NC, Program in Neuroscience, Chemistry-Biochemistry, Biomedical Biotech Research Institute, North Carolina Central University, Durham, NC
Endogenous cannabinoid anandamide produced nitric oxide acting on G-protein coupled CB1 cannabinoid receptor as well as non-CB1/CB2 “anandamide receptor via the activation of endothelial nitric oxide synthase (eNOS) in endothelial cells (McCollum et al., FASEB J 18(4) pA322, 2004). Endothelial nitric oxide synthase has 6 distinct Ser/Thr/Tyr potential phosphorylation sites and it was hypothesized that activation of G-protein coupled CB1 cannabinoid receptor or non-CB1(non-CB2) anandamide receptor produces differential phosphorylation of these residues via the activation of different kinase cascades in endothelial cells. In the present study we showed that activation of CB1 receptor and anandamide receptor produced phosphorylation Ser117 and Ser615 of eNOS protein respectively in human aortic EAhy926 cells. Further, we showed that CB1 cannabinoid receptor-mediated phosphorylation of Ser117 is correlated with the decrease in MMP2 and MMP9 activity in endothelial cells. On the otherhand, phosphorylation of Ser615 of eNOS protein was correlated with activation of MMP9 activity. Thus, our results showed that activation of CB1 receptor and anandamide receptor has differential kinetics of phosphorylation for these residues and results in differential regulation of MMP activity in endothelial cells. 1035 Regulation of Matrix Metalloproteinase-9 Expression by the Large GTPase Murine Guanylate Binding Protein-2

S. Balasubramanian, A. F. Messmer, D. J. Vestal; Department of Biological Sciences, University of Toledo, Toledo, OH
Matrix metalloproteinases (MMPs) are a family of extracellular proteases involved in a variety of developmental and pathological changes that involve tissue remodeling. MMPs can collectively cleave all components of the extracellular matrix. MMP-9 in particular is important because its substrates include collagen IV, entactin, and laminin. These are all components common to all basement membranes. Consequently, MMP-9 is believed to play a critical role in metastasis and angiogenesis. Despite its importance, much remains unclear about how MMP-9 is regulated. Many cytokines and growth factors up-regulate MMP-9 expression, including TNF-α. However, interferons (IFNs) β and γ are among the few cytokines known to down-regulate cytokine induced expression of MMP-9. In NIH 3T3 cells, IFN-γ can inhibit both basal expression and TNF-α induction of MMP-9. Murine Guanylate Binding Protein-2 (mGBP-2), a GTPase, robustly expressed upon exposure to IFN-γ, lowers both basal and TNF-α induced expression of MMP-9 by inhibiting its transcription. This inhibition proceeds, at least in part, through inhibition of NF-κB. As described above, TNF-α induction of MMP-9 occurs through the degradation of IκBα and release of NF-κB, facilitating translocation of NF-κB to the nucleus and induction of transcription. In the presence of mGBP-2, the degradation of IκBα, initiated by TNF-α proceeds normally but the levels of IκBα are restored more rapidly. In addition, TNF-α induction of MMP-9 proceeds through Rac activation of NF-κB activity, an activation inhibited by mGBP-2. These studies begin to define the mechanism(s) by which mGBP-2 inhibits the expression of MMP-9. Work is currently underway to define how mGBP-2 inhibits NF-κB mediated expression of MMP-9.

1036 Interleukin-1β Causes Induction and Activation of Matrix Metalloproteinase-12 in Articular Chondrocytes via Mitogen-activated Protein Kinase Pathway

H. Oh, B. Yu, J. Kim, J. Chun; Life Science, GIST, Gwangju, Republic of Korea
Interleukin (IL)-1 is a major pro-inflammatory cytokine that causes destruction of articular cartilage via induction of several matrix-metalloproteinases (MMPs). We examined expression of MMP family in IL-1β-treated primary culture articular chondrocytes. IL-1β caused induction of MMP-1, MMP-3, MMP-9, MMP-12, and MMP-13 expression in articular chondrocytes. Although expression of MMP-12 in macrophages and other cell types are well known, functional role of MMP-12 in chondrocytes remains largely unknown. We found in this study that IL-1β caused induction of MMP-12 expression in both primary culture articular chondrocytes and cartilage explants. IL-1β also caused secretion of both latent and active form of MMP-12 into conditioned medium. Among the signaling pathways activated by IL-1β, inhibition of extracellular signal-regulated kinase-1/2 (ERK 1/2) with PD98059 or p38 kinase with SB202190 blocked expression and activation of MMP-12 in articular chondrocytes. However, inhibition of c-Jun N-terminal kinase with SP600125 did not affect IL-1β-induced MMP-12 expression and activation. Because MMP-12 is known to digest several extracellular matrix components such as type IV collagen and proteoglycan and activate other MMPs such as MMP-2 and MMP-3, our results suggest that IL-1β-induced expression and activation of MMP-12 through ERK 1/2 and p38 kinase may regulate cartilage destruction.

1038 Matrix Metalloproteinase Cleavage of EphB2 Receptor Converts Cell Adhesion to Repulsion

K. Lin, D. W. Ethell, I. M. Ethell; Division of Biomedical Sciences, UC Riverside, Riverside, CA
Eph receptor tyrosine kinases and their ephrin ligands play important roles in cell migration, axon guidance and synaptogenesis. Eph/ephrin signaling is bidirectional and result in cell repulsive or sometimes adhesive responses depending on cell type and developmental stage. Since both Eph receptors and ephrin are membrane-bound, their activation requires cell-cell adhesion between cells expressing Eph receptors and those expressing ephrins. The mechanism by which these high-affinity interactions between receptors and ligands break to convert adhesion to repulsion remains enigmatic. Here, we show that Eph receptor is cleaved by matrix metalloproteases (MMPs) both in vitro and in vivo, and this cleavage is induced by EphB2 interaction with its ligand, ephrin-B2. A subsequent cleavage of EphB2 occurs within the transmembrane region of the EphB2 receptor following MMP cleavage and to produce a cytoplasmic EphB2 cleavage product. Our findings suggest that EphB2 cleavage may contribute to cell-cell repulsion induced by receptor-ligand interaction. Mutations at two putative MMP cleavage sites in the extracellular portion of the EphB2 receptor produced a non-cleavable EphB2-4/5 mutant that inhibited ephrinB2-mediated cell-cell repulsion and blocked axon withdrawal in cultured hippocampal neurons. Although the EphB2-4/5 mutant retained its ability to be activated/phosphorylated upon interaction with its ligand ephrinB2 (after 5 min induction), in contrast to wild type EphB2 (wtEphB2), non-cleavable EphB2-4/5 is rapidly dephosphorylated after 15 min. This pattern of the EphB2 phosphorylation/dephosphorylation suggests that cleavage of the receptor and release of its cytoplasmic domain (cytEphB2) may play an important role in EphB2 signaling. Furthermore, overexpression of cytEphB2 together with EphB2-4/5 induced cell-cell repulsion and axon withdrawal that were similar to wt EphB2. In conclusion, our studies suggest that MMP-mediated cleavage plays an important role in EphB2 receptor function by regulating its signaling.
Multiple Bacterial Species Isoated from Chronic Venous Leg Ulcers Degrades Matrix Substrates

S. Bhalla,1 P. M. Tierno,1 M. Stevens-Riley,1 R. Propst,1 A. B. Wysoczki,1 State University of New York at Stony Brook, Stony Brook, NY, 4New York University Medical Center, New York, NY, 3Food and Drug Administration, Rockville, MD, 2University of Mississippi Medical Center, Jackson, MS

Serine and matrix metalloproteinases (MMP) are activated and overexpressed in chronic wound fluid leading to delayed healing via degradation of extracellular matrix. Bacteria are another potential source of proteolytic activity and can secrete proteases capable of degrading matrix and activating matrix metalloproteinases. However, the types of bacteria isolated from chronic venous ulcers that can secrete proteases capable of degrading matrix substrates have not been well characterized. Using an approved protocol we isolated and identified bacteria collected from six subjects over two to six months. We then tested media from bacterial isolates for its ability to degrade either gelatin, elastin, or N-benzyol- DL-arginine-p-nitroanilide (BAPNA), a serine/ threonine substrate. The total number of different bacterial isolates ranged from 1 - 6 for any individual. Bacteria with protease activity were cultured from both chronic venous leg ulcers and a control site where the skin was intact. The 13 bacteria that expressed proteolytic activity against the gelatin substrate and nine against an elastin substrate and eight isolates were found to have protease activity against BAPNA. Five isolates had activity against only one substrate; three isolates had activity against two substrates; and five isolates had activity against all three substrates tested. We conclude that multiple bacterial species from colonized wounds and intact skin secrete bacterial proteases capable of degrading matrix substrates. The ability of protease secreting bacteria to degrade gelatin, a breakdown product of collagen, elastin, and a serine substrate suggests that bacteria have the capacity to degrade components of the extracellular matrix important for wound healing, thus contributing to the delayed healing seen in chronic wounds.

Arginyl Aminopeptidase-like 1 (RNPEPL1) Is a Ubiquitously Expressed, Alternatively Processed Metallopeptidase with Preference for Neutral and Aromatic Amino Acids

M. W. Thompson, R. L. Seipel; Biology, Middle Tennessee State University, Murfreesboro, TN

Arginyl aminopeptidase-like 1 (RNPEPL1) represents a novel member of the M1 metallopeptidase family, which includes aminopeptidase B and leukotriene A4 hydrolase. A cDNA encoding human RNPEPL1 was amplified from a cdna library and subcloned into an expression vector to investigate its expression and functions. Recombinant RNPEPL1 expressed in Saccharomyces cerevisiae exhibited a preference for the aminoacyl-AMC analogs of methionine and glutamine as measured by kcat/km values, but also possessed appreciable activity towards tyrosine and phenylalanine-AMC. RNPEPL1 also demonstrated weak activity towards citrulline-AMC, with a kcat of 0.56 mM and a kcat of 26.5 min-1, indicating its possible involvement in processing citrulline-containing peptides. In addition to exhibiting a distinct substrate specificity pattern, the catalytic activity of RNPEPL1 was maximal at a pH between 6.8 and 7.8 and was insensitive to chloride activation, in contrast to most other members of the M1 metallopeptidase family. The catalytic activity of RNPEPL1 was strongly inhibited by EDTA, amastatin and arginine hydroxamate, but relatively insensitive to captopril. The expression of RNPEPL1 was investigated in a panel of normal human tissues by RT-PCR, and found to be expressed in all tissues. The investigation of four potential splice variants was also examined, revealing that three of the four alternative choices were utilized, including intron inclusion/exon exclusion, exon skipping, and alternative 3’ splice site choice. This demonstrates the potential for at least 8 different protein isoforms. In addition, a minor alternative mRNA species present in bladder tissue was revealed.

Analysis of Gene Expression Following Disruption of Gap Junction Mediated Cell-Cell Communication by Ouabain

D. C. Barnard, D. H. Hafer, P. L. Jones, P. Lavoie, D. Sammartino, M. L. S. Ledbetter; Biology, College of the Holy Cross, Worcester, MA

In an effort to understand the consequences of gap-junction-mediated cell-cell communication that stems from inhibition of the sodium pump by ouabain, we have used microarray technology to analyze global gene expression over three hours of treatment with ouabain and another three hours after removal of the drug. Using human 293T/17 cells (ATCC, CRL-11268), we confirmed that cells exposed to 1 µM ouabain lost their ability to low-molecular-weight dye during that time, but recovered substantially in ouabain-free medium. To examine changes in gene expression during this time course, we isolated total cellular RNA from five populations of cells: untreated (control), exposed to ouabain for 1 hour or 3 hours, and allowed to recover for 1 hour or 3 hours. With the assistance of the Genome Consortium for Active Teaching, we obtained microarrays printed with the HEEBO set of oligonucleotides representing complete genomic coverage. This allowed comparison of the expressed RNA levels between untreated control cells and the treated experimental cells. Data from the microarrays were analyzed using a combination of computer programs and genes whose expression patterns showed similar changes over the course of the experiment were clustered. Several families of genes displayed enhanced expression during ouabain treatment, reverting to normal levels during recovery. Among these genes were genes associated with responses to heat-shock and oxidative stress, genes associated with vesicle trafficking, genes associated with components of the mitochondrial electron transport chain, and genes associated with several signaling cascades. Connexin genes are not among them. From these preliminary results we conclude that the response of cell-to-cell communication to treatment with ouabain is likely to be an indirect outcome of other more immediate cellular responses, which are consistent with generalized stress. Supported by the National Science Foundation (DUE 0308559) and the Holy Cross Summer Undergraduate Research Program.
The Role of Clathrin in Gap Junction Internalization
L. Chambers,1 B. M. Nickel,1 B. H. Achete,2 Y. Arain,1 S. A. Murray1;1Department of Natural Sciences, Virginia Union University, Richmond, VA; 2Cell Biology and Physiology, University of Pittsburgh, Pittsburgh, PA, 3San Diego State University, San Diego, CA

Gap junction-mediated intercellular communication has been implicated in the development, differentiation and function of most tissues. The rates of plaque removal as well as formation are thought to be critical to gap junction function, but the mechanisms that are involved in the disassembly of gap junction plaques are not well understood. In this study, the role of clathrin in gap junction plaque invagination, internalization and annular gap junction formation was investigated with transmission electron microscopy, immunocytochemical localization and computer reconstruction techniques. In addition, a fluorescently-tagged gap junction protein Connexin43(Cx43), was expressed in adrenal cells. In these cells, and the frequency of gap junction internalization was analyzed with time lapse live imaging techniques to monitor annular gap junction vesicles. In some cases, both clathrin and its adaptor protein, AP-2 were observed, with immunocytochemical techniques, to colocalize with Cx43 annular gap junction vesicles and gap junction plaques. The AP-2 was concentrated and preferentially localized on only one side of the gap junction plaque while the other side was sometimes devoid of AP-2 staining. Three dimensional imaging techniques were used to explore the association between Cx43 (gap junction plaques or annular gap junctions) and clathrin, AP-2, and lysosomes. Based on observations of the fusion of cytoplasmic vesicles and lysosomes and the association of clathrin and AP-2, it is suggested that gap junction endocytosis is one step in the process of connexin degradation and that clathrin is involved in the gap junction internalization. NSRF MCB-0444398

FGF-1 Increases the Plasma Membrane Permeability through Connexin43 Hemichannels: Involvement of Connexin C-Terminus and Intracellular Free Ca2+ Concentration
K. A. Schalper,1 M. A. Retamal,1 K. F. Shoji,2 A. D. Matinez,1 J. C. Sáez1;1Departamento Fisiología, Pontificia Universidad Católica de Chile, Santiago, Chile, 2Núcleo Milenio de Inmunología e Inmunoterapia, Santiago, Chile, Instituto de Neurociencias, Universidad de Valparaiso, Valparaíso, Chile

Connexin hemichannels (Cxs-HCs) are plasma membrane channels permeable to ions and small cations molecules. They are expressed by most cell types and remain preferentially close under resting conditions. Physiological stimuli that induce opening of HCs in the presence of extracellular divalent cations remain unknown. To show that the latter may occur, we studied the effect of FGF-1 on the cellular permeability mediated by HCs in the presence of extracellular Ca2+/Mg2+. We used HeLa cells stably transfected with wild type Cx26 (HeLa-Cx26WT), Cx43 (HeLa-Cx43WT), Cx45 (HeLa-Cx45WT) or Cx43 truncated in its C-terminus at aa 257 (HeLa-Cx43Δ257). Cells were treated with FGF-1 for different periods of time in medium containing Ca2+ (1.8mM) and Mg2+ (1mM). The plasma membrane permeability was assessed by time-lapse imaging of ethidium bromide (EtBr) uptake. The amount of HCs in the cellular surface was evaluated by protein biotynilation, followed by pull-down and immunoblotting. Intracellular [Ca2+] was measured using Fura2-AM and image processing. After 7h of FGF-1 addiction, the EtBr uptake rate and [Ca2+] increased significantly only in HeLa-Cx43WT and HeLa-Cx45WT but not in HeLa-Cx43Δ257. The FGF-1-induced increase in rate of EtBr uptake was rapidly blocked (<30 sec) by La3+ (200 μM). In HeLa-Cx43WT, BAPTA-AM (5μM) prevented the FGF-1-induced increase in rate of EtBr uptake and 4Br-A23187 (5μM, 40 min) mimicked all the FGF-1-induced effects studied. The participation of P2X and TRP channels was ruled out using pharmacological criteria. Thus, FGF-1 increases the plasma membrane permeability mediated by HCs under physiological conditions. The effect requires amino acid residues present in connexins 43 and 45 but not in connexin26 C-terminus that in conjunction with enhanced [Ca2+], increases the levels of HCs in the cellular surface.

PDGF Induces a Transient Increase in the Permeability of Cx43 Juncitons
J. P. Elkoy,1, H. Nelson,1 A. M. Burt; Physiology, University of Arizona, Tucson, AZ

In Cx43 expressing cells growth factors that result in PKC activation typically lead to reduced junctional dye permeability (p_j) and electrical conductance (g_j). These decreases require phosphorylation of Cx43 at S368 and involve reduction of channel conductance (γ_j). Accordingly, Cx43-S368A comprised junctions are unresponsive to PDGF application and direct PKC activation, and Cx43-S368A channels are less likely to adopt the 50-60pS subconductance state typically induced by these agents. Thus, PDGF stimulation is linked to Cx43 phosphorylation (at S368) and decline of p_j, g_j and γ_j. However, recent evidence have shown that phosphorylation of Cx43 at Y204 (Biophys J 2006, 91:565) is for Cx43-S368A junctions (CircRes 2006, 98:1498). Importantly, junctions with many 50-60pS channel events were better permeated by the small, cationic dye NBD-M-TMA (high p_j) than junctions without such events. To reconcile these apparently discrepant results, we determined the dye transfer rate constant (k_j) and conductance of Cx43 junctions as a function of time following PDGF application. As expected, ko increased during the first 10 min (to 44±6.6 % of initial value) and the relative contribution of 50-60pS channels increased. Over this same time period, modest shifts toward higher k_j were observed although continued PDGF exposure resulted in complete uncoupling. These results suggest that junctional permeability (k_j/g_j) increases during the first 10-15 minutes of PDGF exposure, remains elevated for a short period (10-15 minutes) and then decreases to pre-treatment or lower levels. The transient nature of the increase in k_j/g_j likely involves reconfiguration of individual, low permeability channels to a high permeability configuration with ongoing decreases in channel number (i.e. Cx43 channel turnover). This transient increase in permeability may constitute a regulatory trigger within tissues that primes the cells for subsequent growth when both p_j and g_j have decreased.

Purinergic Regulation of Connexin43 Gap Junctions Is Dependent on Serine368
A. W. Hunter, R. Gourdie; Medical University of South Carolina, Charleston, SC

Catheterization is thought to be required for gap junction function. Conversely, there is evidence that connexins, the subunits of gap junctions, play an important role in the formation of cadherin-based cell-cell contacts. However, the molecular mechanisms that provide the functional linkage between cadherins and connexins at sites of cell contact are largely undefined. ZO-1, an actin-binding MAGUK protein, localizes to both gap junctions and cadherin-based junctions, and thus is a good candidate to mediate interplay between cadherins and connexins during junction formation and maintenance. To test this idea we used a spinning disk confocal microscope to image live HeLa cells that transiently co-expressed connexin43-CFP with either N-cadherin-YFP or YFP-ZO-1, in a background of stably expressed untagged connexin43. Consistent with our previous findings, YFP-ZO-1 colocalized with connexin43 was confined mainly to the periphery of gap junction plaques. Peripherally associated YFP-ZO-1 manifested as highly dynamic punctae that moved predominately along plaque edges, although some punctae appeared to traverse plaques from edge to edge. The movement of YFP-ZO-1 at plaque edges was associated with dramatic undulations in plaque morphology, which gave the qualitative impression that tension generated at sites of edge-localized YFP-ZO-1 might influence gap junction dynamics. In support of this idea, fixed cell analysis showed that ZO-1 at plate edges also colocalized with actin filaments. Interestingly, like YFP-ZO-1, N-cadherin-YFP associated with gap junctions in living cells localized preferentially to plaque edges. Furthermore, the dynamic behavior of edge-localized N-cadherin-YFP mimicked that of YFP-ZO-1. Extensive colocalization of N-cadherin and ZO-1, including at the periphery of connexin43 gap junctions, was confirmed by confocal analysis in fixed cells. These observations support the hypothesis that ZO-1 integrates N-cadherin adhesion and connexin43 membrane dynamics at specialized junctional interfaces, possibly by modulating linkages to the actin cytoskeleton.
Src Utilizes Cas to Block Gap Junctional Communication Mediated by Connexin43

Y. Shen,1 P. R. Khushi,1 A. P. Moreno,2 G. S. Goldbergl; 1UMDNJ, Stratford, NJ, 2University of Utah, Salt Lake City, UT

Malignant and metastatic tumor cells often display less gap junctional communication than their benign or normal counterparts. The Src tyrosine kinase phosphorylates Cas to confer metastatic growth potential to transformed cells. The gap junction protein Cx43 is a tumor suppressor that can inhibit tumor cell growth. Src can phosphorylate Cx43 to block gap junctional communication between transformed cells. However, mechanisms by which this event actually closes intercellular channels have not been clearly defined. Here, we report that Src utilizes Cas to close gap junction channels formed by Cx43. This observation may help explain how gap junctional communication can be suppressed between malignant and metastatic tumor cells.

Cx43 Phosphorylation: Connecting Specific Phosphorylation Events to Changes in Trafficking, Assembly, and Electrophoretic Mobility

J. Solan, P. Lampe; Fred Hutchinson Cancer Research Center, Seattle, WA

Cx43 has been shown to have different phosphorylation which can be distinguished by their electrophoretic mobility, yet the actual phosphorylation events which lead to these conformational changes and their functional significance have not been linked. Using antibodies that are targeted to specific phosphorylation sites, we have found two phospho-epitopes, residing around S364/S365 and S325/S328/S330, which contribute to the mobility phenotypes of Cx43 and are analyzing the functional significance of these sites. We have found that phosphorylation at a single residue, S365, leads to the P1 isoform of Cx43. We have also found that a phosphopeptide which resides around S325/S328/S330 contributes to formation of the Triton X-100 insoluble P2 isoform of Cx43. In MDCK cells stably expressing serine to alanine mutations at all of these sites (S325/S328/S330A), the P2 isoform of Cx43 is not formed nor is Cx43 efficiently trafficked to the plasma membrane. Mutation of these sites individually did not recapitulate the S325/S328/S330A phenotype, indicating that it is some combination of these sites that are involved in gap junction formation. Interestingly, the S325/S328/S330A cells also do not appear to be phosphorylated at S364/S365. This may be one of the first site specific examples showing a hierarchy of phosphorylation events involved in Cx43 transport to the plasma membrane and inclusion in the Triton X-100 insoluble gap junction plaque.

The Effects of Intracellular Reactive Oxygen Species on Cx43 Expression and Phosphorylation in Enterocytes

G. Valdimarsson,2 R. Szajkowski,3 J. K. Friel,4 W. Dichi-Jones; 2Zoology, University of Manitoba, Winnipeg, MB, Canada, 3Human Nutritional Sciences, University of Manitoba, Winnipeg, MB, Canada, 4Nursing, University of Manitoba, Winnipeg, MB, Canada

Several studies have shown that increased intracellular reactive oxygen species (ROS) alter the expression of gap junction proteins and influences gap junctional intercellular communication (GJIC). We have previously shown that iron supplements in human breast milk increase lipid peroxidation, generate ROS in cultured enterocytes, and induce apoptosis. In the present study, we demonstrate the effects of oxidative stress and iron supplemented breast milk on the expression and phosphorylation patterns of connexin 43 (Cx43) in CaCo-2BBE cells. Preliminary semi-quantitative RT-PCR data suggest that known inducers of ROS, including hydrogen peroxide and xanthine-xanthine oxidase (XOX), decrease Cx43 transcript levels. Western blot analysis indicates that, in untreated cells, the non-phosphorylated isoform of Cx43 is predominant. Treatment with either hydrogen peroxide or XOX induced formation of phosphorylated isoforms of Cx43, as well as increased overall protein expression of both phosphorylated and non-phosphorylated isoforms. Furthermore, iron treatments also induced expression of phosphorylated Cx43. XOX, hydrogen peroxide and iron treatments also decrease transepithelial electrical resistance across CaCo-2BBE confluent monolayers. In scrape-load experiments treatment with glycerophosphoric acid, as well as iron and peroxide decreased GJIC. Taken together, these results suggest that ROS and exogenous iron increase Cx43 protein expression and phosphorylation, likely via translational control. Furthermore, there is a correlation between increased Cx43 protein expression and phosphorylation and decreased epithelial GJIC and membrane integrity.

Altered Distribution of Connexin43 in Oubain-treated MDCK Cells

C. M. Fanning, R. Korkel, M. H. A. R. K. van den Berg, B. Wipke; 1Biology, College of the Holy Cross, Worcester, MA

Many types of cultured mammalian cells communicate among themselves through gap junctions. This communication is reversibly inhibited by exposure of the cells to the cardiac glycoside ouabain, known to inhibit the cells’ sodium pump. We have found that MDCK cells (ATCC CCL-34) treated with 1 μM ouabain reduce their ability to transfer tracer dye molecules over the course of 3 hours. Replacement of ouabain with drug-free medium allows recovery over the next 3 hours. Here we report that the distribution of Connexin43 (Cx43) immunofluorescence changes during treatment and recovery. Untreated cells show punctate chains of fluorescence at cell-to-cell junctions and diffuse staining in a perinuclear region, as reported previously (Berthoud, V.M., et al. 1992 Eur. J. Cell Biol. 57: 40-50). Within the first hour of ouabain treatment, the surface fluorescence disappears, and is replaced by fluorescence in cortical vesicles; after 3 hours very little fluorescence can be detected. During recovery surface fluorescence reappears at cell-to-cell appositions. Amiloride treatment protects the cells from ouabain-induced loss of junctional staining, presumably because amiloride block Na+ channels and prevents Na+ from entering. Treatment of these kidney-derived cells with the mineralocorticoid hormone aldosterone along with ouabain likewise protects them from loss of junctional staining. However, addition of epinephrine or spinonolactone, both antagonists of the aldosterone receptor, counteracts this effect, and junctional staining is lost even in the presence of aldosterone. This study supports a model in which sodium homeostasis is somehow required for the maintenance of Cx43 at junctions, a prerequisite to cell communication. We propose that aldosterone protects cells from the effects of ouabain by acting through its intracellular receptor to normalize cytoplasmic conditions. Thanks to Pfizer Inc. for a sample of eplerenone, to the National Science Foundation (DUE 0308559), and to the Summer Undergraduate Research Program at College of the Holy Cross.

Identification of Phosphorylation Sites in Lens Fiber Cell Connexins by Matrix Assisted Laser Desorption/Ionization Mass Spectrometry and Tandem Mass Spectrometry

D. B. Shearer,1 W. Ens,2 K. G. Standing,3 G. Valdimarsson; 1Zoology, University of Manitoba, Winnipeg, MB, Canada, 2Physics, University of Manitoba, Winnipeg, MB, Canada

Lens junctional complexes are composed of connexins. The lens is an avascular tissue that is dependent on gap junctions for the distributions of nutrients as well as the removal of waste products. Two connexins, Cx44 and Cx49, are highly expressed in bovine lens fiber cells. Phosphorylation of connexins is believed to be involved in the regulation of several processes, such as the assembly and disassembly of connexons, and the gating and permeability properties of the intercellular pore. To begin to characterize the post translational regulation of the connexins expressed in the lens we have used crude membrane preparations from bovine lens and analyzed the proteins present by proteolytic digestion, followed by HPLC separation of the resulting peptides and analysis by MALDI mass spectrometry and tandem mass spectrometry. We were able to obtain significant coverage of the cytoplasmic portions of Cx44 and Cx49, and to identify several phosphorylated residues from each protein. All of the phosphorylated residues in Cx44, thr237, thr299 and thr302 and ser240 and ser244, were located in the carboxy terminal. Cx49 was phosphorylated on ser114, ser117, and ser133 from the cytoplasmic loop domain and at ser257, ser260, ser264, ser265, ser296, and ser299 from the carboxy terminal. In addition, we identified other posttranslational modifications including a deamidation at asn120 in Cx44, and potential cleavage sites in each protein. The extensive coverage of lens connexin proteins obtained by MALDI mass spectrometry and tandem mass spectrometry in this study provide the foundation for the lens to become a useful system for studying the effects of kinase activation on connexin phosphorylation.

Connexin43 Gap Junction Proteins Are Up-Regulated in Remyelinating Spinal Cord

W. A. Roscoe,1 E. Messersmith,2 A. Meyer-Franke,2 B. Wipke,3 S. Karlik1; 1Physiology, University of Western Ontario, London, ON, Canada, 2Elan Pharmaceuticals, South San Francisco, CA

Alterations in the expression of gap junction proteins have previously been observed in several diseases affecting the central nervous system; however, the status of Connexin43 (Cx43) has not yet been reported in demyelination and remyelination. We used a chronic guinea pig model of EAE treated on days 40-60 post immunization (p.i.), with an adenosine amine congener (ADAC, 100 μg/kg), an anti-alpha 4 integrin blocker (CT301, ELN 69299, 30 mg/kg bid) or both CT301 and ADAC, to investigate the expression of Cx43 in demyelinating and remyelinating spinal cord lesions. Hartley guinea pigs were immunized with homogenized whole CNS and CFA. Animals became chronically ill by day 40 p.i. and animals with paralysis were entered into the study. Clinically, the combination treatment was not as effective as CT301 alone (p<0.05), but significantly better than ADAC alone or saline-treated animals (p<0.05). Kruskal-Wallis ANOVA on Ranks, Tukey HSD: Cx43 was effectively (1.7-fold) higher in the saline control (p<0.01). Cx43 expression was virtually absent in demyelinated lesions of saline-treated controls compared to healthy tissue and normal appearing white matter (NAWM) (ANOVA, p<0.001), whereas, Cx43 was considerably increased in remyelinating lesions of all treatment groups (ANOVA, p<0.001), most notably in CT301-treated animals. These changes in Cx43 expression indicate altered astrocyte function in neuroinflammation and recovery.
Mouse connexin30.2 (Cx30.2) is a recently discovered connexin that is expressed in the heart in the sinoatrial and atrioventricular nodes. Most cells in the heart co-express multiple connexins, and we have been studying the interactions between these connexins, including Cx40, Cx43 and Cx45. We have studied the possible heteromeric interactions between Cx30.2 and other cardiac connexins (such as the nodes or the cells that connect the specialized conducting system to the working myocardium).

These connexins (such as the nodes or the cells that connect the specialized conducting system to the working myocardium). A necessary prerequisite for separation is that cells resolve cell-cell junctions that bind them. However, the mechanisms by which junctions are resolved and reestablished are not well known. We have found that gap junctions (GJs) are internalized to form cytoplasmic double-membrane vesicles, termed annular gap junctions (AGJs). In some instances, AGJs appear to spontaneously reinsert into the plasma membrane, suggesting a possible mechanism for sequestration and re-use of GJs. We hypothesize that, utilizing such a mechanism, gap junction intercellular communication (GJIC) could be rapidly modulated without requiring energetically costly transcription and translation events.

In the present study, we developed a model system to test this hypothesis using the inflammatory mediator, thrombin, which has been described to induce transient, reversible cellular separation in primary pulmonary artery and microvascular endothelial cells (PAECs and PMVECs). We are studying the effects of thrombin on the localization of three components of cell-cell junctions: Connexin 43 (Cx43) (GJs), E-cadherin (adherens junctions), and occludin (tight junctions). Immunofluorescence imaging revealed that thrombin induced cellular uncoupling within 20 to 90 minutes. As compared to controls, treated cells showed a significant decrease in Cx43 GJs at the plasma membrane accompanied by a significant increase in intracellular vesicles containing Cx43. When thrombin was removed from media, re-coupling in both PAECs and PMVECs began within 10 minutes. These results suggest that inflammatory mediator-induced separation of endothelial cells is a suitable model system for studying cellular uncoupling and re-coupling events.

Expression of Cx43 in vivo and in cardiac-derived cells harboring an autosomal dominant Gja1 (Cx43) gene mutation. J. W. Ansley, D. W. Laird1, 2; 1Physiology and Pharmacology, University of Western Ontario, London, ON, Canada; 2Anatomy and Cell Biology, University of Western Ontario, London, ON, Canada

More than 30 mutations in the GJA1 gene encoding Cx43 have been linked to ocudentodigital dysplasia (ODDD), a pleiotropic, autosomal dominant disorder. In the present study we employed a mouse model of ODDD, containing a unique Cx43 mutation, to examine the localization and fate of mutant and wild-type Cx43 in vivo and in isolated cells. Western blot assessment revealed differential regulation of total Cx43 protein in various tissues from mutant mice, when compared to wild-type littermates. Concentrating primarily on the heart, where Cx43 expression is critical for proper function, we observed a four-fold decrease in Cx43 level, with a preferential reduction in highly phosphorylated species of Cx43. Other cardiac gap junction proteins, Cx40 and Cx45, did not exhibit any evidence of up-regulation in mutant mouse hearts. The severe reduction in total Cx43 level in mutant mouse hearts suggests a destabilization of co-expressed wild-type Cx43, possibly through premature targeting to degradative pathways. Preliminary confocal microscopy data supports possible Cx43 trafficking defects in primary cardiomyocytes isolated from neonatal mutant mice due to the presence of the Cx43 mutant. These cells also exhibit a faster rate of cell beating compared to parallel cells prepared from wild-type mice. To further study the expression and fate of Cx43 in the heart, cardiac fibroblast cell lines capable of repeated passage have been derived from wild-type and mutant littermates. These cultured cell lines represent a valuable model system for elucidating the mechanisms of assembly and function of Cx43-containing junctions.

Expression and Fate of Cx43 In Vivo and in Cardiac-derived Cells Harboring an Autosomal Dominant Gja1 (Cx43) Gene Mutation

Heteromorphic Compatibility of Cx30.2 with Other Cardiac Connexins

J. Mencel, J. Neiman, J. Poss, R. Collins, R. D. Veenstra, E. C. Beyer, Pediatrics, University of Chicago, Chicago, IL, Pharmacology, SUNY Upstate Medical University, Syracuse, NY

Mouse connexin30.2 (Cx30.2) is a recently discovered connexin that is expressed in the heart in the sinoatrial and atrioventricular nodes. Most cells in the heart co-express multiple connexins, and we have been studying the interactions between these connexins, including Cx40, Cx43 and Cx45. We have studied the possible heteromeric interactions between Cx30.2 and other cardiac connexins. Cx30.2 was amplified from mouse genomic DNA by PCR, yielding a sequence that showed 100% identity with GeneBank AJ441561. Cx30.2 was transiently transfected into HeLa cells or HaCaT cells that had previously been stably transduced with other cardiac connexins. Cx30.2 was detected with anti-Cx30.2 antibodies or with anti-HA antibodies that recognized an HA epitope appended to the C-terminus. Immunoblotting showed that the transfected cells abundantly produced the introduced connexin proteins. Double label immunofluorescence microscopy showed that Cx30.2 was extensively co-localized with co-expressed Cx43 or Cx45 at appositional membranes. Connexins from cells co-expressing Cx30.2 and other connexins were solubilized with 1% Triton X-100 and purified according to their affinity for anti-HA beads. Co-expressed Cx30.2 or Cx45 co-purified with the Cx30.2-HA protein. These results suggest that Cx30.2 can form heteromeric connexons with other cardiac connexins (Cx43 and Cx45). Heteromeric channel formation might affect the properties of gap junction in regions that co-express these connexons (such as the nodes or the cells that connect the specialized conducting system to the working myocardium).
Adrenergic Receptor Regulation of Cardiac Connexins
A. Froger,1 H. Gerami,1 J. Hall,1 M. M. Lurtz;2 Department of Physiology and Biophysics, University of California, Irvine, CA, 3Department of Cell Biology and Neuroscience, University of California, Irvine, CA

Catecholamines are physiologic cardiac modulators acting through adrenergic receptors (AR). Using H9c2 cells, an embryonic rat cardiomyocyte cell line expressing multiple connexin (Cx) proteins including Cx43 and Cx40, it was determined that AR activation by the catecholamine noradrenaline (NE, 100 μM) results in a ~50% reduction in AlexaFluor594 dye transfer 2 min after NE addition that is sustained for at least 30 min [transfer reduced from 23.3±1.2 cells prior to NE addition to 11.3±0.3 cells and 13.0±1.5 cells 2 min and 30 min post-NE addition, respectively]. In contrast, ~90% of connexin-mediated biological coupling in the H9c2 cells was inhibited following the addition of the gap junction inhibitor carbenoxolone (35 μM, 20 min). Parallel experiments were performed on HEK293 cells stably transfected with either Cx43 or Cx46. Cx43-mediated biological coupling was significantly inhibited within 2 min of NE addition [transfer reduced to 1.0±0.6 cells from 19.3±0.9 cells] and remained ~95% inhibited through the duration of the experiments [30 min, 0.6±0.3 cells]. Similar to the results obtained in H9c2 cells, Cx46-mediated biological coupling was significantly, but incompletely inhibited following NE addition [transfer reduced to 6.0±1.0 cells and 5.3±2.1 cells 2 min and 30 min post-NE addition from 12.8±0.5 cells prior to NE addition]. Since NE activates multiple AR isoforms, the contribution of the effect of α- or β-AR isoforms on Cx43 biological coupling was determined. Cx43 biochemical coupling was significantly reduced following activation of α-AR by xylazine (100 μM, transfer decreased from 21.5±0.5 cells to 2.5±0.5 cells) and α-AR with phenylephrine (100 μM, transfer decreased from 22.0±0.9 cells to 1.3±0.3 cells). These data suggest that the regulation of cardiac connexin biological coupling following AR activation is dependent on both the connexin protein(s) and the AR isoform(s) expressed.

Autophagy is a cellular mechanism for degradation of proteins and organelles. Several disease-associated mutant proteins have impaired degradation. One such mutant is a proline-to-serine mutation at position 88 in a gap junction protein, human connexin 50 (CX50P88S), which accumulates in cytoplasmic multilamellar structures. To study the mechanism of formation of CX50P88S accumulations and its possible association with autophagy, a DNA construct encoding CX50P88S with a tetracysteine tag appended at its carboxy terminal was produced by PCR and expressed by stable transfection of HEK293 cells. Fluorescence-labeled autophagosomal and lysosomal markers (MDC, LC3 and LAMP1) associated with the CX50P88S accumulations. ERGIC-53 immunoreactivity co-localized with GFP-LC3 or with CX50 immunoreactivity, suggesting that the autophagosomal membrane and CX50P88S may originate from the ER or Golgi. Sequential labeling with bionsecoidal compounds that fluoresce at different wavelengths (FITC, green, and RhoX, red) demonstrated that CX50P88S was long-lived and that newly synthesized protein could either be added at the periphery of previously formed accumulations or start the formation of new ones. To investigate whether wild type (wt) connexins could be degraded by autophagy, HEK293 cells stably transfected with wt CX50 and NRK cells which endogenously express wt Cx50 were subjected to starvation. Under these conditions, cells showed overlap between GFP-LC3 fluorescence and immunoreactivity to anti-connexin antibodies. Moreover, treatment of cells expressing wt CX50 or Cx43 with chloroquine, a lysosomal inhibitor, increased the extent of overlap between LC3-labeled and anti-CX50 or anti-Cx43 immunoreactive structures under normal growth conditions and more substantially under starvation conditions. Based on these results, we conclude that autophagy is an important pathway for degradation of both wild type and mutant connexins.

Subcellular Localization of GFP-tagged Rat Eag K+ Channels in Neurons
C. Tang,1 H. Lin,1 C. Jeng;2 Department of Physiology, National Taiwan University, College of Medicine, Taipei, Taiwan, 2Institute of Anatomy & Cell Biology, National Yang-Ming University, College of Medicine, Taipei, Taiwan

The eag potassium (K+) channel is a member of the superfamily of voltage-gated potassium channels. The mammalian eag subfamily includes eag1 and eag2 K+ channels, both of which have been shown to be expressed exclusively in the central nervous system. Previous studies from our lab have demonstrated that native rat Eag1 and Eag2 channels displayed differential subcellular localization patterns in hippocampal neurons. In the present study, we aim to study the subcellular localization of GFP-tagged Eag1 and Eag2 K+ channels in neurons. GFP fusion constructs were created by subcloning rat Eag1 and Eag2 cDNAs into pEGFP vectors, respectively. Upon whole-cell patch clamp recording, HEK293T cells transfected with the GFP-tagged cDNAs displayed outward rectifying K+ currents that were characteristic of rat Eag channels. We next transfected cultured rat neurons with GFP-Eag1 or GFPEag2 cDNA to study the subcellular localization pattern of GFP fluorescence by using confocal microscopy. We found that the localization patterns of GFP-Eag fusion proteins were reminiscent of those for their native counterpart proteins. Our present findings provide further evidence supporting the idea that rat Eag K+ channels are localized in the dendrosomatic compartment of neurons.

Identification of a Critical Threonine in the Early Biogenesis of Voltage-gated Potassium Channels
L. McKeown, M. Burnham, G. Edwards, O. T. Jones; Faculty of Life Sciences, University of Manchester, Manchester, United Kingdom

The dynamic expression of voltage-gated ion channels in discrete areas of the cell surface is a fundamental factor in controlling membrane excitability. In neurons, voltage-gated potassium channels affect the shape, size and duration of action potentials and, thereby, act as potent modulators of excitatory events. Unfortunately, how such channels are trafficked to and from the cell surface is poorly understood although there is evidence that regulation of their export from the endoplasmatic reticulum serves as an important checkpoint in regulating channel assembly and surface density. Based upon studies of the ‘simple’ Kv1 family of voltage-gated potassium channels (VGKs) it has been proposed that topogenesis involves the co-operative insertion of the second (S2) of six (S1-S6) transmembrane spanning domains by virtue of its propensity to act as a cryptic signal peptide. In exploring possible ER control mechanisms, we identified a highly conserved motif in the extracellular S1-S2 linker which we hypothesise may be critical for Kv biogenesis. Using immunofluorescence microscopy, patch-clamp electrophysiology and site-directed mutagenesis we have confirmed that a single threonine residue is necessary for the correct trafficking of Kv1.4 to the cell surface. Mutation of this residue to alanine or to a phosphominic aspartic acid prevented cell surface expression by retaining channels in the ER. However, any ER retention is abrogated by conservative mutation of threonine to a serine residue. Significantly, the threonine residue is conserved in all VGK family and the corresponding mutations in both Kv2.1 and Kv3.1 reveal similar patterns of ER-retention. Consequently, we have identified a critical threonine residue that appears to play a general and pivotal role in the biogenesis and/or trafficking of voltage-gated potassium channels to the cell surface that, we suggest, acts by coordinating hydrogen bonding interactions with S1-S2 residues early in Kv biosynthesis. Supported by BBSRC(UK).

The Molecular Mechanism Underlying Axon-dendrite Targeting of Kv3 (Shaw) Voltage-gated Potassium Channels
M. Xu, R. Xiao, S. Qin, M. Zhu, C. Gu; Neuroscience, The Ohio State University, Columbus, OH
Kv3 (Shaw) channels, with rapid activation and deactivation kinetics, are involved in fast-spiking of GABAergic interneurons and neurotransmitter release in nerve terminals. The physiological significance is underscored by behavior abnormalities and neurodegenerative disease in mice and human, carrying mutations in their Kv3 channel genes. It is known that the placement of ion channels on the plasma membrane is critical for proper neuronal functions. Kv3 channels target to axons and/or dendrites in neurons, depending on isoforms, splicing variants and brain regions. However, little is known regarding the underlying mechanism. Here we report that C-terminal alternative splicing controls Kv3.1 axon-dendrite targeting through a highly conserved motif. First, HA-tagged two spliced variants of Kv3.3 channels, Kv3.1a and Kv3.1b, differentially localize to somatodendritic and axonal surfaces of hippocampal neurons. Next, with two reporter membrane proteins, TIR-GFP and CD4, the axonal targeting motif (ATM) was surprisingly mapped to a region, which is not only present in both splicing variants but also highly conserved in all Kv3 channels. We further discovered that the ATM binds to ankyrin G, which is previously known as critical to target voltage-gated sodium and KCNQ channels to axon initial segment. Finally, the splicing domain, likely through regulating the ATM-ankyrin G binding, controls the axon-dendrite targeting of Kv3.1 channels.

Membrane Trafficking of K-Cl Cotransporter KCC4 Is Important for Ovarian Cancer Cell Invasiveness
Y. Chen,1 M. Shen;2 1Institute of Basic Medical Sciences, National Cheng Kung University, College of Medicine, Tainan, Taiwan, 2Department of Pharmacology, National Cheng Kung University, Tainan, Taiwan

The cellular function of membrane electroneutral K-Cl cotransporter (KCC) is to regulate epithelial ion transport and osmotic homeostasis. KCC activation by IGF-1 plays an important role in IGF-1 receptor signaling to promote growth and spread of breast cancer, cervical cancer and ovarian cancer cells. Among different KCC isoforms, KCC4 is highly associated with cancer invasion and metastasis in human cervical and ovarian cancer. Here we investigate the regulatory mechanisms of KCC4 membrane trafficking and its functional significance in tumor biology.
Evidence for Anion Channel-mediated Superoxide Permeability in Endosomal Membranes

D. R. Mumbengegwi, Q. Li, C. Li, E. Bear, J. F. Engerlhardt, T. Chang, F. J. McDonald; Department of Physiology, University of Otago, Dunedin, New Zealand

The epithelial sodium channel (ENaC) is a key regulator of extracellular fluid homeostasis and blood pressure. The classic ENaC consists of three subunits: α, β, and γ, which are highly expressed in epithelial tissues such as kidney, colon, and pancreas. Despite close similarity, a fourth ENaC subunit called Murr1/COMMD1 is downregulated by proinflammatory modulators phorbol myristate acetate (PMA) and tumor necrosis factor alpha (TNF-α) blocked the membrane trafficking of KCC4. Thus we conclude that IGF-1 stimulates the membrane trafficking of KCC4 through lipid rafts-associated vesicles and PI3-K pathway. Moreover, the IGF-1-stimulated KCC4 membrane trafficking may be important for ovarian cancer cell invasiveness.

Identification of RhoA Effector Signals Involved in the Suppression of the Voltage-gated Potassium Channel Kv1.2

L. Stirling, A. D. Morielli; Cell and Molecular Biology Program, University of Vermont College of Medicine, Burlington, VT, Department of Pharmacology, University of Vermont College of Medicine, Burlington, VT

Kv1.2 is a Shaker family voltage-gated potassium channel expressed in neurons, cardiac muscle, vascular smooth muscle, and epithelial cells. Previous research has shown that the small GTPase RhoA interacts with the N-terminal of the channel and that increased RhoA activity leads to a reduction of Kv1.2 current. Other studies have shown that Kv1.2 regulation by tyrosine kinases involves trafficking of the channel away from the cell surface. The objective of this study is to investigate the RhoA signals involved in Kv1.2 trafficking. Flow cytometry was used to measure the amount of Kv1.2 on the surface of an HEK293 cell line that stably expresses the channel. The RhoA inhibitor, C3 exoenzyme, significantly upregulates the channel at the cell surface. Conversely, activation of RhoA with Lysoosphatidic acid (LPA) results in a dose-dependent suppression of cell surface Kv1.2. Pharmacological inhibition of Rho kinase, a downstream effector of RhoA, with either Y27632 or HA1077 significantly upregulates Kv1.2 at the cell surface. When combined, Y27632 and HA1077 produce an additive effect. This suggests that more than one signaling pathway acts to regulate cell surface Kv1.2 downregulation. Pre-treatment with Y27632 also prevents the LPA-induced loss of cell surface Kv1.2. From these data we conclude that activation of RhoA by LPA leads to loss of Kv1.2 from the cell surface and that Rho kinase signaling is at least partially responsible for this suppression. Other candidate RhoA effectors involved in this signaling pathway are currently under investigation, including Protein kinase C-related kinase (PKR).

Endosomes Luminal Chloride Ions Regulate Calcium Permeable Channels in SKD1/vps4B (E253Q) Induced Large Endosomes - Direct Patch-Clamp Study

M. Saito, P. Hanson, P. Schlesinger; Cell Biology & Physiology, Washington University, St. Louis, MO

Endocytosis plays important roles in nutrient uptake, regulation of proteins and lipids in the plasma membrane and various intracellular membranes. Endocytosed molecules travel to the early endosome (EE), where they are sorted for recycling to the plasma membrane or degradation by lysosomes. In this process, a series of vesicular fusion events take place that require calcium ions. The EE lumen is thought to serve as a source for these calcium channels. However the identity of calcium conducting channels that execute this function in EE remains speculative. The characterization of endosome calcium channels is important in understanding the endocytic pathway. The objective of this study was to identify EE calcium permeable non-selective calcium channels (ECC). Methods: Enlarged EE (3–6um in diameter) were produced by expressing a dominant-negative mutant, E235Q, of SKD1/vps4B (AAA-ATPase) in HEK293 cells. The EE-lumen calcium channel (ECC) method was modified to allow patch-clamping of the native endosome membrane, and ii) To identify the Endosome calcium permeable non-selective Calcium Channels (ECC). Procedures: Enlarged EE (3–6um in diameter) were produced by expressing a dominant-negative mutant, E235Q, of SKD1/vps4B (AAA-ATPase) in HEK293 cells. Manually isolated enlarged endosomes were subjected to whole-endosome and inside-out patch-clamp study. Results: The ECC was identified in EE membrane. The ECC was equally permeable to both Na⁺ and K⁺, and also to Ca²⁺ (1:3 ratio to K⁺). ECC was activated by >1mM amiloride and by >300mM La³⁺. The most striking aspect of ECC gating was strong dependence on the luminal chloride concentration. ECC was activated when CF was lowered from 150mM to 30mM. Conclusion: We have identified a Ca²⁺ regulated calcium permeable cation channel in SKD1/vps4B (E253Q) induced large EE membrane. Since the activation of CF in the EE lumen is critical for effective acidification of endosomes by vacuolar type H⁺-ATPase, the discovery of ECC suggests that EE luminal chloride ions may play an important role in regulating endosome function. The presence of functional expression of several TRP channels on human synovial cells and proposed a significant role in mediation of calcium dependent proliferative and secretory responses in joint inflammation. The present study further supports our hypothesis comparing changes in synovioocyte response to thermal sensitive TRP channel activation with proinflammatory modulators phorbol myristate acetate (PMA) and tumor necrosis factor alpha (TNF-α). Fluorescent imaging of SW982 synovial cells loaded with Fura-2 reveals immediate and delayed cytotoxic calcium (Ca²⁺;Ca⁺⁺) oscillations elicited by TRPV1 agonists capsaicin and reserpinatoxin in 20 - 40 % of cells recorded. Pretreatment with TNF-α (1 - 50 ng/ml for 4 - 12 hours) significantly increased numbers of cells responding as well as the frequency of capsaicin induced [Ca²⁺]c spikes, while minimally affecting basal oscillation rate. No changes in capsaicin and reserpinatoxin mediated [Ca²⁺]c responses were observed after pretreatment with PMA (25 nM, 5 min - 12 hours). Next, heat (43 °C) induced [Ca²⁺]c changes in synovioocytes

2006 ASCB Annual Meeting Abstracts
were recorded using a temperature controlled chamber. The two-peaked response to heat with rapid transient spikes and a subsequent slow rise reflected TRPV1 and TRPV3 channel activations, respectively. Pretreatment with TNF-α increased average amplitude of heat induced [Ca2+]c responses and accentuated the second rising phase. Five minute pretreatment with PMA caused disappearance of the [Ca2+]c response declining phase which appeared as a single calcium wave with fast and slow rising phases. Thus, TNF-α and a PKC activator provide differentially enhanced calcium responses in syneurocytes during inflammation depending on the TRP stimuli. Supported by the Dana Foundation and NIH P01 NS011255-31.

1071 The Role of TRP Channels in Mechanotransduction of HUVEC
Y. Katunouchi, T. Suemori, K. Naruse; Cardiovascular Physiology, Okayama University, Okayama, Japan
Human umbilical vein endothelial cells (HUVEC) at the interface between the bloodstream and the vessel wall are continuously subjected to mechanical stimulations in vivo, such as shear stress, hydrostatic pressure and stretch, and it is widely recognized that they are playing an important physiological role in cardiovascular system. In response to stretch, we reported that intracellular Ca2+ increased transiently through the activation of mechanosensitive (MS) cation channel in HUVEC. However, the molecular entities that form the MS cation channel in the cell remain unknown. Recent papers report some members of the transient receptor potential (TRP) channel have been suggested as one of components of MS channels. To identify the molecules forming MS in HUVEC, we investigated the expression and localization of TRP channels in this cell. We observed the expression of several isoforms of TRP channels in HUVEC using semi-quantitative RT-PCR and immunoblotting method. Among these channels, immunocytochemistry using anti-hTRP2 antibody revealed that hTRP2 was localized very close to the mesh-structure of the cortical-actin, and the cyskeleton spectrin network tethered by ankyrin, in semi-intact plasma membrane of HUVEC. Moreover, hTRP2 co-immunoprecipitated the cyskeleton proteins and several components of focal adhesion molecules. These interactions were reduced by the deletion of cytoplasmic domain in TRP2. It was noteworthy that stretch-induced change in [Ca2+]c measured by fura2 was significantly higher in hTRP2 transfected HEK293 cells and that the stretch-induced change in [Ca2+]c was significantly inhibited in HUVEC treated with siRNA against hTRP2. From these results, we would like to discuss molecular complex that forms MS channel, above all the possible involvement of TRP2 in HUVEC.

1072 Pkd1l3 and Pkd2l1, Two Members of the TRP Family of Ion Channels, Are Co-expressed in a Subset of Taste Receptor Cells
N. D. Lopez-Jimenez, M. M. Cavenagh, E. Sainz, M. A. Cruz-Ithier, J. F. Battey, S. L. Sullivan; Laboratory of Molecular Biology, NIDCD/NIH, Rockville, MD
Taste receptor cells (TRCs) are responsible for detecting incoming tastants. The detection of sweet, bitter, and savory tasting compounds is mediated through G protein coupled receptors, whereas sour (protons) and salty (sodium ions) stimuli are thought to act by directly passing through or modulating ion channels. To better define taste signal transduction pathways, we constructed and sample sequenced a TRC-enriched library. One of the clones in this library encoded PKD1L3, a largely uncharacterized member of the transient receptor potential (TRP) family of ion channels. Here we report the genomic structure, polymorphic variations, and expression patterns of Pkd1l3. In order to determine the expression of Pkd1l3 in taste receptor tissues, we performed cDNA microarray analysis of RNA isolated from mouse tongue-derived taste bud cells and human TRC-enriched libraries. In addition, we performed in situ hybridization and immunohistochemical studies that Pkd1l3 is specifically expressed in a subset of TRCs. Furthermore, we show that in TRCs Pkd1l3 is co-expressed with Pkd2l1, also known as Trpp3. Given the precedence for PKD/TRP channels to function as heteromers, these results suggest that within TRCs Pkd1l3 and PKD2L1 may function as a heterodimer. The TRCs expressing Pkd1l3 and Trpp3 are distinct from those that lack co-expression, lending support to the hypothesis that Pkd1l3 and TRPP2 play a role in sour or salty taste signal transduction. These results provide the first evidence for a role of PKD/TRP channels in taste receptor cell function.

1073 A Role for Reactive Oxygen Species in Activation of Store-operated Ca2+ Channels in RBL-1 Cells
Y. Wang, R. Bloom, V. Nguyen, J. Schroder; Division of Biological Sciences, University of California, San Diego, La Jolla, CA
Store-operated Ca2+ entry plays important roles in intracellular Ca2+ store replenishment and Ca2+ signaling in excitable cells. However, the mechanisms linking Ca2+-store depletion to the ensuing Ca2+ channel activation in the plasma membrane remain elusive. Here we show that depletion of intracellular Ca2+ stores results in the production of reactive oxygen species (ROS), and that the ensuing Ca2+ influx requires ROS production in RBL-1 cells. Both store depletion-induced ROS production and Ca2+ influx were inhibited by two independent ROS scavengers, MCI-186 (edaravone) and BH(2)(3-s-tetra-4-hydroxyniosene). Application of hydrogen peroxide activated inward Ca2+ currents, and also caused cytosolic Ca2+ elevation in RBL-1 cells. The iPLA2 inhibitor, 2-APB and the two ROS scavengers, MCI-186 and BH4 inhibited both H2O2-induced responses as well. Together, our results suggest that ROS play a pivotal role in signaling the depletion of Ca2+ stores to the activation of store-operated Ca2+ channels in the plasma membrane.

1074 Reducing Agents Enhance Hemichannel Permeability by Increasing Open Probability of Connexin43 Hemichannels, a Cysteine Dependent Action
M. A. Retamal, K. A. Schalper, K. F. Shoji, F. F. Bukauskas, J. C. Saez, M. V. L. Bennett; 1Departamento de Ciencias Fisiologicas, Pontificia Universidad Catolica de Chile, Nucleo Milenio de Immunologia e Inmunoterapia, Santiago, Chile, 2Neuroscience, Albert Einstein College of Medicine, Bronx, NY
In astrocytes, connexin43-hemichannels in non-junctional membrane (Cx43-HCs) are opened by metabolic inhibition and can then be closed by reducing agents (see accompanying abstract). Here, we examined whether reducing agents affect HCs formed of different connexins under normoxic conditions. We used HeLa cells stably transfected with mouse Cx43 or Cx43-EGFP (Cx43 with EGFP on the C-terminal), both of which have cytoplasmic (MS) cation channel in the cell. Here we show that depletion of intracellular Ca2+ stores results in the production of reactive oxygen species (ROS), and that the ensuing Ca2+ influx requires ROS production in RBL-1 cells. Both store depletion-induced ROS production and Ca2+ influx were inhibited by two independent ROS scavengers, MCI-186 (edaravone) and BH(2)(3-s-tetra-4-hydroxyniosene). Application of hydrogen peroxide activated inward Ca2+ currents, and also caused cytosolic Ca2+ elevation in RBL-1 cells. The iPLA2 inhibitor, 2-APB and the two ROS scavengers, MCI-186 and BH4 inhibited both H2O2-induced responses as well. Together, our results suggest that ROS play a pivotal role in signaling the depletion of Ca2+ stores to the activation of store-operated Ca2+ channels in the plasma membrane.

1075 How Metabolic Inhibition Increases Membrane Permeability through Connexin Hemichannels
M. A. Retamal, K. Schalper, K. Shoji, L. Reuss, G. Ahlstein, M. V. L. Bennett, J. C. Saez; 1Departamento de Ciencias Fisiologicas, Pontificia Universidad Catolica de Chile, Nucleo Milenio de Immunologia e Inmunoterapia, Santiago, Chile, 2Neuroscience, Cell Biology, University of Texas Medical Branch, Galveston, TX, 2Neuroscience, Albert Einstein College of Medicine, Bronx, NY
Connexin-based hemichannels (HCs) form cell-cell channels at gap junctions and are also found in non-junctional membranes, where their open probability is low. In rat cortical astrocytes, metabolic inhibition (MI) increases permeation through non-junctional HCs by insertion of new HCs into the surface with little change in open probability. HC opening may contribute to cell death by a role for cystines in the Cx43, Cx43-257stop, Cx43-EGFP truncated at aa 257 (Cx43-257), Cx43-EGFP truncated at aa 257 (Cx43-257EGFP), Cx43-EGFP truncated at aa 257 (Cx43-257EGFP). The amount of surface Cx43 and Cx43-EGFP increased only ~15% after 10 min DTT treatment, markedly less than the increase in dye uptake or single channel activity at positive potentials. Thus, DTT increased opening of HCs in single channel activity at positive potentials. This action appears to require cytoplasmic cysteines, which are present in the Cx43 and Cx43-EGFP C-terminus, but not in other connexins tested.

2006 ASCB Annual Meeting Abstracts
1076 Contribution of Aquaporins on Cellular Water Transport Observed Using Microfluidic Cell Volume Sensor

S. P. O'Hara, B. Huang, P. Splinter, J. Nelson, X. Chen, N. LaRusso; Center for Basic Research in Digestive Diseases, Mayo Clinic, Rochester, MN

Internalization of the obligate intracellular apicomplexan parasite, Cryptosporidium parvum, results in the formation of a unique intramembranous yet extracellulosic nodule on the apical surface of susceptible host epithelial cells, a process that depends on host cell membrane extension. Recently, we showed that C. parvum infection of biliary epithelial cells (cholangiocytes) induces localized membrane translocation/insertion of SGLT1, a Na+/glucose cotransporter, and aquaporin 1 (AQP1), a water channel, at the attachment site (PNAS, 2005; 102:6338). The expression of AQP1 was localized in the basolateral membrane of the proximal tubules. In the present study, we have used the yeast two-hybrid approach to investigate the putative TAT1-associated proteins in the rat small intestine. TAT1 message was detected in intestine, placenta and liver in rats. In the small intestine, TAT1 immunoreactivity was detected in the basolateral membrane of enterocytes. Inhibition of AQP3 with HgCl₂ reduced the swelling rate by 60%, but it had almost no effect on cells transfected with AQP4, consistent with previous reports. The cell volume cytometer appears able to serve as a simple quantitative tool to rapidly assay AQP3 activity. References: [1] A.S. Verkman. J. Cell Biol. 118, 3225 (2005). [2] D. A. Ayala, F. Sachs, S. Besch, P. Gottlieb, and S. Z. Hua. Analys. Chem. 77, 1290 (2005).

1077 Aquaglyceroporin AQP9 Is the Major Glycerol Channel in Mouse Erythrocytes

Y. Liu,1,3 D. Promenez,1 A. Rojek,1 N. Kumar,1 S. Nielsen,1 P. Agre,1 J. Carbrey1; 1Cell Biology, Duke Medical Center, Durham, NC, 2Biological Chemistry, Johns Hopkins University School of Medicine, Baltimore, MD, 3Water and Salt Research Center, University of Aarhus, Aarhus, Denmark, 4Malariology Research Institute and Department of Molecular Microbiology and Immunology, Johns Hopkins University Bloomberg School of Public Health, Baltimore, MD

It has been observed for many years that human and rodent erythrocytes are highly permeable to glycerol, which can be inhibited by HgCl₂. Recently, aquaglyceroporin AQP3 was discovered and proposed to be the major glycerol channel in human and rat erythrocytes. However, AQP3 was not found in mouse erythrocytes. We revisited this question and identified another aquaglyceroporin, AQP9, instead of AQP3, in mouse erythrocytes. The expression level of AQP9 in mouse erythrocytes increases as reticulocytes mature into erythrocytes, and as neonatal pups develop into adult mice. Compared to wild-type mice, those from AQP9 deficient mice are defective in the rapid transport of glycerol across the cell membrane. The expression of AQP1 and the urea transporter-B in the AQP9 null erythrocytes is the same as in wild type cells, and as a consequence, the water and urea permeabilities are intact in AQP9 null erythrocytes. In an osmotic fragility test, AQP9 null erythrocytes are much more resistant to lysis by 0.3 M glycerol than wild type and heterozygous erythrocytes. In vitro experiments reveal that mature erythrocytes are much more sensitive to hypotonic shock. Here we report that mature erythrocytes produce glycerol. However, plasma glycerol is an important substrate of lipid biosynthesis for intraerythrocytic malarial parasites. AQP9 null mice that are infected with Plasmodium berghei, the mouse malarial parasite, survive longer during the initial phase of infection compared to wild type mice. We conclude that AQP9, but not AQP3, is the glycerol channel expressed in mouse erythrocytes. The higher expression of AQP9 in mature mouse erythrocytes indicates that AQP9 maybe an important channel for small neutral molecules other than glycerol or urea under specific physiological conditions. During malarial infection, AQP9 affects the pathogenesis of malarial parasites and may be an important part of a pathway that provides Plasmodium with glycerol for lipid biogenesis for maximal growth.

1078 Myosin II-dependent Membrane Translocation of SGLT1 and AQP1 Is Required for Efficient Host-Cell Membrane Protrusion during C. parvum Cellular Invasion

S. P. O'Hara, B. Huang, P. Splinter, J. Nelson, X. Chen, N. LaRusso; Center for Basic Research in Digestive Diseases, Mayo Clinic, Rochester, Rochester, MN

The obligate intracellular apicomplexan parasite, Cryptosporidium parvum, results in the formation of a unique intramembranous yet extracellulosic nodule on the apical surface of susceptible host epithelial cells, a process that depends on host cell membrane extension. Recently, we showed that C. parvum infection of biliary epithelial cells (cholangiocytes) induces localized membrane translocation/insertion of SGLT1, a Na+/glucose cotransporter, and aquaporin 1 (AQP1), a water channel, at the attachment site (PNAS, 2005; 102:6338). The resultant localized water influx facilitates parasite cellular invasion by promoting host-cell membrane protrusion. However, the molecular mechanisms by which C. parvum induces membrane translocation/insertion of SGLT1/AQP1 are obscure. It is known that non-muscle myosins localized to the cortical actin meshwork of epithelial cells are involved in vesicle trafficking. Thus, we report here that cultured human cholangiocytes express several non-muscle myosins including myosin Ia, Ic, IIa, IIb, Va, Vc and X. Moreover, translocation/insertion of SGLT1/AQP1 are obscure. It is known that non-muscle myosins localized to the cortical actin meshwork of epithelial cells are involved in vesicle trafficking. Thus, we report here that cultured human cholangiocytes express several non-muscle myosins including myosin Ia, Ic, Ila, Ib, Va, Vc and X. Moreover, C. parvum infection of cultured cholangiocytes results in the localized selective aggregation of two host-cell myosins: Ib and X at the region of parasite attachment as assessed by both dual-label immunofluorescent confocal microscopy and transfection of cells with GFP-tagged constructs. Furthermore, inhibition of myosin light chain kinase with ML-7, or specific myosin II inhibition by blebbistatin, significantly decreases (p < 0.02) C. parvum-induced accumulation of SGLT1 at infection sites. Finally, treatment of cells with either ML-7 or blebbistatin significantly inhibits (p < 0.05) C. parvum cellular invasion. Thus, localized actomyosin-dependent membrane translocation of transporters/channels initiated by C. parvum promotes membrane extension and parasite internalization, a phenomenon that may also be relevant to the mechanisms of cell membrane protrusion in general.

1079 Identification of the Intracellular Binding Protein with T-type Amino Acid Transporter TAT1 Using the Yeast Two-Hybrid Screening

N. Anzai,1 S. Khamdang,2 D. Kim,1,4 Y. Kanai,1 H. Endo2; 1Department of Pharmacology and Toxicology, Kyorin University School of Medicine, Tokyo, Japan, 2Chouun University College of Dentistry, Department of Oral Physiology, Republic of Korea

TAT1 (T-type amino acid transporter 1) is a Na⁺/amino acid transporter that is expressed in the kidney and intestine. It is involved in the transport of amino acids and is thought to be a candidate protein for the TAT1-mediated amino acid transporters. In this study, we screened a mouse kidney cDNA library using TAT1 as a bait. We found a cDNA clone that encodes a protein of 104 amino acids. We designated this clone as MASP-1. The sequence of MASP-1 is highly homologous to human MASP-1. We then examined the expression of MASP-1 in various tissues and found that it is highly expressed in the kidney and intestine. We also found that MASP-1 is localized to the basolateral membrane of kidney epithelial cells. In conclusion, MASP-1 is a candidate protein for the TAT1-mediated amino acid transporters.

1080 Formation of a P2X4/7 Heteromeric Receptor

C. Guo, O. S. Qureshi, R. D. Murrell-Lagirdo; Pharmacology, Cambridge University, Cambridge, United Kingdom

Extracellular ATP affects many different biological processes in cells by activating plasma membrane P2 receptors. The ionotrophic P2X receptors are non-selective cation channels and 7 transmembrane domain receptors. They are activated by extracellular ATP and are involved in many physiological processes, including neurotransmission, inflammation, and pain transmission. In this study, we investigated the formation of a P2X4/7 heteromeric receptor. We found that P2X4 and P2X7 form a functional heteromeric receptor, which is different from the homomeric receptors. The heteromeric receptor has unique properties, such as increased sensitivity to agonists and decreased desensitization. We also found that the heteromeric receptor is involved in many physiological processes, including pain transmission and inflammation. In conclusion, the P2X4/7 heteromeric receptor is a novel and important receptor type that is involved in many physiological processes.
Nonosecond Electroporation and Electrophoretic Phosphatidylserine Translocation - In Vitro and In Silico

P. Vernier, M. J. Ziegler, Y. Sun, M. A. Gundersen; MOSIS, Information Sciences Institute, University of Southern California, Marina del Rey, CA, Mork Family Department of Chemical Engineering and Materials Science, University of Southern California, Los Angeles, CA, Department of Electrical Engineering-Electrophysics, University of Southern California, Los Angeles, CA
Electroporation technology is widely used to facilitate transport of normally excluded substances --- nucleic acids, pharmaceutical compounds, and other materials --- into biological cells. Microsecond, kilovolt-per-meter pulses produce conductive pores in the cytoplasmic membrane, permitting migration of charged species and large molecules across the compromised membrane barrier presented by the membrane lipid bilayer. Nanosecond, megavolt-per-meter pulses --- much higher power but lower total energy than electroporative pulses --- produce large intracellular electric fields without destructively charging the plasma membrane. Nanoelectroporation perturbation of human lymphoid cancer cells (and other cell types) results in two immediate physiologically and biophysically significant events: intracellular calcium release and externalization of phosphatidylserine (PS) from the inner leaflet of the plasma membrane to the outer face of the cell. Nanoelectropulsed cells subsequently display evidence of a progression to apoptosis (programmed cell death), including chromatin condensation, caspase activation, and characteristic changes in cell morphology. Experimental observations and molecular dynamics simulations of membrane perturbations driven by nanosecond, high-field electric pulses support the hypothesis that nanoelectropulse-induced phosphatidylserine (PS) externalization is associated directly with nanoelectropulse exposure, is driven by the electric potential that develops across the lipid bilayer during an electric pulse, and is facilitated by the poration of the membrane that occurs even during pulses as brief as 3 ns. Molecular dynamics simulations of phospholipid bilayers in supraphysiological electric fields show a tight association between PS externalization and membrane pore formation on a nanosecond time scale, are consistent with experimental evidence for confinement of PS translocation to the anode-facing pole of the cell, and provide theoretical support for details of a developing biophysical model for nanoelectroporation and nanosecond PS externalization.

Diazoxide Acts More as a PKC-ε Activator, and Indirectly Activates MitoKATP Channel in Cardiomyocytes

M. Kim, I. Ahn, I. Yoon, S. Lee, E. Baik, C. Moon, Y. Jung; Department of Physiology, School of Medicine, Ajou University, Suwon, Republic of Korea
Diazoxide (DZX), a well-known mitoKATP channel opener, has been demonstrated to exert cardioprotective effect against ischemic injury through mitochondrial ATP-sensitive potassium (mitoKATP) channel and protein kinase C (PKC). The aim of this study was to clarify the role of PKC isoforms and the relationship between the PKC isoforms and the mitoKATP channel in DZX-induced cardioprotection. PKC-ε activation was examined by Western blotting and kinase assay. Flavoprotein fluorescence, mitochondrial Ca²⁺ and mitochondrial membrane potential were measured by confocal microscopy. Cell death was determined by TUNEL assay. Treatment with 100 μM DZX induced translocation of PKC-ε from the cytosolic to the mitochondrial fraction, and a specific blockade of PKC-ε by either εV1-2 or dominant negative mutant PKC-ε (PKC-ε:KT) abrogated the anti-apoptotic effect of DZX. DZX-induced flavoprotein oxidation was remarkably inhibited by either εV1-2 or PKC-ε KR, while DZX-induced translocation and activation of PKC-ε remained unaltered after treatment with 5-hydroxydecanoyl (5-HD). A direct PKC activation by transfection of wild type PKC-ε mimicked flavoprotein-oxidizing effect of DZX, and this effect was completely blocked by either εV1-2 or 5-HD. During hypoxia, DZX prevented the decrease of mitochondrial Ca²⁺, mitochondrial depolarization and cytochrome c release induced by hypoxia, and all these effects of DZX were blocked by εV1-2 as well as 5-HD. In summary, these results suggest that DZX induces isoform-specific translocation of PKC-ε as an upstream signaling molecule for mitoKATP-channel, rendering cardiomyocytes resistant to hypoxic injury through inhibition of mitochondrial death pathway.

Global Elevation of Cytosolic Ca²⁺ Concentration Activates Ca²⁺-induced Ca²⁺ Release, but Is Not Essential for Ca²⁺ Store Refilling in Jurkat T Lymphocytes

S. Dadsetan, A. Forina; UC Davis, Davis, CA
Precise control of many T cell functions relies on release of Ca²⁺ from the intracellular store. Refilling of the store is vital for maintaining prolonged Ca²⁺ signaling; however this process remains poorly understood. We investigated the relationship between the elevation of cytosolic Ca²⁺ concentration ([Ca²⁺]c) triggered by store depletion and the extent of store refilling which was assessed by [Ca²⁺]c measurements during sequential application of cyclopiazonic acid (30μM), a reversible SERCA blocker. We found that in Jurkat T cells the [Ca²⁺]c levels measured following activation of store-operated calcium entry (SOCE) inversely correlated with the extent of store refilling. Moreover, pretreatment of cells with blocking concentrations of ryanodine (400μM) facilitated store refilling while reducing SOCE. These results indicate that global cytosolic Ca²⁺ elevation activates a Ca²⁺-Induced Ca²⁺ Release (CICR) via ryanodine receptors, which prevents Ca²⁺ accumulation within the store. In addition, elevation in global [Ca²⁺]c, was efficiently blocked by extracellular La³⁺ with an IC₅₀ ~ 50 μM. However, store refilling persisted even when global cytosolic Ca²⁺ elevation was abolished with 0.1-1 μM La³⁺. Higher concentrations of La³⁺ (>10 μM) were required to prevent store refilling. These data indicate that a small number of active plasma membrane Ca²⁺ channels may support global cytosolic Ca²⁺ elevation, whereas activation of a large number of channels stimulates CICR to further amplify cytosolic Ca²⁺ signaling. Research described in this abstract was supported by Philip Morris USA Inc. and Philip Morris International.

TGN to Plasma Membrane Transport of HSV-1 Capsids Requires PKD

C. Mihai, J. Duron, R. Lippe; Pathology & Cell Biology, University of Montreal, Montreal, PQ, Canada
The TGN plays a central role in sorting proteins for delivery to various organelles, secretion or expression at the cell surface. Work from other laboratories has shown that PKD is an important regulator at the TGN for the transport of cargo destined for the basolateral membrane. PKD recruitment from cytosol to the TGN depends on diacyl glycerol (DAG), whose depletion develops across the lipid bilayer during an electric pulse, and is facilitated by the poration of the membrane that occurs even during pulses as brief as 3 ns. Molecular dynamics simulations of phospholipid bilayers in supraphysiological electric fields show a tight association between PS externalization and membrane pore formation on a nanosecond time scale, are consistent with experimental evidence for confinement of PS translocation to the anode-facing pole of the cell, and provide theoretical support for details of a developing biophysical model for nanoelectroporation and nanosecond PS externalization.

Arf1p Is Involved in Transport of the GPI-anchored Protein Gas1p from the Late Golgi to the Plasma Membrane

Y. Liu, S. Lee, F. Lee; Institute of Molecular Medicine, National Taiwan University, Taipei, Taiwan
Arl1p Is Involved in Transport of the GPI-anchored Protein Gas1p from the Late Golgi to the Plasma Membrane

C. Mihai, J. Duron, R. Lippe; Pathology & Cell Biology, University of Montreal, Montreal, PQ, Canada

Bioisynthetic Trafficking and Sorting of Caveolin-1 Visualized by Multicolor Imaging

A. Hayer, C. Bissig, A. Helenius; Biochemistry, ETH Zurich, Zurich, Switzerland
Caveolae are flask-shaped membrane invaginations involved in endocytosis, transcytosis, lipid homeostasis, and modulation of signaling. Their functional principle is distinct from other known vesicular transport mechanisms in that once assembled, they are stable, and do not undergo cycles of assembly and disassembly. Our previous results suggested that caveolar domains are initially formed in the Golgi complex. Using various fluorescence microscopy techniques in cells expressing a GFP-tagged version of caveolin-1 (Cav1), the major structural component of caveolae, we further investigated how caveolar domains assemble and how they are transported from the Golgi complex to the cell surface. FRAP analysis of the Golgi pool of Cav1-mGFP revealed that the protein is highly immobile in this compartment. Mutants of Cav1 incapable of forming caveolae were highly mobile in the Golgi complex, suggesting that loss of diffusion...
mobility correlates with caveolar domain formation. We then tested the molecular requirements for efficient Golgi-exit of Cav1 by overexpressing FAPP1-PH and dominant negative versions of Arf1 and Dynamin-2 in cells. Comparing the effect of these constructs on transport of Cav1-mGFP, GFP-GPI and VSVG-GFP suggested that Cav1-mGFP and GFP-GPI are transported to the surface by a common mechanism that is distinct from transport of VSVG-GFP. Finally, two-color live-cell imaging in cells coexpressing Cav1-mCherry with either GFP-GPI or VSVG-GFP showed that Cav1-mCherry and GFP-GPI left the Golgi in common vesicles, while there was no overlap between Cav1-mCherry and VSVG-GFP. When vesicles positive for both GFP-GPI and Cav1 arrived at the cell surface, the GFP-GPI was overexpressed, while the caveolar domain remained stable. Together, these results are consistent with a model in which caveolar biogenesis occurs in the Golgi complex. These newly assembled caveolar domains can incorporate lipid-raft components such as GFP-GPI during transit to the cell surface, but exclude non-raft proteins such as VSVG.

Phosphatidylinositol 5-Kinase Stimulates Apical Biosynthetic Traffic via Arp 2/3-dependent Actin Comets
C. J. Guerriero, K. M. Weisel, J. R. Bruns, O. A. Weisz; Cell Biology and Molecular Physiology, University of Pittsburgh, Pittsburgh, PA
Polarized epithelial cell function relies on the proper sorting and distribution of newly synthesized proteins to the apical and basolateral membrane domains. We are interested in how these delivery pathways are regulated by phosphatidylinositol 5-kinase. Overexpression of murine phosphatidylinositol 4-phosphate 5-kinase alpha (PISK) in Madin-Darby canine kidney (MDCK) cells stimulated the rate of surface delivery of the apical marker influenza hemagglutinin (HA) but had no effect on the traffic of another apical protein (p75) that is sorted via a distinct mechanism. PI(3K)-mediated increases in phosphatidylinositol 4,5-bisphosphate (PI(3,5)P2) levels result in activation of Wiskott-Aldrich syndrome protein (WASP)/Scar family members and lead to cytoskeletal rearrangements, including Arp2/3-dependent formation of actin comets. To test the potential role of N-WASP in HA delivery, we inhibited Arp2/3 function by expressing the HA domain from Scar1, another WASP family member. Expression of the HA domain significantly inhibited activated actin comet formation and slowed the rate of HA delivery, while having no effect on p75 delivery. Similarly, pharmacological inhibition or stimulation of actin comet formation correlated with parallel effects on HA delivery. PI(3K) and HA (but not p75) were visualized at the tips of actin comets in fixed MDCK cells, consistent with a role for actin comets in delivery of this marker. Our data suggest that multiple classes of apically destined transport carriers exist in polarized epithelial cells, and implicate a role for PI(3,5)P2-stimulated actin comets in the transport of a subset of these carriers.

Drab6 and the Secretory Pathway Organize Microtubule-based Transport of Osk mRNA to the Posterior Pole of the Drosophila Oocyte
In the Drosophila oocyte, polarized secretion occurs towards restricted neighboring cells and asymmetric transport controls the localization of several mRNAs to distinct cortical compartments. How the differential sorting of the axis determining mRNAs is coordinated during Drosophila oogenesis is at present poorly understood. mRNAs are in part properly localized by the orchestrated action of Microtubule-based motors such as Kinesin, Dynemin, and Dynemin-interacting proteins such as Bicaudal D (BicD). In this study, we have characterized the function of Drab6, the Rab6 GTPase ortholog, during oogenesis. Rab proteins organize membrane exchanges between intracellular compartments and specify their identities, suggesting that they may also play an important role in the establishment of intracellular polarity. We show that Drab6 interacts with BicD, indicating that, as in mammalian cells, Drab6 and BicD likely co-ordinate Dynenei powered movements of transport vesicles along Microtubules (MTs). In the absence of Drab6, a severe effect on oocyte polarity was observed. First, polarized transport and delivery of components to the plasma membrane, such as the TGF-ε homolog Gurken, were affected. Second, osk mRNA transport was impaired. We also provide evidence that Drab6 is required for the organization of part of the MT network, possibly by focusing MT plus ends to the posterior. Our results point to an interesting connection between Rab protein-mediated secretion, mRNA transport and the organization of the cytoskeleton.

Apical Biosynthetic Trafficking Itineraries in Polarized Epithelial Cells
K. O. Cressawn, B. A. Potter, A. Ozcan, G. Apodaca, O. A. Weisz; Medicine, University of Pittsburgh, Pittsburgh, PA
The crucial function of polarized epithelial cells is to sort proteins to distinct membrane domains along both the biosynthetic and endocytic pathways. Sorting signals in basolaterally-destined proteins have been well characterized and generally involve specific cytoplasmic peptide motifs. In contrast, proposed apical sorting signals include associations with lipid rafts, cytoplasmic peptide motifs, and N- or O-glycans. Our lab has previously shown that biosynthetic apical delivery of the sialomucin endolyn is dependent on a subset of its N-glycans. A similar N-glycan-dependent sorting signal is also required for apical delivery along the endocytic pathway, suggesting that sorting along both pathways may occur at a single site. Traditionally it has been thought that biosynthetic sorting occurs in the trans-Golgi network, however endolyn internalized from the cell surface does not access this compartment. Recently it has been shown that basolateral proteins can access common recycling endosomes en route to the plasma membrane and that biosynthetic sorting may occur at this site. Because internalized endolyn can access common recycling endosomes, we determined whether this might represent a common sorting site for newly synthesized and postendocytic endolyn. However, selective inactivation of common recycling endosomes after internalization of horseradish peroxidase-conjugated transferrin did not perturb apical delivery of newly-synthesized endolyn. Similar results were obtained for other apical proteins including influenza hemagglutinin and p75(TNF)
.
. Our data suggest that unlike basolateral proteins, apical proteins do not transit common recycling endosomes en route to the plasma membrane.

The Arf GAP Centaurin Alpha-1 Is Implicated in Immature Secretory Granule Trafficking and Maturation in PC-12 Cells
J. L. Laramore, C. Chapman, A. Smith, A. Theibert; Neurobiology, University of Alabama at Birmingham, Birmingham, AL, Natural Sciences, Longwood University, Farmville, VA
Centaurin alpha-1 is a high affinity PtdIns(3,4,5)P3 binding protein that is a candidate transducer in the neuronal receptor-activated PI 3-kinase cascade. Centaurin alpha-1 has a GAP homology domain and overexpression reduces cellular levels of Arf6-GTP, supporting its function as an Arf GAP. In addition to other binding partners such as actin, casein kinase, PKC, nucleolin, and KIF13b, the clathrin adaptor protein AP-3 has been identified as a potential centaurin alpha-1 interacting protein. AP-3 localizes to endosomes and secretory granules. Endogenous centaurin alpha-1 localizes to punctate structures in the PC12 neurosecretory cell line and cultured hippocampal neurons. Using immunocytochemistry with markers of vesicular compartments, our studies show that endogenous centaurin alpha-1 does not colocalize significantly with transferrin, the transferrin receptor or EEA1, suggesting that it does not associate specifically with endocytic vesicles. In contrast, we observe substantial co-localization (25-50%) between centaurin alpha-1 and markers of dense core vesicles including furin and the chromogranin, and between centaurin alpha and AP-3. Manipulation of centaurin alpha-1 expression by overexpression or siRNA-mediated knock-down leads to changes in the localization of several secretory granule proteins. Treatment of PC-12 cells with brefeldin A, a known inhibitor of secretory granule maturation, results in a change of centaurin alpha localization similar to changes in furin localization resulting from brefeldin A. These data support the hypothesis that centaurin alpha-1 is an Arf GAP that functions in the regulated secretory pathway and is likely to be involved in the trafficking and maturation of immature secretory granules.

N-terminus of Naked2 Directs TGF-containing Exosome Vesicles to the Lower Lateral Membrane of Polarized Mkdck Cells
C. Li, M. Hao, Z. Cao, W. Ding, R. Graves-Deal, J. Hu, D. Piston, R. Coffey; Dept. of Medicine, Vanderbilt University, Nashville, TN, Dept. of Molecular Physiology and Biophysics, Vanderbilt University, Nashville, TN, Dept. of Cell and Developmental Biology, Vanderbilt University, Nashville, TN, Dept. of Medicine and Cell and Development Biology and Dept. of Veterans Affairs Medical Center, Vanderbilt University, Nashville, TN
TGFα is the major autocrine EGF receptor ligand in vivo. In polarized epithelial cells, proTGFα is synthesized and delivered to the basolateral cell surface. We previously reported that Naked2 interacts with basolateral sorting determinants in the cytoplasmic tail of a Golgi-processed form of TGFα and that TGFα is not detected at the basolateral surface of Mkdck cells expressing myristoylation-deficient (GA2) Naked2 (Proc Natl Acad Sci 101:5571-5576, 2004). Herein we demonstrate that wild type, but not GA2, Naked2-associated vesicles fuse at the plasma membrane by total internal reflection fluorescence microscopy. These vesicular exports are delivered to the lower lateral membrane of polarized Mkdck cells in a µIB-independent manner. Naked2 residues 1-173 redirect the apical adaptor protein NHERF1 to the basolateral plasma membrane of polarized Mkdck cells and deletion of residues 39-51 results in loss of polarized sorting. We propose that Naked2 acts as a monomeric adaptor to ensure the correct delivery and fusion of TGFα-containing vesicles to a distinct domain at the basolateral surface of polarized epithelial cells.
Involvement of the Small GTPase rab11 in Rhodopsin Trafficking

J. Mazelova, L. M. Astuto-Gribble, D. D. Deretic; Surgery/Ophthalmology, University of New Mexico, Albuquerque, NM

The rhodopsin-terminus sorting signal, VXPX-CAAX, regulates its incorporation into specialized transport carriers (RTC's), which are targeted to rod outer segments of retinal photoreceptors. Using a retinal cell-free system, we have previously established that the budding from the Golgi/TGN, and the incorporation of rhodopsin into RTCs, is regulated by direct binding of the VXPX-CAAX motif to the small GTP-binding protein ARF4. We find that the inhibition of RTC budding with an ARF4 blocking antibody is accompanied by the changes in subcellular distribution of ARF4 and the small GTPase rab11, previously localized to RTCs. Anti-ARF4 antibody resulted in the accumulation of ARF4 on the Golgi/TGN membranes and the release of rab11 into the cytosol, suggesting an involvement of ARF4 in the recruitment of rab11 to the RTC budding sites. Rab11 is an essential component of the budding machinery, as RTC budding in the cell-free assay was decreased by 30% with six-fold reduction of rab11 by cytosol immunodepletion. By confocal microscopy, rab11 was localized to punctate structures distributed along the Golgi/TGN, where it co-localized with a BAR domain protein involved in membrane bending and fission, ASAP1, an ARF-GAP with the preference for class II ARFs, such as ARF4. A regulatory ARF/rab11 binding protein Arfophilin/FIP3, was also present in these structures. Subcellular fractionation and co-immunoprecipitation experiments suggest that ASAP1, rab11 and FIP3 may be a part of a macromolecular complex whose assembly is regulated by the binding of ARF4 to rhodopsin. Sequential membrane dissociation of ARF4, ASAP1 and FIP3, and the retention of rab11 on RTCs, suggest that this complex may couple cargo sorting, formation of transport carriers, and concomitant recruitment of the molecular machinery necessary for RTC fusion. The presence of rab11 on RTCs may subsequently ensure the recruitment the Sec68 tethering complex involved in RTC fusion.

Dual Interaction of Arfophilin/Rab11-FIPs with ARFs and Rab11

H. Koga, H. W. Shinn, K. Nakayama; Department of Physiological Chemistry, Graduate School of Pharmaceutical Sciences, Kyoto University, Kyoto, Japan

In eukaryotic cells, intracellular membrane trafficking of proteins between organelles is mediated by vesicular carriers. Vesicles bud from a donor compartment, and dock and fuse with an acceptor one to deliver cargos. Small GTPases belonging to the ARF and Rab families regulate various steps of membrane trafficking. The ARF GTPases trigger budding of coated carrier vesicles by recruiting coat protein complexes onto donor membranes, whereas the Rab GTPases regulate targeting and docking/fusion of vesicles with acceptor membranes. These GTPase cycle on an inactive GDP-bound state and an active GTP-bound state, in which they are allowed to interact with various effector molecules. Both FIP3 and FIP4 (also referred to as arfophilin-1 and -2) have been recently identified as Rab11-interacting protein and bind not only to Rab11 but also to ARF5 and ARF6 through their C-terminal regions, suggesting their functional roles in vesicle trafficking. However, the regions responsible for Rab11- and ARF-binding have not been determined in detail, and their physiological roles are poorly understood. To elucidate the functions of FIP3 and FIP4 in vesicle trafficking and how they mediate a crosstalk between ARF5 and Rab11, we have investigated the interactions of FIP3 and FIP4 with ARF5, ARF6 and Rab11. Here we show that FIP3 and FIP4 have distinct C-terminal binding regions for Rab11 and ARF5; Rab11 binds the most C-terminal region of FIPs, whereas ARF5 binds a region immediately upstream of the Rab11-binding region. They bind ARF5 and Rab11 simultaneously but not competitively. Furthermore, when expressed in cells, FIPs recruit both ARF5 and Rab11 onto endosomal structures. These findings suggest that FIP3 and FIP4 regulate membrane traffic by coordinate binding to ARFs and Rab11.

Exo70p Mediates the Secretion of Specific Exocytic Vesicles at Early Stages of Cell Cycle for Polarized Cell Growth

B. He, F. Xi, J. Zhang, X. Zhang, W. Guo; Biology, University of Pennsylvania, Philadelphia, PA

In budding yeast, two classes of post-Golgi secretory vesicles carrying different sets of cargos typified by Bgp2p and invertase, respectively, are delivered to the plasma membrane for secretion. The exocyst complex is implicated in tethering these vesicles at the bud tip membrane prior to fusion. Here, we report that mutations in the exocyst component, Exo70p, specifically block the secretion of the Bgp2p vesicles. Further disruption of the invertase vesicles trafficking through endosomal compartments in the exo70 mutant is detrimental to cell growth. We also found that the secretion defect was most pronounced during the early budding stages, which delays the polarized growth of the daughter cells. The selective secretion block does not take place at the vesicle formation or sorting stage at the donor compartment, because the exocytic vesicles are properly generated and protein processing is normal in the exo70 mutant. Our study suggests that specificity of vesicle secretion can be regulated at the target membrane as well as the donor membrane. Exo70p, unlike other members of the exocyst complex, functions specifically at early stages of cell cycle in the exocytosis of the Bgp2p vesicles, which are critical for polarized cell growth.

CRMP-2 and Slp1 Mediate Anterograde Transport of TrkB through Kinesin-1

N. Arimura, K. Kaibuchi; Cell Pharmacology, Graduate School of Medicine, Nagaoka University, Nagaoka, Japan

Collapsin response mediator protein-2 (CRMP-2) is enriched at the distal part of growing axons in primary hippocampal neurons and plays a critical role in axon differentiation. We previously reported that CRMP-2 associates with tubulin heterodimer, and promotes microtubules assembly and axon elongation. CRMP-2 also binds to light chain of kinesin-1 (KLC), and serves as a cargo receptor of kinesin-1 to transport tubulin heterodimer or axonal proteins into the distal part of growing axon. This time, we report that CRMP-2 regulates the transport of TrkB, a receptor of neurotrophic factor. CRMP-2 forms a complex with synaptotagmin-like protein 1 (Slp1), Rab27 and KLC. These proteins locate along microtubules at growth cones. Slp1 is localized on a vesicular structure and is partially co-localized with Trks. Knockdown of Slp1, CRMP-2, or KLCs reduces the frequency of anterograde transport of TrkB-GFP. Thus, CRMP-2, Slp1, and Rab27 appear to mediate the anterograde transport of TrkB as a cargo receptor linking vesicles and kinesin-1. Since CRMP-2 is highly phosphorylated by GSK-3beta in the brains affected by Alzheimer's disease (AD), we would further discuss the potential role of CRMP-2 in AD.

Mechanisms of Activation and Golgi Targeting of Phosphatidylinositol 4-kinase II Alpha

B. Barylko, Y. Mao, P. Wlodarski, H. Sun, G. Jung, H. Yin, J. Albanesi; 1Department of Pharmacology, UT Southwestern Medical Center, Dallas, TX, 2Department of Physiology, UT Southwestern Medical Center, Dallas, TX

Phosphatidylinositol 4-kinase II (PI4KII) generates a pool of PI(4)P that regulates trafficking from the trans Golgi network (TGN) and endosomes. It is highly enriched in the TGN, and is also found on intracellular vesicles of the secretary/endoctic pathway. We previously reported that more than 90% of the PI4KIIa in cells is tightly associated with membranes by virtue of its palmitoylation in a cysteine-rich motif (C1C3C5C7) located within the catalytic domain. Here we present evidence that palmitoylation is essential for PI4KIIa's lipid kinase activity and for its enrichment at the TGN. When palmitoylated PI4KIIa partially redistributes to the plasma membrane, where it is otherwise nearly undetectable with normal palmitoylation. Enzymatic activity is rescued, and even enhanced, if all the cysteines in the palmitoylation motif are converted to the hydrophobic phenylalanine residues. This FFPFF mutant has a similar subcellular distribution as wild-type palmitoylated PI4KIIa, establishing the importance of a hydrophobic membrane-anchoring loop for PI4KIIa's kinase activity and TGN localization.

The Glut4 FQQI Motif Is Necessary for AS160-dependent Exit, but Not GGA-dependent Entry into the Insulin-Responsive Storage Compartment

E. Capilla, N. Suzuki, J. E. Pessin, J. C. Hou; Pharmacological Sciences, Stony Brook University, Stony Brook, NY

We have recently reported that newly synthesized GLUT4 enters into the insulin-responsive storage compartment without transiting to the plasma membrane in a process that is dependent upon the adaptin protein GGA (Golgi-localized γ-carboxyl-containing Arf-binding protein). Moreover, recent studies have shown that GLUT4 intracellular retention into the specialized compartment and insulin-stimulated translocation to the plasma membrane are regulated by AS160 (Akt Substrate of 160 kDa). Using a variety of loss-of-function and gain-of-function function GLUT4/GLUT1 chimeric proteins we have shown the structural domains involved in these GLUT4 initial sorting events and demonstrated that the amino terminus and the large cytoplasmic loop of GLUT4 are both necessary and sufficient to recapitulate normal GLUT4 trafficking in adipocytes. In the present study, taking advantage of these chimeras and several GLUT4 point mutations we have analyzed the specific motifs of GLUT4 that are important for GGA and AS160 regulation of the sorting of GLUT4 into and out of the insulin-responsive storage compartment. GLUT4 mutant at the Phylamines domain in position 5 to Alanine (GLUT4 AQQQ), when co-expressed with both wild type GGA and AS160, resulted in loss of GLUT4 intracellular retention in the basal state. Nevertheless, similarly to GLUT4 wild type, the plasma membrane localization of GLUT4 AQQQ was completely inhibited by co-expression of GGA dominant negative. In addition, co-expression of GLUT4 wild type with AS160 4P (which contains 4 of its 6 Akt phosphorylation sites mutated) abolished insulin-stimulated GLUT4 translocation. AS160 4P, however, was not able to inhibit insulin-stimulated GLUT4 AQQQ translocation. Together, these data demonstrate that the FQQI motif within the amino terminus of GLUT4 is necessary for the AS160 regulated intracellular retention but not for the GGA-dependent sorting of GLUT4 into the insulin-responsive compartment.
Membrane-mediated Interactions between Proteins Lead to Aggregation and Budding

B. Reynolds, M. Deserno, K. Kremer; MPI for Polymer Research, Mainz, Germany

Cellular control of membrane conformation is governed, in part, by proteins that individually induce a local curvature in the membrane. Such a protein could be a wedge-shaped trans-membrane protein that creates an asymmetry in the bilayer or it could be a peripheral membrane protein whose curved surface adsorbs to the membrane and distorts it. When two such proteins approach each other, but before the proteins themselves come into contact, the deformed regions of the membrane around them begin to overlap, causing a membrane-mediated interaction between the two proteins. We investigate the effect of such membrane-mediated interactions on curvature-inducing proteins using coarse-grained molecular dynamics simulations. We observe aggregation and budding of curvature-inducing proteins without any direct protein-protein interaction.

Computational Dissection of Adenovirus Motion on the Cell Surface

C. J. Burchhardt,1 J. F. Shalazarini,1 J. A. Helmuth,7 H. Ewers,5 P. Kroumoutsakos,2 U. F. Greber1; 1Institute of Zoology, University of Zürich, Zürich, Switzerland, 2Institute of Computational Science, ETH Zürich, Zürich, Switzerland, 7Institute of Biochemistry, ETH Zürich, Zürich, Switzerland

The earliest steps of virus host cell interactions are incompletely understood. In the case of human adenoviruses, they involve viral attachment to the coxsackie virus B adenovirus receptor CAR, and alpha v integrins followed by endocytic uptake and infection. How the virus finds the appropriate domain on the plasma membrane to engage in endocytosis or, alternatively, how the endocytic machinery is recruited to the receptors engaging the virus particle is unknown. Here we are using live fluorescence imaging at high temporal resolution to systematically map the motion of adenoviruses on the plasma membrane of human epithelial cells. Powerful single particle tracking algorithms allow us to generate large sets of virus trajectories. Surprisingly, the individual trajectories are of considerable heterogeneity. To unravel the information contained within these trajectories, we developed a novel segmentation approach based on neural networks. This approach revealed four distinct patterns, confined motions, slow drifting motions, fast drifting motion and nonclassified restricted motion. Adenovirus motion at the cell surface is mostly subdiffusive. Immediately upon attachment to the cells, viruses were mostly immobile, i.e. confined. Subsequently, short sequences of nonclassified restricted motion were observed, followed by confined motions and CAR and actin dependent slow drifting motions. Quantitative comparisons of the surface trajectories on alpha v integrin positive and negative cells indicate that integrins promoted the nonclassified restricted motions while reducing both slow drifts and confined motions. In addition, dual color fluorescence imaging experiments allow us to correlate virus surface motions with the recruitment of endocytic machinery, such as dynamin and clathrin light chain. Together, our data indicate that adenoviruses move in variable patterns of subdiffusive motions on the surface. These motions are determined in part by CAR and integrins, and are terminated by the recruitment of endocytic effector proteins leading to infectious virus entry.

Photobleaching Recovery Identifies Three Distinct Large-Scale Plasma Membrane Lipid Domains, Which Correlate with Differential Intracellular Trafficking

D. Tyteca, L. D'Auria, T. Medts, S. Carpenter, A. Platek, M. Mettlen, P. Van Der Smissen, P. de Diesbach, P. Courtoy; CELL Unit, Université Catholique de Louvain and Christian de Duve Institute of Cellular Pathology, Brussels, Belgium

Biological membranes show lateral heterogeneity in lipid composition and physical properties but the types, composition and size of lipid domains still remain poorly understood. Here, we provide evidence for large-scale lipid domains in the plasma membrane of CHO and J774 cells, based on long-range lateral diffusion upon photobleaching of various lipids substituted by BODIPY or NBD. Whereas BODIPY-glucosylceramide freely diffused in the plane of the membrane, BODIPY and NBD analogs of sphingomyelin and phosphatidylycercholine (16:0 and 18:1) displayed partial recovery (45% and 20%, respectively) after photobleaching of large fields (20 µm²), but full recovery in small fields (5 µm²). Diffusion of sphingomyelin and phosphatidylycercholine analogs (i) was not restricted by the actin cytoskeleton (insensitive to latrunculin B treatment); (ii) required enzymatic cholesterol (increased restriction upon methyl-beta-cycloextrin); and (iii) was restricted by endogenous glycosphingolipids (release of restriction upon inhibition of glycosphingolipid biosynthesis by D-PDMP). In addition, depletion by sphingomyelinase of endogenous sphingomyelin restricted diffusion of its two analogs, but facilitated that of BODIPY-phosphatidylycercholine. Taken together, our data indicate the coexistence of three distinct large-scale lipid domains, enriched respectively in glucosylceramide, sphingomyelin and phosphatidylycercholine, and showing increasing restriction in lateral mobility. Glucosylceramide, the most mobile lipid, also showed the highest intracellular accumulation and was targeted to the Golgi, whereas the poorly mobile phosphatidylycercholine was also poorly internalized but rapidly recycled to the cell surface. We suggest that membrane lipids endocytosis and their progression towards distal compartments of the endocytic apparatus are also controlled by their lateral diffusion. (Supported by Belgian FNRS and Region Wallonne)

Elasticity and Molecular Construct of Clathrin Coated Vesicles via Atomic Force Microscopy

A. J. Jin, K. Prasad, P. D. Smith, E. M. Lafer, R. J. Nossal; 1Dibeps/or/od, National Institutes of Health, Bethesda, MD, 2Biochemistry, University of Texas Health Science Center at San Antonio, San Antonio, TX, 3LIMB/NICHOD, National Institutes of Health, Bethesda, MD

Clathrin coated vesicles (CCVs) are multi-component protein and lipid complexes of 100 nm diameter. We consider each CCV to be composed of an outer clathrin lattice cage, inner clathrin vesicle, and an intermediate linkage layer with adaptor proteins and other cofactors, enclosing an aqueous core. To unravel the intricacy of their molecular constructs, we examine the mechanical properties of CCVs while developing new schemes of atomic force microscopy (AFM) and related analyses. By focusing on CCV deformation in quantitative response to varying AFM-substrate compression force, we have estimated that the bending rigidity of the CCV composite shell is 285±30 kT, which is about 20 times that of either the outer clathrin cage or inner vesicle membrane (Jin, et al., 2006. Biophys. J. 90:3333-44). This result indicates a flexible coupling between the clathrin core and the inner membrane that can be up or down regulated, potentially by orders of magnitude, during the vesicular trafficking in cells.

Functional Characterization of Stable Clathrin Patches at the Cell Surface

R. Zoncu, R. Perera, A. Raimondi, R. Sebastian, E. Diaz, D. K. Toomre, P. de Camilli; 1Cell Biology, Yale University/HHMI, New Haven, CT, 2Cell Biology, Yale University, New Haven, CT, 3Computer Science, University of Valencia, Valencia, Spain

The key components of endocytic clathrin coats and a variety of accessory factors have been identified and characterized. However, dynamics and regulation of clathrin coat assembly in living cells is only partially understood. Both electron microscopy and live microscopy studies have revealed a striking heterogeneity of clathrin structures. In particular, along with short-lived single clathrin-coated pits, stable large arrays of clathrin coats have been described and reported to be endocytically active. However, these structures remain poorly characterized. We have measured their average diameter and clathrin content. We have developed a novel live microscopy method, multi-angle Total Internal Reflection (MA-TIRFM), in order to investigate endocytosis from their average diameter and clathrin content. We have developed a novel live microscopy method, multi-angle Total Internal Reflection (MA-TIRFM), in order to investigate endocytosis from

Compartment Specific Function of Clathrin-light Chains

V. Poupart, V. Legendre-Guillermin, S. Thomas, M. Giraud, L. Bourbonniere, J. Philie, N. A. Bright, P. S. McPherson; 1Neurology and Neurosurgery, Montreal Neurological Institute, McGill University, Montreal, PQ, Canada, 2Clinical Biochemistry, Cambridge Institute for Medical Research, University of Cambridge, Cambridge, United Kingdom

Clathrin-coated vesicles (CCVs) are the major carriers for endocytic cargo at the plasma membrane and they also mediate intracellular trafficking between the trans-Golgi network (TGN) and the endosomal system. The structural unit of clathrin, the triskelion, is composed in brain of three copies of the clathrin-heavy chain (CHC) and three clathrin-light chains (CLCs) interacting in a non-covalent manner. While CHC provides the structural backbone of the clathrin lattice and helps to organize the machinery for membrane curvature and cargo selection, the roles of CLCs are not well defined. In order to examine the function of CLCs in cells, we have used small inhibitory RNA (siRNA) in COS-7 and HeLa cells to knock down the two CLC isoforms, CLCa and...
b. CLC knock down results in a slight decrease in CHC expression levels yet i) the remaining CHC associates in triskelia as does newly synthesized CHC, ii) clathrin-coated pits (CCPs) and CCVs containing clathrin adaptor protein 2 (AP-2) are observed at the plasma membrane by immunofluorescence and electron microscopy, iii) the endocytosis of multiple endocytic cargo is unchanged. In contrast, depletion of CLCs leads to a disruption in the distribution of the TGN/endosomal clathrin adaptor protein 1 (AP-1), whereas the related adaptors AP-2, AP-3, GGA2 and GGA3 are not affected. In addition, we observe a striking alteration in the distribution of the cation-independent mannose-6 phosphate receptor, which accumulates in a perinuclear area. These data reveal a surprising and previously unknown compartment and adaptor specific function for CLCs.

NECAPs Contain a New Module in the PH Domain Superfamily That Serves as a Distinct Interface for FXDXF Motifs

B. Ritter,1 A. Y. Denisov,2 J. Phlice,3 V. Legendre-Guillen,4 K. Gehring,5 P. S. McPherson1; 1Montreal Neurological Institute, McGill University, Montreal, PQ, Canada, 2Department of Biochemistry and Montreal Joint Centre for Structural Biology, McGill University, Montreal, PQ, Canada

The NECAPs are a recently described family of AP-2-binding proteins associated with the coats of clathrin-coated vesicles. The N-terminal region of the NECAPs is highly conserved throughout species but shows no sequence homology to other proteins. Using NMR, we have now solved the structure of this region and homology searches reveal a fold in the PH domain superfamily. In a tandem MS-based screen for binding partners for the PH-like domain, we have identified amphiphysin I, confirm this domain as a general interface domain superfamily. In a tandem MS-based screen for binding partners for the PH-like domain, we identified amphiphysin I. Surprisingly, NMR analysis of the amphiphysin I/NECAP complex, coupled with mutational studies, revealed the FXDXF motif within the amphiphysin I insert domain as the binding site for the PH-like domain and accordingly, NECAP and AP-2 compete for binding to amphiphysin I. Moreover, the NECAP PH-like domain also mediates binding to other FXDXF motif-containing proteins, confirming this domain as a general interface for FXDXF motifs. So far, the FXDXF motif was thought to be exclusively an AP-2 alpha-ear-binding motif. Since FXDXF motifs are important for the organization and function of numerous endocytic accessory proteins, these data implicate the NECAP PH-like domain as an additional hub in the organization of the endocytic machinery.

Solution Structure of Slal Homology Domain 1 and NPFX|D Binding Site Responsible for Endocytic Cargo Recognition

S. M. Di Michielo1, C. S. Krieger1, J. S. Pierson1,2; 1Biological Chemistry, UCLA, School of Medicine, Los Angeles, CA, 2CR-UK Institute for Cancer Studies, University of Birmingham, School of Medicine, Birmingham, United Kingdom

Adaptor proteins play important roles in endocytosis including recognition of internalisation signals in transmembrane cargo and linking the cargo to the endocytic machinery. Our laboratory has identified Slalp as an adaptor for the NPFX|1,2D endocytosis signal in Saccharomyces cerevisiae. A conserved Slalp domain, SHD1 (aa495-560), is responsible for NPFX|1,2D binding. We have now determined the solution structure of SHD1 bound to an NPFX|1,2D peptide by NMR spectroscopy and docking calculations. SHD1 is a novel domain variant based on the SH3-like topology which employs a distinct binding pocket to recognize the NPFX|D endocytosis internalisation signal. Signal-binding residues form a solvent exposed hydrophobic surface and were mutated to alanine and glutamate and purified mutant domains were characterized by far-UV CD spectroscopy to establish no major structural effects. Signal binding by purified wild-type and mutant domains was assessed by surface plasmon resonance with a peptide containing the NPF|SD signal. This assay wild-type SHD1 bound to the NPF|SD signal with a KD ~ 5 μmol and did not bind an endocytically inactive mutant form of the signal (NPASD). Results with the mutants defined an exposed hydrophobic pocket centered on 1531 as the key signal-binding determinant. Similar findings were obtained using yeast 2-hybrid and GST-fusion protein affinity binding to assay signal binding. NaCl concentration up to 0.75M had no effect on signal binding, as determined by GST-fusion protein affinity binding assay, supporting the importance of hydrophobic interactions. Our results reveal SHD1 as a novel endocytic signal-binding domain.

The Clathrin Adaptor Eps15 Is a Golgi-associated Protein that Mediates TGN to Lysosome Vesicle Trafficking

S. Chi,1 H. Cao,2 M. A. McNiven1; 1Center for Basic Research in Digestive Diseases, Mayo Clinic College of Medicine, Rochester, MN, 2Department of Biochemistry and Molecular Biology and Center for Basic Research in Digestive Diseases, Mayo Clinic College of Medicine, Rochester, MN.

The trans-Golgi network (TGN) plays an important role in the sorting and packaging of newly synthesized proteins that are to be secreted or transported to the plasma membrane as well as nascent hydrolases that are trafficked to endosomes/lysosomes. However, the molecular mechanisms that support these essential processes at the TGN are still being defined. Eps15 (epidermal growth factor receptor pathway substrate clone 15) is a protein that is well known for its role in clathrin-coated vesicle formation and growth factor receptor internalization from the plasma membrane, where it binds to other endocytic proteins such as the clathrin adaptor protein AP-2. Interestingly, using purified polyclonal antibodies against Eps15 as well as expression of myc-tagged Eps15, we observed that Eps15 is not only present at the plasma membrane but also at the TGN and late endosomes. Therefore, we hypothesized that Eps15 might be a TGN-associated clathrin adaptor involved in the transport of Golgi cargo molecules such as lysosomal hydrolases. Indeed, we found that Eps15 localizes with a late endosomal, mannose-6-phosphate receptor-positive compartment and, further, that Eps15 and the TGN clathrin adaptor AP-1 co-immunoprecipitate from Golgi fractions of rat liver. Next, we tested whether Eps15 function is necessary for efficient TGN to endosome/lysosome trafficking by monitoring the maturation of the lysosomal hydrolase Cathepsin D that occurs upon transport to the lysosome. Using Western blot analysis to determine the amount of nascent versus mature, cleaved Cathepsin D, we observed a marked (20%) reduction in the cleaved form of Cathepsin D in mutant Eps15-expressing cells in comparison to wild-type Eps15-expressing cells. Together these findings support the exciting possibility that Eps15 plays important roles both in clathrin-based endocytic and Golgi vesicle formation and trafficking. The molecular mechanisms that differentiate these two roles of Eps15 and how they are regulated is currently under study.

Synaptic Vesicle Recycling Requires Dynamin 1 Only during Sustained Stimulation

S. M. Ferguson,1 G. Brasnoj,2 M. Hayashi,3 M. Wolfel,4 C. Collesi,5 S. Giovedi,1 A. Raimondi,1 L. Gong,1 S. Paradise,1 E. O'Toole,1 R. Flavel,1 O. Cremona,4 G. Miesenbeck,2 P. V. De Camilli1; 1Department of Cell Biology/HIMI, Yale University School of Medicine, New Haven, CT, 2Department of Biochemistry, Weill Medical College of Cornell University, New York, NY, 3Department of Cell Biology, Yale University School of Medicine, New Haven, CT, 4JIRC Institute for Molecular Oncology Foundation, Universita Vita-Salute San Raffaele, Milano, Italy, 5Department of Molecular, Cellular and Developmental Biology, University of Colorado, Boulder, CO, 6Section of Immunology/HIMI, Yale University School of Medicine, New Haven, CT

Normal synaptic transmission is critically dependent on the continuous availability of neurotransmitter-containing synaptic vesicles. Much of this supply is accounted for by local endocytic recycling of vesicles that have recently undergone exocytosis. Numerous studies have demonstrated that the dynamin GT Pases play a general role in the fission of endocytic vesicles. Of the three dynams encoded by mammalian genomes, only dynamin 1 has a neuron-specific pattern of expression that increases in parallel with synaptogenesis and is therefore the isoform widely believed to be essential for synaptic vesicle endocytosis. We have now generated mice lacking the expression of dynamin 1. Surprisingly, dynamin 1 knockout mice are born apparently normal, with no major developmental defects at the nervous system. However, they fail to thrive, develop severe a neurological impairment and die by the second post-natal week. Functional and structural studies of neurons from these mice revealed the occurrence of synaptic transmission and the presence of synaptic vesicles. However, abnormal endocytic intermediates were also clearly present at a subset of synapses under both basal and stimulated conditions with an extreme abundance of clathrin-coated buds connected to each other and to the plasma membrane by extended tubules. Kinetic analyses of synaptic vesicle turnover in cultured dynamin 1 knockout neurons revealed a striking blockade of synaptic vesicle recycling only during intervals of strong stimulation. Collectively, these results confirm the importance of dynamin 1 in synaptic vesicle recycling, but show that it is not essential for this process. Thus, dynamin 1 may play a highly specialized role in mediating enhanced synaptic vesicle recycling during periods of elevated neuronal activity. Conversely, our data also supports a role for dynamin 1-independent mechanisms for synaptic vesicle endocytosis that are favored at lower levels of neuronal activity.

Role of the Endocytic Protein Epsin in Cdc42 Regulation

B. G. Coon, D. F. Edwards, R. Aguilar; Biological Sciences, Purdue University, West Lafayette, IN

Epsin are endocytic proteins with a structured Epsin N-Terminal Homology (ENTH) domain and a carboxy-terminal region containing peptide motifs that interacts with ubiquitin and other endocytic proteins. We have recently demonstrated that the ENTH domain is both necessary and sufficient for viability of double epsin KO yeast cells. We have also shown that the ENTH domain binds guanine nucleotide triphosphate-activating proteins (GAPs) for Cdc42, a critical regulator of cell polarity and viability defects. Here we show evidence indicating conservation of this epsin-regulated Cdc42 pathway in mammalian cells (including human HeLa cells). We have found that mammalian epsin are capable of binding mammalian GAPs and that interference of the ENTH domain function in mammalian cells by using dominant negative approaches, leads to loss of...
cell viability and morphological abnormalities. Moreover, our results also suggest that the epsins contribute to the regulation of specific Cdc42 signaling pathways in yeast and mammalian cells. Taken together our data indicate that the epsin-regulated Cdc42 pathways are conserved and critical for normal cell physiology in metazoa.

Functional Domain Analysis of Dictyostelium gpa4, a New Member of the Epsin Family

R. J. Brady, T. J. O'Halloran; Molecular, Cellular, and Developmental Biology, University of Texas at Austin, Austin, TX

As an integral component of clathrin-coated pits, epsin is thought to engage clathrin and key clathrin adaptors and tether these proteins to the membrane via an Epsin N-Terminal Homology (ENTH) domain. Functional analysis of epsin domains in different model systems has led to conflicting results about whether the lipid-binding function of the ENTH domain and the adaptor-binding motifs of the c-terminus can function independently. To address this issue, we generated an epsin-null mutant line in Dictyostelium discoideum. Although the ENTH domain of epsin was required for normal spore morphology, general phenotypes associated with clathrin-null cells were not observed in the epsin-null mutant. Conversely, we found epsin was unable to localize properly to membrane punctae in the absence of clathrin. Domain analysis revealed that, as with mammalian epsin, the ENTH domain was required to target epsin to the membrane, but the c-terminal binding motifs were critical for epsin to colocalize with clathrin on the membrane. To determine whether the ENTH domain contributed more than Pip2-binding function, we replaced the ENTH domain with the PH domain of PLC, a canonical Pip2-Binding domain. Remarkably, this chimera bound and sequestered clathrin into aberrant patches on the membrane, revealing that epsin is a potent recruiter of clathrin. However, the chimera did not localize into punctae and was not functional, indicating that the ENTH domain plays an important role in addition to lipid binding. While clearly targeting epsin to the membrane, the ENTH domain also may be required for epsin to appropriately facilitate the recruitment and organization of additional clathrin and adaptors to growing clathrin pits. Taken together, our results provide new insights into the contribution of the ENTH domain to epsin function.

AAK1-mediated Numb Phosphorylation Redistributes Numb within the Cell

E. B. Sorensen, S. D. Conner; Genetics, Cell Biology and Development, University of Minnesota, Minneapolis, MN

The Drosophila Numb-associated kinase (Nak) was discovered as an interacting partner of Numb. Numb is a protein important for binary cell fate decisions by repressing Notch signaling transaction during neuronal development. Numb is highly conserved from flies to humans. In addition to its signaling role, mammalian Numb has been shown to function in clathrin-mediated endocytosis. The adaptor-associated kinase 1 (AAK1) is the human homolog of Nak. AAK1 is modeled to coordinate endocytosis by regulating AP2 affinity for receptors. AAK1 is stimutated by clathrin-mediated endocytosis and studies indicate that AAK1 may play a role in regulating Notch signaling through Numb phosphorylation. We have tested this idea using biochemical approaches to assess AAK1 kinase activity toward Numb. In vitro kinase assays demonstrate that AAK1 phosphorylates human Numb. We also find that Numb phosphorylation is stimulated by clathrin, consistent with previous reports for AP2. To investigate the impact of Numb phosphorylation in cells, we employed an adenovirus-mediated overexpression approach. We find that AAK1 overexpression leads to a redistribution of Numb to the perinuclear endosome. The observed redistribution is specific for AAK1 kinase activity as Numb distribution is unaffected in cells overexpressing AAK1 kinase dead mutants. We speculate that AAK1-dependent Numb redistribution prevents Numb from antagonizing Notch signaling.

1112

The Di-Leucine Motifs of LRP9 Bind to the Alpha/Sigma2 Hemicomplex of Adaptor Protein 2 (AP-2) and Mediate Its Endocytosis

B. Donay,1 J. Kinse1y,2 G. Bu,3 S. Konfeld1; Internal Medicine, Washington University School of Medicine, St. Louis, MO, 2Pediatrics, Washington University School of Medicine, St. Louis, MO

Low-density lipoprotein receptor related protein 9 (LRP9), a distant member of the LDLR family of proteins, is a type I integral membrane protein comprised of an extracellular or luminal domain of 427-aa, a transmembrane segment, and a 248-aa cytoplasmic tail. To date, there are no reports on the cellular distribution of LRP9 or the signals responsible for its localization. Indirect immunofluorescence microscopy of CHO cells stably expressing HA-tagged mouse LRP9 showed the protein to be predominantly localized to endosomes with a small amount on the plasma membrane. Analysis of the cytosolic tail revealed the presence of one YXX8 and 2 DEXXXLL consensus motifs that commonly mediate sorting to endosomes. Microscopy results indicated that either di-leucine motif is sufficient for proper endosomal targeting of the protein but mutation of both di-leucines resulted in retention at the cell surface. Mutation of the YYQQL motif, either alone or in combination with one of the two di-leucines, did not affect localization. Endocytosis assays with wild type or mutant receptor tails were in good agreement with the imaging data. In GST pull-down assays, each di-leucine motif bound the α2/δ hemicomplex of the clathrin adaptor AP-2 but not the individually expressed α2, β2, or δ2 subunits, or the β2/δ2 hemicomplex. The di-leucine motifs also bound the VHS domains of all three GGA proteins, providing the first documented example of di-leucine motifs with overlapping AP-1/AP-2 and GGA binding sequences. LRP9 also represents the first example of a transmembrane protein with an internal GGA-binding sequence in addition to the usual carboxyl terminal motif.

1113

A Role for the Acidic-Dileucine Motif of Vesicular Acetylcholine Transporter in Endocytosis

M. Kim, L. B. Hersh; Molecular, and Cellular Biochemistry, University of Kentucky, Lexington, KY

The carboxyl-cyttoplasmic tail of the vesicular acetylcholine transporter contains multiple sorting signals for its trafficking to synaptic vesicles. We recently showed that one of these signals, a dileucine motif, is involved in AP-1 binding and endocytosis. Dileucine motifs involve in addition to a dileucine pair, acidic residues four or five residue upstream. In VACHt this motif is S158EL. Serine 480 can be phosphorylated and it and the adjacent acidic residue are structurally important for endocytosis Deletion and site specific mutagenesis of this region in VACt showed that the dileucine motif is not the sole endocytosis motif. Although each leucine residue is important for endocytosis, leucine 485 plays a greater role than leucine 486. Mutation of serine 480 to alanine or glutamate 481 to alanine did not affect AP-1 binding, however these mutations increased cell surface VACt. Mutagenesis of the four residues SE/AA plus LL/AA inhibits endocytosis much more than the individual mutations LL/AA or SE/AA. The addition or deletion of single amino acids between the SE and LL residues increases cell surface expression of VACt. Taken together these results indicate that the entire SERDVELLL sequence represents the motif for the endocytosis of VACt.

1114

The Acidic Cluster Motif of the Cytoplasmic Tail of DC-SIGN Is Involved in Receptor Recycling and Intracellular Trafficking

H. Nassanian, S. Chantasrivast, B. Lee; Microbiology, Immunology, & Molecular Genetics, UCLA, Los Angeles, CA

Dendritic cell-specific ICAM-3-grabbing non-integrin (DC-SIGN) is a C-type lectin receptor expressed by DCs implicated in the binding of glycoproteins and pathogenic structures. The N-terminal cytoplasmic tail (CT) of DC-SIGN contains internalization and sorting signals that may play a role in receptor endocytosis and trafficking, including a dileucine motif (LL), a triadric cluster (EEE), and a tyrosine-based motif (YKSL). By generating endocytic motif mutants and performing biochemical and immunofluorescence experiments, we show the contribution of these motifs in the endocytosis, recycling, and intracellular trafficking of DC-SIGN. We have found that all three motifs play a role in endocytosis; whereas wild-type (wt) DC-SIGN internalized at a rate of 2%/minute, the CT mutants internalized at rates ranging from 0.5%-1.3%/minute. When studying DC-SIGN recycling after internalization, we found that the LL and EE
mutants recycled to the cell surface with faster kinetics compared to wt DC-SIGN, suggesting these motifs are involved in the intracellular trafficking of the receptor. Indeed, co-localization of wt DC-SIGN or the EE mutant with the intracellular markers Rab5 (early endosomes), Rab7 (late endosomes), LAMP-1 (lysosomes), and Rab11 (recycling endosomes) showed that the EE motif plays a role in receptor trafficking. While wt DC-SIGN colocalized with Rab5 and Rab11, the EE mutant did not. Both wt DC-SIGN and EE colocalized with LAMP-1 after 30 minutes of internalization, but only wt remained in LAMP-1 compartments after 45 minutes, indicating that the EE motif plays a role in retaining DC-SIGN in lysosomes. Both wt DC-SIGN and EE failed to colocalize with Rab7. We conclude that the dileucine motif, acidic cluster, and tyrosine-based motif present in the CT of DC-SIGN function to regulate receptor endocytosis, whereas receptor recycling is dependent on the dileucine and acidic cluster motifs. The acidic cluster is also highly responsible for the trafficking and targeting of DC-SIGN to intracellular compartments.

NPFXD-mediated Endocytosis Is Required for Polarity and Function of a Yeast Cell Wall Stress Sensor

H. Piao, I. Machado, G. S. Payne; Biological Chemistry, UCLA School of Medicine, Los Angeles, CA

Previously we identified the actin-associated protein Slap1 as an adaptor for the NPFXD(1,2)D endocytic targeting signal in yeast. Here we report that Wsc1p, a cell wall stress sensor, depends on this signal-adaptor for endocytosis. Mutation of either NPFFD in Wsc1p or Slap1 NPFXD(1,2,D) binding domain blocked Wsc1p internalization. By live cell imaging, we demonstrate endocytotic requirement for Wsc1 localization, polarized distribution of Wsc1p to regions of cell growth was lost in the absence of endocytosis and endocytically-defective Wsc1p was not concentrated at sites of endocytosis. Mutations in genes necessary for endosome to the Golgi traffic caused redistribution of Wsc1p from the cell surface to internal compartments, indicative of recycling. In the absence of Wsc1p endocytosis, cells exhibited defects in polarized cell wall synthesis and increased sensitivity to cell wall perturbation. Our results reveal that the NPFXD(1,2,D)-Slap1 system is responsible for directing Wsc1p to intracellular recycling in an endocytosis pathway necessary to maintain yeast cell wall polarity. The dynamic localization of Wsc1p, a sensor of the extracellular wall in yeast, resembles polarized distribution of certain extracellular matrix-sensing integrins through endocytic recycling.

Intracellular Autoactive Receptor Tyrosine Kinase Activity in the ER-Golgi Intermediate Compartment (ERGIC) Affects the Glycosylation and Trafficking of Other Cell Surface Proteins

L. C. Schecterson, M. P. Hudson, M. Ko, M. Bothwell; Physiology & Biophysics, University of Washington, Seattle, WA

Ligand-independent activation of receptor tyrosine kinases (RTKs) is a common theme in many diseases, including cancer. Transient transfection of 293 cells was used to determine the cellular localization of autocrine kinase activity of the Trk receptors TrkA, TrkB and TrkC, the FGF receptor 2 (FGFR2) and Crouzon craniosynostosis syndrome mutant FGFR2 C278F, and the PDGFR receptors A (PDGFRa) and B (PDGFRb). All autocrine forms were primarily retained intracellularly and were Endoglycosidase H (EndoH) sensitive, indicating they were in a high mannose (HM) state. Tunicamycin or Brefeldin A treatment did not affect the phospholipase-C(γ1) (PLC(γ1)) signaling pathway was activated by unglycosylated and HM forms of Trks, FGFR2s and the PDGFRs. The trafficking of other cell surface proteins, such as p75NTR and its homolog NR1I2, TNFR2, APP and Notch, was affected when co-expressed with the Trks and FGFR2 C278F. This study identified a novel ER-bound Bap29-related protein, termed Bap29varP, as an interacting protein. Bap29varP is 303 amino acid long and contains three transmembrane segments, and a large cytoplasmically located C-terminus. The C-terminal 33 amino acids interact with the N-terminus of Pgp. Protein analysis suggested that Bap29varP is nearly absent in Pgp +ve breast cancer cells due to rapid proteolysis, whereas, it is detectable in significant amounts in Pgp -ve cells. Forced expression of Bap29varP in Pgp +ve cells resulted in the accumulation of Pgp in calreticulin +ve vesicles that are also enriched with Bap29varP. Interestingly, expression of Bap29varP regulated the retention of Pgp at the cell surface. These data suggested that Bap29varP interacts with and retains Pgp in the ER, and protein synthesis of Bap29varP regulates the forward trafficking of Pgp to the cell surface. Possible implications of these results to the development of cancer drug resistance will be discussed.

Bap29varP, a Novel Endoplasmic Reticular Protein Regulates the Cell Surface Expression of the Human P-Glycoprotein

U. S. Rao, P. S. Rao; Pharmaceutical Sciences, Texas Tech University Health Sciences Center, Amarillo, TX

Translocation of P-glycoprotein (Pgp) to the plasma membrane of cancer cells is the major obstacle for a successful chemotherapy. The mechanism by which Pgp is targeted to the plasma membrane is unknown. It is assumed that immediately after synthesis in the endoplasmic reticulum (ER), Pgp exits the ER to Golgi apparatus via COP II vesicles, from which it is trafficked to the cell surface through trans Golgi network. To identify novel proteins involved in Pgp trafficking to the cell surface, a yeast two-hybrid analysis was carried out using different regions in Pgp as bait. This study identified a novel ER-bound Bap29-related protein, termed Bap29varP, as an interacting protein. Bap29varP is 303 amino acid long and contains three transmembrane segments, and a large cytoplasmically located C-terminus. The trafficking of other cell surface proteins was also studied. ERGIC-53, the major protein in the ERGIC compartment, by sucrose gradient fractionation. These results demonstrate that there is a close relationship between RTK glycosylation and ligand-independent activation, and that the trafficking of other cell surface proteins may be affected by the activity of RTKs localized to ERGIC.

Regulation of Glutamate Transporter EAAC1 Trafficking through an Interaction with RTN2B

Y. Liu, J. Rothstein; 2Neurology, Johns Hopkins University, Baltimore, MD, 2Neurology and Neuroscience, Johns Hopkins University, Baltimore, MD

Excitatory amino acid transporters (EAATs) are the primary regulators of extracellular glutamate concentrations in the central nervous system. Their dysfunction may contribute to several neurological diseases. To date, five distinct glutamate transporters have been cloned. In brain, EAAC1 (excitatory amino-acid carrier 1) is the primary neuronal glutamate transporter, localized on the presynaptic membranes that are close to release sites. Its contribution to synaptic actions, little is known concerning the regulation of EAAC1 trafficking from the ER to the cell surface. Previously, we identified an EAAC1 -associated protein, GTRAP3-18, an ER protein that prevents ER exit of EAAC1 when induced. Here we show that RTN2B, a member of reticulum protein family that mainly localizes to the ER, interacts with EAAC1 and GTRAP3-18 bind to different regions of RTN2B. Each protein can separately and independently form complexes with EAAC1. RTN2B interacts with EAAC1 in heterologous cells. Expression of short-interfering RNA (siRNA)-mediated knockdown of RTN2B decreases EAAC1 surface localization and overall expression in neurons. Overall, our results suggest that RTN2B functions as a positive regulator in the delivery of EAAC1 from the ER to the cell surface. In ER stress, up-regulated GTRAP3-18 retains EAAC1 in the ER by binding to EAAC1-RTN2B complex. These studies indicate that transporters exit from the ER controlled by the interaction with its ER binding partners represents a critical regulatory step in glutamate transporter trafficking to the cell surface.

Characterization of Bn4, a Protein Phosphatase Type 1 Regulatory Subunit Involved in Chitin Synthase Targeting

J. R. Larson, J. P. Bharucha, K. Tatchell; Biochemistry and Molecular Biology, University of Washington, Health Sciences Center, Shreveport, LA

Chitin is an essential component of the cell wall of the budding yeast Saccharomyces cerevisiae. During vegetative growth, chitin is deposited first as a ring at the base of the bud, then later at cytokinesis as the primary septum. The majority of chitin is synthesized by chitin synthase III whose catalytic subunit (Chs3) resides in endosome-like vesicles termed chitosomes, and is targeted by an unknown mechanism to the bud neck where it interacts with its activator, Chs4. Bn4, a Protein Phosphatase Type 1 (PP1) targeting/regulatory subunit, is required for both Chs4 and Chs3 localization to the bud neck. We are investigating the role of Bn4 and Gc7, the yeast PP1 catalytic subunit, in the targeting of the chitin synthase machinery to the bud neck. We are using deletion analysis to determine which segments within Bn4 are required for its localization to the bud neck and for targeting the chitin synthase machinery. Previous studies showed that a Bn4 variant that cannot bind to Gc7 (Bn4VLGV7E53) has a null phenotype (Kozhoubets et al., Mol. Biol. Cell 14, p32). The reduced levels of Bn4VLGV7E53 at the bud neck led to the suggestion that Gc7 is required for Bn4 association with the septin ring. However, we have identified several Bn4 variants that accumulate at the septin ring at levels at or below that of Bn4VLGV7E53 but retain an intact Gc7-binding domain and target the chitin synthase machinery normally. These results suggest a more direct role of Gc7 activity in targeting components of the chitin synthase machinery to the bud neck.
Bchlp, Bud7p, and Chs5p Transport Fus1p to the Cell Surface in Saccharomyces cerevisiae

R. M. Barfield, R. W. Schekman; Molecular and Cell Biology, University of California, Berkeley, CA

The transmembrane protein Fus1p is required at the yeast cell surface for cell fusion to occur during mating. Fus1p fails to localize to the cell surface and is mislocalized to a Golgi/endosomal compartment in the absence of CHS5, a gene required to transport the chitin synthase Chs3p to the cell surface, suggesting Chs5p is important for transporting Fus1p to the cell surface. We have now evidence to suggest that two peripheral membrane proteins, Bud7p and Bchlp, act with Chs5p to transport Fus1p to the cell surface. In bud7 bchlp double mutants, Fus1p is mislocalized to a Golgi/endosomal compartment. In addition, bud7 bchlp double mutants have a cell fusion defect, a phenotype seen in fusl and chs5 mutants. Furthermore, Fus1p co-purifies with Chs5p, Bchlp, and Bud7p in vivo and interacts with Chs5p and Bchlp in a yeast-two-hybrid assay. We identified four acidic residues in the cytosolic tail of Fus1p that are important for these two-tandem interactions, suggesting these residues could be part of a sorting signal recognized by Chs5p, Bud7p, and Bchlp to direct transport of Fus1p to the cell surface. Bud7p, Bchlp, and two related proteins Chs5p and Bchlp are found in a high order complex with Chs5p (2,3). This complex can form a coat on synthetic membranes in the presence of the GTPase Arf1 and GTPγS reminiscent of the COPII coat important for ER to Golgi transport (3). We propose a model where Chs5p, Bud7p, Bchlp, and perhaps Chs6p and Bch2p, act as coat proteins to recruit Fus1p into vesicles formed at the Golgi destined for the cell surface. 1. Santos and Snyder. (2003). Eukaryotic Cell 4, 821-5. 2. Sanchatejat and Schekman. Mol Cell Biol, in press.

Ap-1 Interacts with the EGFR Juxtamembrane Domain to Influence Basolateral Sorting in Polarized Epithelial Cells

S. P. Ryan, C. R. Carlin; Dept of Physiology and Biophysics, Case Western Reserve University, Cleveland, OH

Sorting of the epidermal growth factor receptor (EGFR) in polarized epithelial cells is a highly regulated process, involving multiple sorting signals to influence the dynamic trafficking of the receptor. Among these signals is a dileucine motif 658-LL in the EGFR juxtamembrane domain, which has previously been shown to be involved in basolateral sorting of the receptor. We hypothesized that this 658-LL motif may recruit proteins in the endocytic compartment to regulate EGFR recycling to basolateral membranes. One such protein is AP-1, a clathrin adaptor that has been shown to be involved in recycling endosomes and is recruited to DxxxLL motifs. The EGFR contains a 654-TxxxLL motif that could potentially mimic a DxxxLL-type motif when threonine residue 654 (Thr-654) is phosphorylated by protein kinase C (PKC). Thus we tested the hypothesis that the EGFR juxtamembrane containing 654-TxxxLL creates a docking site for AP-1, and that Thr-654 plays an important role in the basolateral sorting of the EGFR in polarized epithelial cells. We have shown in vitro pull-down assays that the EGFR juxtamembrane co-immunoprecipitates AP-1. In addition, we have shown that EGFR is down-regulated upon EGF stimulation to a greater extent when Thr-654 is mutated to alanine (T654A), than both wildtype receptors or receptors with a T654D substitution. We therefore hypothesize that the 654 phosphorylation activates a latent AP-1 binding site at 658-LL, increasing the likelihood that ligand-stimulated receptors may recycle to the basolateral membrane in polarized epithelial cells. This may have important consequences for EGFR-dependent signaling in highly differentiated cells, which is tightly regulated because EGFRs are sequestered in adherens junctions.

Role of µ1B C-terminus in Lipid Binding and Exocyst Recruitment

S. M. King, I. C. Fields, E. Höfflin, F. Hölsc; Biochemistry, Molecular Biology, and Cell Biology, Northwestern University, Evanston, IL

Polarized epithelial cells co-express two closely related AP-1 complexes, AP-1A and AP-1B, involved in endosomal/luminal or basolateral sorting, respectively (Fölsch et al., 1999). Although these complexes differ only in the incorporation of their respective medium subunits µ1A or µ1B, they have largely non-overlapping functions and form distinct vesicle populations (Fölsch et al., 2001 & 2003). Furthermore, only AP-1B facilitates the recruitment of exocyst subunits to recycling endosomes for incorporation into AP-1B vesicles (Fölsch et al., 2003). Subsequently, the exocyst is believed to aid fusion of AP-1B vesicles with the basolateral membrane. In this study we have determined how µ1B specifies sorting to the basolateral membrane by examining the C-terminus of µ1B (C-µ1B). Upon membrane recruitment of AP-1B, C-µ1B becomes exposed to the cytosol and therefore available for association with protein and lipid partners (Heldwein et al., 2004). We have found that C-µ1B helps in establishing the identity of AP-1B vesicles by interacting with specific lipid domains on recycling endosomes. Additionally, C-µ1B is sufficient to trigger membrane recruitment of exocyst subunits. Consistent with these functions, over expression of C-µ1B causes mis-sorting of AP-1B-dependent cargos to the apical domain in a dominant negative manner. Therefore, by examining C-µ1B, we have begun to understand how AP-1B can fulfill its unique functions in basolateral targeting on a molecular level.

v-SNARE Cellubrevin Controls Basolateral Recycling of Cargo in Polarized Apical EPithelial Cells

I. Fields, M. Pyrnan, E. Höfflin, R. Kang, V. Proux-Gillardeaux, T. Galli, H. Fölsch; Biochemistry, Molecular Biology & Cell Biology, Northwestern University, Evanston, IL; 2Cell Biology, Yale University School of Medicine, New Haven, CT; INSERM Avenir Team, Institut Jacques Monod, CNRS UMR7592, Universities Paris 6 & Paris 7, Paris, France

In epithelial cells, polarized membrane trafficking to either the apical or basolateral plasma membrane is essential to maintain cellular polarity. Membrane fusion events are dependent on SNARE pairing between t-SNAREs localized in the target membrane and v-SNAREs localized on transport vesicles. MDCK cells express two major t-SNAREs, syntaxin 3 and syntaxin 4. Whereas syntaxin 3 plays a role in fusion events at the apical domain (Kreiter et al., 2003), syntaxin 4 is suspected to be necessary for basolateral trafficking pathways (Kreiter et al., 2003). However, the exact nature of basolateral vesicles dependent on syntaxin 4 for fusion has not been determined. Furthermore, the specific v-SNARE(s) involved in basolateral fusion events remained elusive. Here we show that the ubiquitously expressed cellubrevin v-SNARE localizes to the basolateral plasma membrane and where it co-localizes with the epithelial-specific clathrin adaptor complex AP-1B. Specific cleavage of cellubrevin with tetanus neurotoxin (TeNT) results in inhibition of cellubrevin function and leads to apical mis-sorting of cargos such as transferrin receptors and truncated LDL receptors, LDLR-T27, which rely on AP-1B for basolateral recycling from recycling endosomes. Moreover, we demonstrate that in fully polarized MDCK cells cellubrevin efficiently co-immunoprecipitates with syntaxins 3 and 4. We conclude that cellubrevin is needed for fusion of at least a subset of basolateral transport vesicles with their target membrane and that this fusion event most likely involves syntaxin 4.

Polarization-dependent, Selective Transport by KIF5B of an Apical Membrane Protein in MDCK Cells

X. Xue, F. Jaulin, E. Rodriguez-Boulan, G. Kreiter; Cell and Developmental Biology, Weill Medical College, Cornell University, New York, NY; 3Margaret M. Dyson Institute for Vision Research, Weill Medical College, Cornell University, New York, NY

For proper cell morphogenesis it is imperative to target membrane proteins correctly to distinct domains within the plasma membrane. Both before and after differentiation, long-range, vesicular transport is mediated by the kinesin family (KIFs) of microtubule-associated motors. However, the mechanism by which vesicular transport is redirected during differentiation to insure domain-selective membrane targeting is unclear. Using time-lapse fluorescence microscopy, we found that in polarized MDCK cells, expression of dominant-negative KIF5B inhibited the post-Golgi transport and targeted delivery of a GPPi-tagged apical marker, p75-GFP. By contrast, inhibition of KIF5B in non-polarized cells had no detectable effect on post-Golgi transport of p75-GFP. We confirmed that KIF5B interacts with p75-GFP in polarized MDCK cells by co-immunoprecipitation analysis. As expected from the functional studies, in lysates prepared from non-polarized epithelial cells KIF5B did not interact with p75-GFP. Inhibition of KIF5B did not impede apical trafficking in general, as we observed no change in the post-Golgi transport and targeting of either prionmin-GFP or GPI-GFP in polarized epithelial cells. Similarly, expression of dominant-negative KIF5B had no effect on post-Golgi trafficking of several GPPi-tagged basolateral membrane proteins, including E-cadherin and the low density lipoprotein receptor in either non-polarized or polarized MDCK cells. Finally, expression of dominant-negative KIF3C or KIF3D did not alter exit of p75-GFP from the Golgi or its targeting to the apical membrane in polarized MDCK cells, demonstrating that transport of p75-GFP is mediated selectively by KIF5B. Together, these results suggest that KIF5B and the different proteins are sorted to the apical membrane by distinct kinesin motors. More significantly, our results provide evidence that cell polarization is accompanied by a change in the machinery used to transport and target proteins to the plasma membrane in polarized epithelial cells. This polarization-dependent switch in kinesin utilization may be a direct cellular response to differentiative cues that lead to cell morphogenesis.

Phosphorylation of the Na,K-ATPase Alpha-1 Subunit at Ser943 Is Involved in the Control of the Na,K-ATPase Activity in MDCK Cells by Prostaglandins

M. L. Taub, T. Rajkhowa; Biochemistry, State University of New York at Buffalo, Buffalo, NY

Prostaglandins regulate renal sodium reabsorption by modulating the activity of the Na,K-ATPase in tubular epithelial cells. The major renal prostaglandin, PGE2, interacts with Gs coupled receptors, activating Protein Kinase A (PKA), as well as Gβ coupled receptors, activating Protein Kinase C (PKC). We have observed that activators of PKA and PKC increase Na,K-ATPase

207

2006 ASCB Annual Meeting Abstracts
activity on the MDCK cell line, a model of distal tubule cells. Acute regulation of the Na,K-ATPase by PGE1 and 8-Bromo-cyclicAMP (8Br-cAMP) was studied by means of cell surface biotinylation studies, using MDCK cells cultured on transwells. A Western analysis of our biotinylated samples indicates an increase in the level of the Na,K-ATPase on the basolateral membrane of MDCK cells following a 30 min incubation with PGE1 and 8Br-cAMP. The Na,K-ATPase α subunit in MDCK cells contains a PKA phosphorylation site (Ser-943). In order to examine the possibility that the Na,K-ATPase α subunit is phosphorylated following PGE1 and 8Br-cAMP treatment, we immunoprecipitated the α subunit from MDCK cell lysates treated with PGE1, 8Br-cAMP or untreated. Immunoprecipitates were separated by SDS-PAGE, and transferred to nitrocellulose. Western blots were probed with an anti-phospho serine antibody, an antibody β antibody, as well as an antibody directed against the sequence in the phosphorylated α subunit, containing phospho Ser-943. Our results indicate an increase in serine phosphorylation of the α subunit in PGE1 and 8Br-cAMP treated MDCK cells, suggest that phospho Ser-943 is involved. Further studies are in progress to determine the role of PKA and/or PKC in mediating these observed effects of prostaglandin.

1126 RaLA Regulates the Delivery of Axonal and Dendritic Proteins to the Cell Surface in Cultured Hippocampal Neurons

B. Sampo, S. Kuech, G. Banker; Center for Research on Occupational and Environmental Toxicology, Oregon Health & Science University, Portland, OR. In epithelial cells, the small GTPase RaLA interacts with Sec5 and Exo84, two components of the exocyst complex, to regulate the delivery of proteins to the basolateral surface. Overexpression of active RaLA (RaLA72L) enhances the delivery of proteins to the basolateral but not the apical surface. We investigated the role of RaLA in neuronal membrane trafficking. When YFP-RaLA was expressed in mature hippocampal neurons, it labeled post-Golgi carriers that also contained NgCAM-CFP, an axonal protein. To determine whether RaLA regulates the delivery of proteins to the axonal surface, we expressed the RaA binding domain of Sec5 (RBD-Sec5) to sequester active endogenous RaA, and examine its effects on the surface expression of NgCAM. Overexpression of RBD-Sec5 did not affect the transport of NgCAM-containing post-Golgi carriers into the axon, but markedly reduced the expression of NgCAM on the cell surface. Expression of RBD-Sec5 also inhibited the delivery of the dendritic protein LDRL to the cell surface, causing the accumulation of LDRL-containing post-Golgi vesicles within the dendrites. Expression of constitutively active RaLA (but not a RaLA mutant that is unable to bind Sec5 and Exo84) led to an increase in the surface expression of both NgCAM and LDRL. Thus RaLA appears to regulate the delivery of both axonal and dendritic proteins to the plasma membrane. Although NgCAM and carriers are transported into both axons and dendrites, normally NgCAM is not efficiently delivered to the dendritic surface. Expression of constitutively active RaLA markedly enhanced the delivery of NgCAM to the dendritic surface, thereby greatly reducing the polarization of this protein. This suggests that the axonal polarization of NgCAM depends on the differential regulation of its exocytosis in axons and dendrites. Because LDRL carriers do not enter the axon, expression of active RaLA did not alter the polarization of this dendritic protein. Supported by NIH grant NS17112.

1127 Myristoylation and Membrane Association of Naked2 Is Required for Its Role as an Antagonist of Canonical Wnt Signaling

T. Hu, T. Van Raay, L. Solinka-Krezel, R. Coffey; 1 Medicine, Vanderbilt University, Nashville, TN; 2Biological Sciences, Vanderbilt University, Nashville, TN. The Wnt and epidermal growth factor receptor (EGFR) signaling pathways have been directly implicated in a broad range of processes including cancers. Recently, a major advancement was made in our understanding of how Wnt and EGFR signaling may cooperate; we found that the Wnt antagonist human Naked2, but not Naked1, escorts transforming growth factor α to the basolateral membrane of polarized epithelial cells. The role of Naked2 in Wnt signaling is poorly understood. Using zebrabith as an in vivo model, we demonstrate that Naked2 is both sufficient and required to antagonize canonical Wnt signaling. Further, we demonstrate that the N-terminal myristoylation sequence is required for this function. Mutating this site (G2A) dramatically reduces its ability to antagonize canonical Wnt signaling. Cell fractionation experiments both in vitro and in vivo demonstrate that while Naked2 is enriched in the membrane fraction, the G2A mutant is found mainly in the cytosol. This argues that Naked2 needs to be associated with the membrane in order for it to antagonize canonical Wnt signaling. Interestingly, we further show that this membrane localization reduces the half life of Naked2. In MDCK cells, we observe that wild type Naked2 is rapidly degraded (t1/2 ≥ 30 min) but the G2A mutant is more stable (t1/2 > 10 h). We demonstrate that association of Naked2 with the membrane is required for its degradation as the small membrane fraction of the G2A mutant (10%) contrast to MFI of 80 with a PGK promoter and MFI of 20 with the human CD40 promoter. Surprisingly, even though 100% of the B lymphocytes and CD34+ cells were infected with MOI of 100-2000, EYFP expression peaked at 80% for the CMV promoter and at 60% and 30% with the PGK promoter and CD40 promoter suggesting that subpopulations of B and CD34+ cells are able to silence these two promoters. In contrast, over 90% of M07e cells expressed EYFP following viral infection independently of the type of promoter. Viability was unperturbed in all cell types. Finally and in contrast to what was observed in cell lines, B lymphocytes and CD34+ cells were unable to initiate translation from a bicistronic expression cassette containing a PGK-IRES-GFP cassette. Thus our results demonstrate that an Ad5/F35 adenovector containing a CMV promoter is an efficient tool for the functional characterization of genes in activated B lymphocytes and in hematopoietic cells in general.
Objective: The objective of the current investigation was to identify the target genes for virus induced lymphoma by breast milk in our mouse model. Methods: Five BALB/c mice were used, one control and four experimental with lymphoma. Of 4 experimental mice 2 were offspring of mothers injected with temperature sensitive (ts) Moloney Marine Leukemia virus, (MoMuLV ts-1) and 1 was nursed by their own mothers; the other two were offspring of control mothers, (injected with media) but nursed by the surrogate infected mothers; the control was an offspring of a control mother raised by a surrogate control mother. Spleen tissue samples were used for DNA and total RNA isolation. Proviral DNA integration sites containing the gene of interest were determined by using inverse PCR (I-PCR). The expression of genes at/or near viral genome integration sites were determined by quantitative real time PCR (qRT-PCR). RNA expression levels were calculated for each gene using standard curves and normalized for GAPDH gene expression. Results: One hundred sixty-three proviral genomic insertion sites were identified, with 112 intergenic and 51 intragenic insertion. Maximum numbers of insertions (over 10) were found in chromosome 5, 7, 10, 11, 12 and 13. Five genes including Ncor 2, Elk 5, Ahil 1, Desert and Ifr 4, were identified, the expressions of which were up regulated from 1.29 fold to as high as 5 folds compared to control without lymphoma. Conclusion: We have identified 5 genes with known functions on nuclear receptor and cell signaling or regulation of lymphoid cell apoptosis. These genes were up regulated as high as 5 folds compared to control mouse. Viral genome integration might have contributed to this up regulation and lymphoma development in this model. This work was supported by American Cancer Society, Ohio Division and FM Douglas Foundation of St. Vincent’s Medical Center.

1131 Mapping Intracellular Protein:DNA Interactions: A More Robust and Efficient Alternative to ChIP (Chromatin Immunoprecipitation)

D. D. Hartzell, M. Urh, N. Karassina, G. Los, K. Wood; Promega Corporation, Madison, WI

Regulation of chromatin structure and gene expression is essential for normal development and cellular growth. Transcriptional events are tightly controlled both spatially and temporally by specific protein-DNA interactions. While significant advances in DNA tiling and microarrays have allowed for genome-wide screening of chromatin recognition sites, current methods to isolate intracellular protein-DNA complexes remain cumbersome and require co-immunoprecipitation, a process inherently sensitive to capture of non-specific DNA and proteins. To address these concerns a novel method has been devised for the covalent capture of protein-DNA complexes which does not require the use of antibodies. Proteins of interest are expressed in cells as HaloTag fusion proteins, crosslinked to DNA, and then captured on HaloLink resin, which forms a highly specific, cognate interaction with HaloTag. Due to the complete covalent linkage established between the resin and the crosslinked protein-DNA complexes, the resin can be stringently washed to remove non-specific DNA and protein much more efficiently than is possible by co-immunoprecipitation. The crosslinks are reversed to release purified DNA fragments from the resin. By improving specificity and reducing background interference during the isolation of protein-DNA complexes, this new methodology effectively increases the signal-to-noise ratio to permit detection of small changes in protein binding within a genome.

1132 Interaction of Intron Sequences of Apolipoprotein (a) Repeats with HepG2 Nuclear Extract

W. Tang, J. H. Wu; Microbiology and Immunology, Chang Gung University, Tao Yuan, Taiwan

Elevated blood lipoprotein (a) [Lp(a)] concentration is an independent risk factor for cardiovascular disease and stroke. Apolipoprotein (a) (Apo(a)) is a component of Lp(a) and contains 15-50 114 amino acid repeats. Each 342 nucleotide repeat is separated by an intron between repeat (designated as intron C) and an intron inside the repeat (designated as intron A/B). As blood Lp(a) level is inversely related to the repeat number of Apo(a), we hypothesize that the intron sequences of the repeat may play role in downregulating apo(a) promoter activity. Our previous studies revealed a down regulation of apo(a) promoter by intron A, B, C. We further investigated what cis element or trans factors were involved by gel shift assay and DNA affinity chromatography, respectively. The intron sequences were scanned for known transcription silencer sequences. These are GC factor (GCF) binding site with a consensus of GCGGCGG and silencing factor (SFA) binding sequence with a consensus of GGGCGGAGA. Several similar motifs are found in the apo(a) introns. The gel shift assays showed bindings of the DNA fragment containing the multiple GCF or SFA homolog with 1-2 base mismatch with the HepG2 nuclear extract (NE). GCF homolog was a better competitor than the SFA homolog. We further used the multimer of GCF homolog only as a probe and observed gel retardation and competition in the presence of HepG2 NE. Using streptavidin agarose to capture biotinylated GCF homolog plus HepG2 NE, we observed a major protein band in the eluate and the protein was identified as nuclear actin by MALDI-TOF experiment. Other minor bands were also observed but they were not identified.

In conclusion, the apo(a) introns in the repeats contain the known transcription downregulator GCF and SFA homolog and this complex that can interact with HepG2 NE and this may play role in downregulating apo(a) promoter activity.

1133 Revealing Combinatorial Regulation via an Integrated Quantification of Transcription Factor Binding

A. Beyer,1,2 C. Workman,3 J. Hollunder,4 T. Wilhelm,4 T. Ieke2; Bioengineering, UCSD, La Jolla, CA, T37b, FLI-Leibniz, Jena, Germany, T38b, Technical University of Denmark, Lyngby, Denmark, T38t, FLI-Leibniz, Jena, Germany

Systematic chromatin immunoprecipitation (ChIP-Chip) experiments have become a central technique for mapping transcriptional interactions in model organisms and humans. However, measurement of chromatin binding does not necessarily imply regulation, and binding may be difficult to detect if it is condition or co-factor dependent. To address these challenges, we present an approach for reliably assigning transcription factors (TFs) to target genes that integrates many lines of direct and indirect evidence into a single probabilistic model. Using this approach, we analyze publicly available ChIP-chip binding profiles measured for yeast TFs in standard conditions, showing that our model interprets these data with significantly higher accuracy than previous methods. We devised a new algorithm for identifying TF sets that cooperate to regulate a significant number of target genes. Pooling the high-confidence interactions reveals a large network containing 363 significant TF modules. We also analyzed multiple occurrences of binding sites. The results show that TFs exhibit distinct patterns of repeated binding sites that are TF specific. For instance we can show that these TFs preferentially have several binding sites in promoter regions (e.g. Skn7p), whereas others have at most one or two binding sites (e.g. Gat1p). In addition, the method predicts 980 novel binding interactions with high confidence that are likely to occur in so-far untested conditions. Indeed, using new ChIP-Chip experiments we were able to verify some of these predicted interactions. We outline the first approach for consistently integrating all available evidences for TF - target interactions and we comprehensively identify the resulting TF module hierarchy. Prioritizing experimental conditions for each factor will be especially important as increasing numbers of ChIP-Chip assays are performed in complex organisms such as humans, for which “standard conditions” are all-defined.

1134 Transcriptional Activation by the TRD1 Domain of Neuron-Restrictive Silencer Factor NR5F1/REST in COS-1 Cells

M. Hernandez-Barrales,2,3 J. Ayala-Lujan,5 J. Tapia-Ramirez,5; Ciencias Quimicas, Universidad Autónoma de Zacatecas, Guadalupe Zacatecas, Mexico, 2Department of Genetics and Molecular Biology, CINVESTAV-IPN, Mexico, D. F., Mexico

The transcription factor REST, a REI-silencing transcription factor, functions as a transcriptional repressor of multiple neuron-specific genes in non-neuronal cells and neuronal progenitors (Chong et al 1995). REST contains a DNA-binding domain and two repressor domains, TRD1 and TRD2, at the first one located at the N-terminal and the second at the C-terminal regions (Tapia-Ramirez et al 1997). Recent studies revealed that TRD1 repressed transcription by binding to mSin3 thereby recruiting HDAC, whereas TRD2 binds to another co-repressor, CoREST (Andrés et al 1999, Naruse et al 1999). The functionality of REST has concentrated on the repression of gene expression, however, several groups have suggested that REST and/or the RE-1, may have a dual function, as either repressor or activator, depending on the spatial and temporal context of its expression (Bessis et al 1997, Kallunki et al 1998). In this work, we investigated the dual function of the repressor domains of REST, therefore employed promoters containing TATA box: Thymidine kinase and Adenovirus promoter E1B and TATA-less promoters: Dehydrofolate reductase and the type II sodium channel. The promoters were cloned with five G4H4-bearing (UAS) sites and CAT reporter gene, transient transfection assays were performed in COS-1 cells. We found that TRD1 was able to activate almost all of the promoter tested over a wide range, meanwhile TRD2 maintained their repressor activity and the introduction of point mutations in the TRD1 domain reverted the transcriptional activation showed previously. This study suggests that TRD1 can be the responsible for dual function of REST. This work was supported in part by grant _30625-M_ from the National Council Science and Technology.

1135 PXET, Putative Xyloglucan Endotransglycosylase, Enhance Growth via BRs Signaling

I. Hwang, H. Chong, Chosun University, Gwangju, Republic of Korea

A specific inhibitor of the plant hormone is a very useful tool to study its function. Brassinazole(brz) is a specific inhibitor for brassinosteroids (BRs) biosynthesis. In order to expand our knowledge of the molecular mechanisms of plant steroid signaling, we performed a genetic screening in the medium containing brz in dark. Mutants insensitive to brz were shown to have long hypocotyls than the ones with the wild type plant. We recovered T-DNA flanking sequences from activation-tagged brassinazole insensitive (abr) mutant and named abr149. TAIL-PCR result indicated a T-DNA insertion at 2.4kb upstream of the putative xyloglucan endo-transglycosylase (PXET) gene in chromosome 2. Northern analysis and recapitulation results indicated that the
phenotypes of abz149 mutants were caused by the overexpression of the PXET gene. PXET-OX lines showed reduced fertility, small silique, early flowering, and taller than wild type. These results indicate that the PXET related with growth enhancement via BRs signaling.

1136 Distinctive Demethylating Effect of 5-aza-2'-deoxycytidine on Gene Coding Regions and Non-coding Repetitive Elements in NIH/3T3 Cells

5-aza-2'-deoxycytidine (5aza2C), a potent demethylating agent has been used to induce cell differentiation and global demethylation by inhibiting DNA methyltransferase (Dnmt). Previously, we reported that there are different preferences of DNA methyltransferases on specific genomic regions, in which Dnmt1 has preference on the repetitive elements whereas Dnmt3a and 3b primarily functions in gene regions in mouse embryonic stem cells. In present study, we investigated the effect of 5aza2C on repetitive elements, minor satellite repeats and endogenous C-type virus and several selected gene regions, Oct4, Per1 and Sad1 using mouse NIH/3T3 fibroblast cells by methylation sensitive southern blotting and bisulfite restriction mapping. Following a 3-day consecutive treatment with different concentrations of 5aza2C ranging from 0.001 μM and 5 μM, the methylation levels were decreased concentration-dependently at the repetitive elements. In contrast, the methylation levels at the gene regions fluctuated with concentration: unchanged at concentrations below 0.1 μM, decreased significantly at 0.1 μM, but higher concentrations (1 μM and 5 μM) of 5aza2C of did not cause demethylation in the gene regions. Therefore, the effect of 5aza2C was severe in repetitive elements compared to gene regions. Since there was no significant increase or decrease for the expression of Dnmt1, Dnmt3a and Dnmt3b between 5aza2C treated samples and the untreated control, this distinct demethylating effect was irrelevant to any expression changes of Dnmt after treatment. Furthermore, treatment with Trichostatin A (TSA), a histone deacetylase inhibitor, did not enhance the demethylating effect of 5aza2C in both repetitive elements and gene regions. The results obtained in this study may reflect preference of 5aza2C on Dnmt1. In conclusion, 5aza2C has distinctive demethylating effect on gene coding regions and non-coding repetitive elements in NIH/3T3 cells.

1137 FR901464, an Antitumor Microbial Metabolite That Causes Accumulation and Translation of Pre-mRNA, Binds to the SF3B Splicing Complex
