FR901464 (FR) is a novel antitumor compound that arrests the cell cycle at G1 and G2/M phases and induces apoptosis in a variety of tumor cell lines. We investigated the mechanism by which FR inhibits the cell cycle progression, and found that a C-terminal truncated form of p27Kip1 (p27*7) was accumulated in the FR-treated cells. Surprisingly, p27*7 was produced by translation of the p27 pre-mRNA with the intron 1 containing an in-frame termination codon. Further analyses indicated that FR accumulates pre-mRNAs of not only p27* but also other genes so far tested. In addition, localization of SC-35, a splicing factor that localizes in nuclear speckles, was changed and polyA-RNA accumulated in the nucleus after FR treatment. To identify the target molecule of FR, we synthesized a biotinylated FR probe that allowed isolation of FR-binding proteins, and identified the SF3B splicing complex as the FR-binding proteins in the HeLa cell extract by using CLASH. Interestingly, knockdown of these splicing factors using siRNA induced p27*7 production and change in the SC-35 localization. These results strongly suggest that FR binds and inhibits the splicing factors, thereby causing accumulation and translation of pre-mRNA.

1138 The Male Specific Gene from the Marine Red Alga Aglaothamnion oosumiense (Rhodophyta): Differential Expression of Gene from ESTs Analysis and Two Dimensional Electrophoresis
W. B. Kim, G. H. Kim; Biology, Kongju National University, Kongju, Republic of Korea
Sexual eukaryotes carry two classes of sex-related genes: sex determination genes act in individual organism to determine their gender or mating type and mate recognition genes encode traits that assure that mating occurs between the correct gender/mating type of correct species. Proteomic study using 2D gel electrophoresis showed that sex-specific proteins were 3.5% of total protein (59/1705). The number of sex-specific proteins was different in each sex (2% in female, 1.5% in male). About 13% (216/1705) of proteins expressed differentially according to sex. ESTs analysis showed that male and female plants have differentially categorized gene groups. The genes involved in transcription and protein destination were more abundant in the male than in the female, but the genes involved in metabolism and signal transduction were expressed more in the female. A full-length cDNA encoding male specific gene from database of ESTs analysis was isolated using the rapid amplification of cDNA ends-PCR method. Check up for male specific gene from real-time Polymerase Chain Reaction assays and got the result.

1139 Expression Analysis of the RPL9 Gene in Lung Tumours
Z. Dlumini, L. Mphalele; University of the Witwatersrand, Johannesburg, South Africa
The human ribosomal protein gene (RPL9) is approximately 5.5 kb in length and contains 8 exons. It is located in chromosome 4p13. This gene encodes a single domain ribosomal protein that is a component of the 60S subunit and it has been localized in the cytoplasm. The possible function of this gene is in cell growth and development as the highest expression levels of this gene has been observed in cells undergoing growth and differentiation and that the expression of expression declines as the tissue reaches developmental maturity. The aim of this study was to determine the expression pattern of RPL9 in various lung cancers. Was embedded tissue sections for the normal lung and lung cancer (small cell lung carcinoma, adenoarcinoma, large cell carcinoma and squamous cell carcinoma) were used to investigate the expression of RPL9. Antisense and sense RNA probes were synthesized by in vitro transcription and labeled with Digxygenase. Anti-sense RNA probe complimentary to the RPL9 mRNA was used to localize RPL9 mRNA transcript in tissue sections by in situ hybridization. Real time quantitative PCR was also done in lung cancer cell lines. RPL9 was found to be accumulating in the cytoplasm and was found to be up-regulated in lung cancer tissue sections as compared to normal lung tissue sections. The expression pattern for RPL9 in lung cancer was found to be significantly higher in small cell lung carcinoma, followed by Adenoarcinoma, Large cell carcinoma and least expressed in squamous cell lung carcinoma. Relative quantification showed that there was a 16 fold increase in the level of expression of the RPL9 mRNA in lung cancers. The up-regulation of RPL9 in lung cancer as compared to normal tissues suggests that RPL9 might be involved in the pathogenesis of these tumours.

1140 Regulation of ZBP1 Gene Expression in Metastasis
W. Gu, R. H. Singer; Anatomy and Structural Biology, Albert Einstein College of Medicine, Bronx, NY
ZBP1 (zincode binding protein) was originally identified as an mRNA regulator, functioning in mRNA localization, stability and translational control. Recent studies revealed that ZBP1 is also a tumor related protein and plays a role in repression metastasis via controlling β-actin mRNA localization. To date, there is no information about how ZBP1 gene is regulated, which could facilitate our understanding of the relationship between ZBP1 regulation and metastasis. In this study, we used rat uterine adenoarcinoma lines as an experimental model to study the regulatory mechanism responsible for ZBP1 gene expression. These two cell lines were from the same tumor; the non-metastatic MTC cell line expresses high levels of ZBP1 and the metastatic MTLn3 cell line has suppressed ZBP1 expression. We demonstrated that repression of ZBP1 gene expression in MTLn3 cells is correlated with the hyper-methylation of its promoter. Transiently transfecting the cell lines with luciferase reporters driven by the ZBP1 promoter revealed that the reporters were actively expressed in MTC cells but were repressed in metastatic MTLn3 cells, implying that a regulatory mechanism exists to control ZBP1 expression in these cell lines. We have identified a 1.5 kb flanking region upstream of the ZBP1 transcriptional initiation site, which contained most of the activities for in vivo ZBP1 gene expression in MTC cells. How this promoter region positively or negatively controls the expression of ZBP1 gene in these two cell lines is under investigation. More interestingly, examining ZBP1 expression in samples of human breast tumors and metastatic tumors derived from the same origin, we detected a greatly reduced ZBP1 expression in the metastatic tissues. This suggests that down-regulation of ZBP1 expression could be a common phenomenon in metastasized breast tumors and it could become a valuable marker to predict metastasis.

1141 Engineering the PP7 Coat Protein for Fluorescent-tagging of mRNAs in Living Cells
J. A. Chao, S. C. Almo, R. H. Singer; Anatomy and Structural Biology, Albert Einstein College of Medicine, Bronx, NY
The specific interaction between the MS2 coat protein (CP) and its cognate RNA stem-loop (SL) has been extensively exploited for molecular and cell biology including the labeling of mRNAs with fluorescent proteins. This technique allows for the fate of individual mRNAs to be followed in real-time in living cells. While this has opened the door for the interrogation of gene expression at the single cell and single molecule level, the reliance on a single RNA-protein complex limits the biological questions that can be addressed and prevents us from taking advantage of the myriad of fluorescent proteins that are now available. In order to expand our current ability to study mRNA in vivo, we have engineered the PP7 CP for use in tandem with the MS2 system. Like the MS2 CP, the PP7 CP binds tightly to its RNA SL and this interaction is orthogonal to any host RNA-protein complex. Importantly, biochemical experiments indicate that the PP7 CP binds its own RNA target 1000-fold tighter than the MS2 SL and we have confirmed this discrimination in a human U2OS cell line containing a transgene that contains 24 repeats of the MS2 SL. Construction of a similar transgene construct containing the PP7 SL is currently underway to validate the system. The MS2 CP-RNA protein interaction has been extensively characterized both biochemically and structurally. To better understand the molecular details of the PP7 CP-RNA interaction, we have crystallized the PP7 CP and determined its structure at 1.8Å resolution and are undertaking crystallization of the PP7 CP-RNA complex. Quantitative RNA-binding experiments will also be used identify which amino acids contribute significantly to the selectivity to the PP7 CP-RNA SL interaction. This work may allow us to design novel RNA-protein complexes that will further expand our ability to study mRNA in live cells.

Generating Amino Acids Substitutions to Alter the Activity and Response Specificity of the Anti-Sigma Factor, ChrR
J. B. Rodríguez-Molina, 1, R. S. Greenwell, 1 T. J. Donohue; 1Industrial Biotechnology, University of Puerto Rico at Mayagüez, Mayagüez, PR, 2Bacteriology, University of Wisconsin-Madison, Madison, WI

The extracytoplasmic function (ECF) sigma factor, $\sigma^E$, of Rhodobacter sphaeroides stimulates transcription in response to singlet oxygen ($O_2$) stress. Its cognate anti-sigma factor, ChrR, is part of a family of zinc-binding anti-sigma factors (ZAS) that releases $\sigma^E$ in response to $O_2$ stress. ChrR is a two domain ZAS, where the N-terminal interacts with $\sigma^E$ and coordinates zinc, and the C-terminal is required for the response. $\sigma^E$ is coordinated by two cysteine residues (Cys$^E_1$ and Cys$^E_2$) and two histidines residues (His$^E_1$ and His$^E_2$) in ChrR. Another member of the ZAS family is RsrA in Streptomycetes coelicolor: RsrA inhibits the activity of $\sigma^E$ until disulfide stress occurs. Between ChrR and RsrA, three of the zinc ligands are conserved in a canonical zinc-binding motif, HXn-CXnH. The fourth zinc ligand differs between RsrA (Cys$^E_3$) and ChrR (His$^E_3$). A mutant ChrR protein containing a cysteine substitution at His$^E_3$ (ChrR-H6C) has been generated and remains functional to inhibit $\sigma^E$. To assess whether ChrR-H6C has altered specificity to stress responses, plate diffusion experiments have been conducted. Interestingly, cells containing ChrR-H6C can respond specifically to superoxide ($O_2^-$). The anti-sigma factor RseA of E. coli is a transmembrane protein that binds the activity of $\sigma^E$. RseA releases $\sigma^E$ in response to periplasmic stress. The structures of RseA and ChrR have been solved in complexes with their respective $\sigma$ factors, and both contain a three-helical structure that interacts with their cognate $\sigma$ factors. While ChrR requires zinc to form this three-helical structure, RseA does not. A zinc-free version of ChrR (ChrRAzA) is being generated by nested PCR mutagenesis reactions to substitute 9 amino acids of ChrR (with those from the RseA domain). This poster will also present on the ongoing experiment to generate ChrRAzA and assess its ability to inhibit $\sigma^E$ activity and respond to $O_2$.

Transcriptional Regulation and Action at a Distance: Using Cells as Test Tubes to Probe DNA Mechanics In Vivo
H. G. García, 1 L. Bintu, 2 J. Kondes, 2 R. Phillips; 1Department of Physics, California Institute of Technology, Pasadena, CA, 2Department of Physics, California Institute of Technology, Pasadena, CA

DNA mechanics plays a central role in gene expression. Transcriptional control is realized through the interaction of the transcriptional machinery with DNA-bound transcription factors which can loop the DNA between two distant sites. DNA mechanics influences the gene expression readout of a wide variety of transcriptional networks. We develop a statistical mechanical model to quantify the in vivo energy cost of different DNA conformations in bacteria, which allows us to extract mechanical properties of DNA and to compare completely different regulatory systems such as the lac operon and the arabinose operon. Based on this quantitative understanding of DNA looping in the lac operon we propose to use an artificial lac system as a tool to probe DNA mechanics in vivo. In particular, by using a fluorescent reporter, we show that eukaryotic nucleosomal positioning sequences are indeed more flexible by characterizing their bending by Lac repressor in bacteria in the complete absence of nucleosomes. This work demonstrates that a careful interplay between quantitative data and quantitative models leads to a consistent picture of transcriptional regulation which yields falsifiable predictions.

Expression of Retinoblastoma Binding Protein 6 (RbP6p) Gene in Human Immunodeficiency Virus Associated Nephropathy (HIVAN)
N. P. Numaite; Faculty of Health Sciences, School of Anatomical Sciences, University of the Witwatersrand, Parktown Johannesburg, South Africa

Background: Since Human Immunodeficiency Virus associated nephropathy (HIVAN) was discovered, HIVAN cases have increased drastically and now the leading cause of end stage renal disease (ESRD) deaths. HIVAN prevalence is constantly linked to people of African descent (90% blacks). Nephritic-range proteinuria, renal insufficiency, and enlarged kidneys are typical features in patients with HIVAN. This is especially the case in patients already with HIVAN. RbP6p isoform 3 a ubiquitinin-like, apoptotic gene when mutated or deleted in cells renders their resistance to apoptotic induction. The Human Immunodeficiency Virus (HIV) uses apoptosis as a means to survive immune attack. It encodes pro-apoptotic proteins which kill both infected and uninfected T lymphocytes through Tumour Necrosis Factor (TNF) or mitochondrial pathway. The aim of this study was to analyze the expression of the three human RbP6p isoforms at the protein level using immunocytochemistry Results: Preliminary results show that there are high levels of the RbP6p isoform 3 protein in the glomerulus and tubules. Higher levels of apoptosis were also demonstrated in glomerular and tubular cells. This was evidenced by brown stained spots in the cytoplasm and nucleus. Mononuclear interstitial infiltration also is a characteristic of HIVAN. In situ hybridization showed up-regulation of RbP6p isoform 3 mRNA. In normal kidney cells the RbP6p isoform 3 gene is mostly expressed in the cytoplasm, in the diseased kidney RbP6p isoform 3 translocates to the nucleus. Conclusion: Elevated levels of RbP6p isoform 3 and apoptosis in HIVAN suggest the involvement of RbP6p isoform 3 in the pathogenesis of this disease. It may be concluded that RbP6p isoform 3 gene is correlated with the levels of apoptosis in HIVAN.

Early Response of Gene Expression to OAT3-mediated Cephalexin Toxicity Assessed by DNA Microarray Analysis
P. Jutabha, T. Muto, H. Endou, Y. Kanai; Pharmacology and Toxicology, Kyorin University School of Medicine, Tokyo, Japan

The primary site for renal elimination of drugs, toxins and their metabolites occurs in renal proximal tubule. It is the important tissue susceptible to the damage by the toxicants. Cephalexin, a first-generation of cephalosporin antibiotic, was known as nephrotoxicant transported into the renal proximal tubular cells by organic anion transporters (OATs). The mechanisms of nephrotoxicity induced by the compound have not yet completely understood. In this study, we examined the toxicity of cephalexin in OAT3-expressing renal proximal tubular cells (S2-OAT3) using cell viability assay. Transcriptionally-mediated cephalexin toxicity was assessed at the molecular level using microarray analysis. The low concentration of cephalexin induced the toxicity process in the cytoplasm, in the diseased kidney RbP6p isoform 3 localizes to the nucleus. Conclusion: Elevated levels of RbP6p isoform 3 and apoptosis in HIVAN suggest the involvement of RbP6p isoform 3 in the pathogenesis of this disease. It may be concluded that RbP6p isoform 3 gene is correlated with the levels of apoptosis in HIVAN.

A Genomic Fossil Reveals Key Steps in Hemoglobin Loss by the Antarctic Icefishes
H. Dietrich, S. K. Parker, T. J. Near; 1Biology, Northeastern University, Boston, MA, 2Ecology and Evolutionary Biology, Yale University, New Haven, CT

Antarctic icefishes are the only vertebrates that do not have hemoglobin and erythrocytes in their blood. These startling phenotypes are associated in several icefish species with deletions of juvenile and adult globin loci, in which red-blooded teleosts are typically composed of tightly linked pairs of $\alpha$- and $\beta$-globin genes. It is unknown if the loss of hemoglobin expression in icefishes was the direct result of such deletions, or if other mutational events compromised globin chain synthesis prior to globin gene loss. In this study, we show that 15 of the 16 icefish species have lost the adult $\beta$-globin gene but retain a truncated $\alpha$ globin pseudogene. Surprisingly, a phylogenetically derived icefish species, Neopagetopsis ionah, possesses a complete, but non-functional, adult $\alpha$-globin complex. This cluster contains two distinct $\beta$-globin pseudogenes whose phylogenetic origins span the entire Antarctic notothenioid radiation, consistent with an origin via introgression. Maximum likelihood ancestral state reconstruction supports a scenario of icefish globin gene evolution that involves a single loss of the transcriptionally active adult $\alpha$-globin cluster prior to the diversification of the extant species in the clade. Through lineage sorting of ancestral polymorphism, two types of alleles became fixed in the clade, 1) the $\alpha$-globin...
pseudogene of the majority of species, and 2) the inactive αβ-globin complex of N. ionah. We conclude that the globin pseudogene complex of N. ionah is a "genomic fossil" that reveals key intermediate steps on the pathway to loss of hemoglobin expression by all icefish species. Supported by NSF grants OPP-9120311, 9402712, 9815381, 0809451, and 0336932 to H.W.D.

1147 Functional Interaction of Nucleolin, c-Jun and Sp1 in PMA-induced Gene Expression of Human PLA₂β
B. Chen, J. Tsou, W. Wang; Chang; Department of Pharmacology, National Cheng Kung University, Tainan, Taiwan

cPLA₂ is the major intracellular form of cPLA₂, which preferentially hydrolyzes membrane phospholipids at the sn-2 position to release arachidonic acid (1). Arachidonic acid metabolism through cyclooxygenase (COX) and lipoxygenase (LOX) pathways generates various biologically active lipids that play important roles in inflammation, thrombosis and tumor progression. It has been shown that PMA provides cPLA₂-activating signals. In this study we found that PMA induced the expression of cPLA₂β in human non-small-cell lung carcinoma (NSCLC) A549 cell. The two Sp1 sites of cPLA₂β promoter were essential for PMA-induced transcription and Sp1 was involved in the regulation of gene expression. PMA stimulation also facilitated access of c-Jun to the promoter resulting in the formation of c-Jun/Sp1 complex, and enhanced the complex binding to the promoter. Furthermore, we identified nucleolin binding to the Sp1 site of the cPLA₂β promoter. Nucleolin also cooperated with c-Jun/Sp1 to regulate the transcriptional activity of cPLA₂β gene. These results indicated that nucleolin/c-Jun/Sp1 complex played an important role in PMA-induced gene expression.

1148 SFHR-mediated Modification of Genomic HPRT without Random Insertion of the Modifying Oligonucleotide
B. Bedayat,1 H. Emamekhoo,1 A. Abdolmohammadi,2 L. Ye,3 J. Cheung,1 J. O’Neill,4 J. A. Nicklas,4 D. C. Gruenert1,2,5; 1Research Institute, California Pacific Medical Center, San Francisco, CA, 2Laboratory Medicine, University of California, San Francisco, San Francisco, CA, 3Cardiovascular Research Institute, University of California, San Francisco, CA, 4Pediatrics, University of Vermont, Burlington, VT, 5Medicine, University of Vermont, Burlington, VT

Gene therapy has opened the door to new therapeutic interventions for the treatment of genetic diseases. In addition to the standard cDNA-based approaches, alternative gene targeting strategies have been developed. In this study, an oligonucleotide gene targeting strategy, small fragment homologous replacement (SFHR), was used to correct a point mutation in exon 3 of the hypoxanthine guanine phosphoribosyltransferase (HPRT) gene that inactivates HPRT in a lymphoblastoid cell line (LT1-1B1) and allows the cells to grow in 6-thioguanine (6TG) containing medium. Because of their mutant status, LT1-1B1 cells will not grow in medium containing hypoxanthine/aminopterin/thymidine (HAT) unless the mutant HPRT is corrected. The LT1-1B1 cell line was transfected with a 579-bp small DNA fragment containing wild-type HPRT sequences at the site of the mutation using the AMAXA Nucleofector. Corrected LT1-1B1 clones were selected in HAT containing medium and further analyzed by PCR, reverse transcriptase PCR (RT-PCR), and Southern blot hybridization. Quantitative analysis showed a SFHR-mediated correction frequency of between 10⁻⁴ to 2 x 10⁻⁴. Southern blot analysis indicated a wild-type restriction fragment length polymorphism (RFLP) consistent with SFHR-mediated correction. No other sites of integration were observed. This work is supported by CPMC Research Foundation Funds

1149 The Transcriptional and Proteomic Response to Cold Shock and Recovery in Saccharomyces cerevisiae
K. D. Dahquist,1 W. T. Citi,2 M. Mejia,2 E. S. Eberhard;2 1Biology, Loyola Marymount University, Los Angeles, CA, 2Chemistry, Vassar College, Poughkeepsie, NY

Previous studies on the global transcriptional response of Saccharomyces cerevisiae to cold shock have revealed that the response can be divided into a set of early response genes (after 15 minutes to 2 hours of cold temperatures) and late response genes (after 12 to 60 hours of cold stress; Sahara et al., 2002; Kandor et al., 2004; Schade et al., 2004). The late response genes include the ESR genes induced by many environmental stresses (Schade et al., 2004). These findings need to be extended to fully characterize the pathways and processes to which the early response genes unique to cold shock, and characterize, and to predict the protein-level response. The global transcriptional response to cold shock and subsequent recovery was measured using DNA microarrays. Yeast cells were grown to early log phase at 30°C, then shifted to 13°C for 60 minutes, and then shifted back to 30°C for another 60 minutes. Samples were collected before cold shock, after 15, 30, and 60 minutes of cold shock, and after 30 minutes and 60 minutes of recovery at 30°C. The samples collected at each time point were split so that both total RNA and total protein lysate could be isolated from the same sample of yeast cells. The total RNA was isolated, amplified, and labeled with Cy3 and Cy5 dyes by the indirect method, and hybridized to DNA microarrays. Protein levels from the same yeast samples were determined by two-dimensional polyacrylamide gel electrophoresis, followed by spot intensity quantitation, and identification by MALDI-TOF mass spectroscopy. We have found that genes belonging to the glycolytic pathway were induced at both the transcriptional and translational level after 30 minutes of cold shock. In addition, genes that are induced or repressed by cold shock return to their pre-cold shock levels after 60 minutes of recovery at 30°C.

1150 Intergenic Transcripts Joining CXC Chemokine Genes CINC2 and Lungkine in Rat Lung
J. N. VanderHart,1 J. Schade,1 B. Bedayat,1 H. Emamekhoo,1 A. Abdolmohammadi,2 L. Ye,3 J. Cheung,1 J. O’Neill,4 J. A. Nicklas,4 D. C. Gruenert1,2,5; 1Research Institute, California Pacific Medical Center, San Francisco, CA, 2Laboratory Medicine, University of California, San Francisco, San Francisco, CA

Intergenic transcripts, containing exon sequences of one gene spliced to those of another, have been described in several systems but their significance is unclear. We present evidence that an intergenic transcript encodes CINC2β, a previously described rat CXC chemokine. The genes for CINC2 (Chemokine Induced Neutrophil Chemoattractant 2) and lungkine (CXXCL15) are 10 kb apart on rat chromosome 14. The CINC2 gene generates two chemokines, CINC2α and CINC2β, that differ only in 3′-terminal amino acids. The source of C-terminal variation is differential splicing of exons specific for CINC2α and CINC2β. In the rat DNA sequence, CINC2α-specific exon 4, encoding C-terminal amino acids, stop codon, 3′UTR and polyadenylation signals, predictably follows the third intron of the CINC2β gene. In contrast, CINC2β-specific exon 4, encoding C-terminal amino acids and the stop codon, shares sequence but not reading frame with exon 2 of the lungkine gene. The 3′UTR of CINC2β mRNA thus contains lungkine-coding-sequence exons 2, 3 and 4, and then terminates in a polyadenylation signal shared with lungkine. RT-PCR with upstream primers in exons 2 or 3 of the CINC2 gene and downstream lungkine primers generated the intergenic CINC2β transcript and several additional intergenic transcripts containing combinations of CINC2α and lungkine exon sequences. Only lung RNA contained these intergenic transcripts among several tissues examined including liver, brain, kidney and heart. CINC2-lungkine intergenic transcripts were observed in a rat distal lung epithelial cell line (X404) but not in a fibroblast line (Rat1). A similarly arranged pair of CXC chemokine genes located close to CINC2 and lungkine (MP2 and GRO) did not generate intergenic transcripts when tested by RT-PCR. Thus, the region of rat chromosome 14 encompassing the CINC2 and lungkine genes generates intergenic transcripts in pulmonary tissue. Supported by NIH grants HL24075 and HL57426.

1151 Characterization of trh924 in Thermosynechococcus elongatus BP-1, a Unique Prochlorophyte
S. D. Lane Njuguna; Biology, Mills College, Oakland, CA

Phycotoxins are photosensizers that enable plants to change light changes in light conditions and adapt via photomorphogenesis or phototaxis. Recently, phycotoxins were found in bacteria and fungi. The major proteins that bind to the GAF domains of these phycotoxins are categorized into four subgroups: the eukaryotic Ph domain, the cyanobacterial Cph domain, the bacterial BphP domain, and the putative photosensitizer Phr family, also referred to as the unorthodox Photos. The Phr family is the most divergent class in its members conserve the GAF domain but lack the PH domain. Thermosynechococcus elongatus BP-1, which was isolated from a hot spring in Beppu, Japan, is a unicellular, rod-shaped cyanobacterium. A computer prediction and similarity search revealed five Phr genes in Thermosynechococcus elongatus BP-1. In the phylogenetic tree of Phr proteins, Thfr924 is a "genomic fossil" that reveals key intermediate steps on the pathway to loss of hemoglobin expression by all icefish species. Supported by NSF grants OPP-9120311, 9402712, 9815381, 0809451, and 0336932 to H.W.D.

1152 Two Novel Splice Variants of Human Vascular Endothelial Growth Factor (VEGF) That Had Been Identified Using the Spliceriminer™ DNA Library Panel
L. Wu; Research and Development, Stratagene, La Jolla, CA
The SpliceMiner™ cDNA library Panel is designed to simplify the discovery of human alternative splice forms that would have been difficult or impossible to detect by other methods currently available. The SpliceMiner cDNA library panel is a comprehensive collection of the human transcriptome. It consists of ~4.6 million primary cDNA clones derived from 15 high quality cDNA libraries representing 28 cancer cell lines and 34 human tissues, including 14 sub-regions of the brain. The panel contains cDNA transcribed from full length and low abundance human mRNAs and is enriched for complete transcripts, while maintaining the diversity of message found in the original human source material. Recently, the SpliceMiner cDNA library panel was employed for screening alternate splice forms of the human vascular endothelial growth factor (VEGF) gene which was demonstrated to be expressed in a variety of tumor cells. PCR was employed on the SpliceMiner cDNA library panel using primers that are complimentary to the terminal exons of VEGF. Multiple PCR products of all size populations across the entire range of cell lines in the panel were sequenced and results were aligned against the published human genomic sequence. In one screen, five VEGF splice variants were identified. Isoform 2, 4 and 6 had been previously identified and published by other research groups. The other two novel splice variants originated from leukemia and colon cancer cell lines contain a putative exon between exon 3 and 4. The two newly-discovered splice variants are believed to be expressed at lower abundance. The separation of cDNA clones into a large number of pools, the SpliceMiner cDNA library panel increases the likelihood of obtaining new alternate splice forms that would have otherwise been masked by more abundant variants. The SpliceMiner cDNA library panel is a unique, efficient method for detecting human alternative splice forms.

Loc1p Is Required for Efficient Assembly and Nuclear Export of the 60S Ribosomal Subunit in Saccharomyces cerevisiae
C. R. Urbiniti, G. B. Gomisalver, J. P. Aris, R. M. Long
biology, Loyola Marymount University, Los Angeles, CA, Microbiology and Molecular Genetics, Medical College of Wisconsin, Milwaukee, WI, Anatomy and Cell Biology, University of Florida College of Medicine, Gainesville, FL

Loc1p was identified as an exclusively nuclear dsRNA-binding protein that affects the asymmetric sorting of ASH1 mRNA to daughter cells in Saccharomyces cerevisiae. In addition to its role in cytoplasmic mRNA localization, Loc1p was identified as a constituent of pre-60S ribosomes. Cells devoid of Loc1p display a defect in the synthesis of 60S ribosomal subunits, resulting in “halfform” polyribosomes. Previously, we reported that Loc1p is located throughout the entire nucleus; however, upon closer inspection we discovered that Loc1p is enriched in the nucleolus consistent with a role in 60S ribosome biogenesis. Given that Loc1p is an RNA-binding protein and presumably functions in the assembly of 60S ribosomal subunits, we investigated if Loc1p has a role in pre-RNA processing and nuclear export of 60S subunits. Analysis of pre-RNA processing revealed that loc1Δ cells exhibit gross defects in 25S RNA synthesis, specifically a delay in processing at sites A0, A1 and A2 in 35S pre-RNA. Furthermore, loc1Δ cells exhibit nuclear export defects for 60S ribosomal subunits, again, consistent with a role for Loc1p in the assembly of 60S ribosomal subunits. It is attractive to hypothesize that the two phenotypes associated with loc1Δ cells, namely altered ASH1 mRNA localization and ribosome biogenesis, are not mutually exclusive, but that ribosome biogenesis directly impacts mRNA localization.

The Major Vault Protein Is Related to the Prokaryotic Toxic Anion Resistance Protein Family, TelA
K. Suprenan, N. Bloom, B. Hendrick, K. Huffman, D. Corey, J. Fang, G. Lushington
Molecular Biosciences, University of Kansas, Lawrence, KS, Pharmacology and Biochemistry, University of Texas Southwestern Medical Center, Dallas, TX, Bioinformatics Core Facility, University of Kansas, Lawrence, KS, Molecular Graphics and Modeling Laboratory, University of Kansas, Lawrence, KS

Vaults are large, hollow ribonucleoprotein particles that are very abundant in certain tumors and multidrug resistant cancer cells. Recent studies have suggested that vaults may function in subcellular or nucleocytoplasmic transport and or as a scaffold in the epidermal growth factor signaling pathways important for cell survival. We initiated a sequence-based approach to understanding vault function because vault structure and composition are conserved amongst eukaryotes. We report that the major vault protein, MVP, is related to the tellurite-resistance protein, TelA, of Rhodobacter sphaeroides strain 2.4.1, given preliminary sequence analysis suggesting multiple conserved motifs between MVP and TelA, and a recently released NMR solution structure of MVP indicating 30% sequence identity conservation within structurally resolved regions and gaps present only in unstructured coil regions. Because the structural correspondence is not enough to guarantee a similar function, we examined whether mammalian cell vaults responded to tellurite treatment and importantly, whether vaults are sufficient for tellurite resistance. Knocking down the expression of vault mRNAs by specific siRNAs does not affect the cytotoxicity of tellurite in HeLa cells. However, in the presence of tellurite, large vault aggregates, or vautosomes, appear at the cell periphery in as little as 15 minutes. Vautosome formation is temperature-dependent, reversible, and occurs in normal human umbilical vein endothelial cells as well as transformed HeLa cervical cancer cells. Vautosomes are unique in that they do not colocalize with ubiquitinated proteins, metalllothionein, the stress granule protein, TIA-1, and other ribonucleoproteins such as PAPP-1 and HnRNP A2. We propose that vautosomes are an unresolved component of a stress response pathway that originated in bacteria. In this regard, vaults may act to integrate the normal cellular pathways of growth and survival with the stress responses evoked by toxic metalloids and chemotherapeutic agents.

Flex Appeal: Exploring the Structural Flexibility of the Functional Interaction between Ku and Telomerase
Department of Biology, Boston College, Chestnut Hill, MA, Department of Chemistry and Biochemistry, University of Colorado, Boulder, CO

Telomerase is a ribonucleoprotein enzyme that stabilizes chromosomes by adding telomeric DNA repeats to the 3’ ends of DNA. The RNA component of yeast telomerase, TELC1, binds a series of proteins, among them the catalytic subunits Est2p, Est1p, the Sm proteins, and the double stranded DNA end-binding protein Ku, which plays a role in recruiting telomerase to chromosome termini. Deletion of the 46-nucleotide Ku binding site on TELC1 (tel1Δ) results in reduced yet stable telomeres, as well as slower de novo telomere addition at broken DNA ends. Previous research has demonstrated that yeast maintain robust cell growth and nearly wild-type telomere length when the essential Est1p binding site is repositioned in the TELC1 molecule. These results showed that relative positioning of Est1p in telomerase is not rigidly constrained and that TELC1 may function as a flexible tether for proteins. Here, we test whether the relative positioning of Ku in telomerase is similarly flexible. We have created tel1 Δ alleles that reposition the Ku binding site within TELC1. We find, using an in vivo assay, that these mutant RNAs retain the ability to recruit telomerase. Strains expressing these tel1 Δ alleles are able to maintain native telomeres at a slightly longer length than tel1Δ strains. However, their ability to add a telomere de novo after induction of a double strand break shows little or no improvement over tel1Δ. These data suggest that there is some structural flexibility in the functional interaction between Ku and telomerase at telomeres, yet there is a limit to this flexibility when telomerase is recruited to broken DNA ends. We are currently exploring the molecular basis behind these differences.

Determinants of Rbp1p Localization in Specific Cytoplasmic mRNA-processing Foci, P-bodies
L. Jang, L. Buu, F. Lee
Institute of Molecular Medicine, National Taiwan University, Taipei, Taiwan

Rbp1p, a yeast RNA-binding protein, decreases the level of mitochondrial porin mRNA by enhancing its degradation, but the intracellular location of the Rbp1p-mediated degradation complex remains unknown. We show here that Rbp1p in xrn1Δ mutant yeast localizes in specific cytoplasmic foci that are known as P-bodies. The N-terminal and RRM1 domains of Rbp1p are
necessary but not sufficient for its localization in P bodies. Rbp1p forms oligomers through its C-terminal domain in vivo; N-terminally deleted, or RRMI mutated Rbp1p can be more efficiently recruited to P-bodies in an xrn1/3 strain expressing a full-length Rbp1p. Although POR1 mRNA is localized to P bodies in an xrn1/3 strain, this localization does not depend on Rbp1p. Decapping activator Dhh1p directly interacts with Rbp1p. In addition, the recruitment of Rbp1p to P-bodies does not require Dhh1p or Crep1. In wild-type cells, Rbp1p can localize to P-bodies under glucose deprivation or treatment with KCl. In addition, Rbp1p-mediated porin mRNA decay is elicited by Xrn1p, a 5' to 3' exonuclease. These results provide new insight into the mechanism of Rbp1p function.

**Lacandonia Granules Are Present in Aloe vera and Tegetes erexcta Cell Nuclei**

Lacandonia granules are intranuclear ribonucleoprotein particles first described in the plant *Lacandonia schismatica* and further in other plants as *Tririx* and *Ginglyso biloba*. Here we used light, electron and atomic force microscopy to analyze the presence of these structures in other plants as *Aloe vera* and *Tegetes erexcta*, representative of monocots and eudicots. By using the specific method of ouimarin ammine we found that *A. vera* display ricinucatated chromatin while *T. erexcta* is chromocentric. Standard transmission electron microscopy and the preferential method for ribonucleoproteins indicate that Lacandonia granules are present in *A. vera* but are absent in *T. erexcta*. Results extend the observations on the existence of Lacandonia granules among plants, and suggest a wider distribution in nature (supported by DGAPA-UNAM IN215106-3).

**The MicroRNA, miR-206, Concentrates in Ribosome-rich Regions of Both the Nucleus and the Cytoplasm**

J. C. R. Politz, F. Zhang, T. Pederson; Biochemistry/Molecular Pharmacology, University of Massachusetts Medical Center, Worcester, MA

MicroRNAs are small 22-24 nucleotide RNAs that have been found to regulate gene expression. miR-206 is a microRNA that is expressed at high levels in *Drosophila*, zebrafish and mouse skeletal muscle, and is thought to be involved in the control and/or maintenance of the differentiated state. We used oligo probes modified with locked nucleic acid nucleotides for in situ hybridization studies to characterize the intracellular localization of miR-206 during differentiation of rat myogenic cells. Like most microRNAs, which are presumed to suppress translation of target mRNAs in polyribosomas, we found that miR-206 occupies a cytoplasmic localization patterns in cultured myoblasts and differentiated myotubes, and that these levels increase in myotubes over the course of differentiation, consistent with previous findings in animal tissues. However, to our surprise, we also observed concentrated signal in the nucleus. A probe for miR-1, which differs from miR-206 by only three nucleotides, did not show nuclear localization. The results of both BLAST and Emboss searches showed that there is no significant complementarity between our probe for miR-206 and any non-coding RNAs (including rRNAs or snoRNAs) in the rat genome (other than miR-206 itself). We further characterized the intracellular localization of the miR-206 and found that a substantial fraction colocalizes with 28S RNA in both the cytoplasm and the nucleas. miR-206 is not concentrated in either the ribosomal centers of the nucleas nor in the dense fibrillar component, where polysorn RNA synthesis occurs and processing begins, but rather is localized in the granular component, the region of the nucleas where ribosomes assembly occurs. These results suggest that miR-206 may be associated with ribosomes not only in the cytoplasm, but also in the nucleas.

**NMD Pathway is Dominant over the A2RE RNA Trafficking Pathway**

M. Ifrim, J. H. Carson2; 1Neuroscience, UConn Health Center, Farmington, CT, 2Molecular, Microbial & Structural Biology, UConn Health Center, Farmington, CT

Intracellular trafficking of normal RNA in eucaellular processes includes: processing in the nuclaus, export to the cytoplasm, transport to specific cytoplasmic localization sites, translation and degradation. RNAs containing premature termination codon (PTC) are processed in the nucleus but then diverge from the normal RNA trafficking pathway and are targeted for degradation by the Nonsense Mediated Decay (NMD) pathway. NMD is a surveillance mechanism that causes PTC-containing RNA to be degraded, preventing accumulation of truncated proteins. All RNA molecules are believed to undergo a pioneer round of translation soon after they are exported from nucleus, during which PTC containing RNAs are degraded by NMD. A2RE is an RNA localization sequence that functions in nuclear cells and is known to inhibit translation until the RNA is localized. We are trying to determine when and where in the RNA trafficking pathway nonsense-containing RNA is distinguished from normal RNA. We also want to determine if RNA containing both PTC and A2RE, is exported, localized and degraded or escapes NMD. Previous timelapse microscopy experiments suggested that PTC containing A2RE RNA is more stable than RNA without A2RE. In order to determine whether RNA containing both PTC and A2RE is degraded by NMD, we created a fluorescent reporter system for monitoring the level and localization of protein expression. Our results indicate that RNA containing both PTC and A2RE is subject to NMD. Also, fluorescent protein resulting from translation of PTC containing RNA is distributed mainly around the nucleus regardless of the presence or absence of A2RE, suggesting that the pioneer round of translation takes place soon after the RNA is exported from the nucleus, even for RNAs containing the A2RE. In conclusion our experiments suggest that NMD pathway is dominant over the A2RE pathway.

**Efficient Gurken Secretion Requires Trailer Hitch, a Component of a Ribonucleoprotein Complex Localized to the ER in Drosophila**

J. E. Wilhelm, M. Busczak, S. Sayles; 1Biological Sciences, University of California, San Diego, San Diego, CA, 2Embryology, Carnegie Institution of Washington, Baltimore, MD

During *Drosophila* oogenesis, dorsomedial cells differentiate into dorsomedial-oocyte complexes that surround the egg chamber. The key signaling molecule in this process is gurken (grk), a TGF-alpha homolog that is a ligand for the epidermal growth factor receptor (EGFR). Gurken signaling is restricted to a subset of follicle cells bordering the oocyte by the gurken mRNA localized to the dorsal anterior region of the oocyte. Localized Gurken secretion activates EGFR, which is ubiquitously expressed in follicle cells, and only cells with activated EGFR adopt a dorsal fate. We have identified a new gene, *trailer hitch* (tral), that is required for dorsal-ventral patterning. Mutations in *tral* disrupt Gurken secretion leading to ventralized eggs. This phenotype is not secondary to a defect in *gurken* mRNA localization or oocyte polarity as both are normal in *trailer hitch* mutants. Surprisingly, biochemical purification of Tral revealed that it is part of a large RNA-protein complex that includes two components required for translational control of localized messages: the RNA helicase, Me31B, and the elf4E binding protein, Cup. Tral, Me31B, and Cup colocalize to subdomains of the endoplasmic reticulum (ER) that overlap and border ER exit sites. Consistent with a role of the complex in regulating ER exit, we found that the transcripts for two components of the ER exit site machinery, Sarl and Sec13, are also associated with the complex. Furthermore, mutations in *tral* alter the distribution of Sarl protein and disrupt normal ER exit site formation. We propose that the efficient secretion of Gurken requires the local translation of proteins at ER exit sites and that tral is required for this process. These findings raise exciting new possibilities for how the mRNA localization machinery could interface with the secretory pathway to promote efficient protein trafficking.

**ZBP1 Mediates Dendritic mRNA Granule Localization through a Direct Interaction with a Novel Kinesin Light Chain (KLC)-like Protein in Neurons**

J. B. Dictenberg, K. J. Verhey, A. Friedland, J. Goldman, S. Huttelmeier; 1Anatomy and Structural Biology, Albert Einstein College of Medicine, Bronx, NY, 4Cell Biology, Emory University, Atlanta, GA

Subcellular localization of mRNAs and local protein synthesis is necessary for proper outgrowth and plasticity in neurons. However the molecular details of how mRNAs granules are recognized by the microtubule motor transport machinery and how their interaction is regulated remains unknown. Here we show a new interaction between the conventional microtubule motor kinesin-I and an integral component of RNA granules, the zipcode-binding protein (ZBP1) which binds to the localization element (zipcode) within the 3-prime-UTR of beta-actin mRNA and targets it to neurites and growth cones in response to synaptic stimulation. ZBP1 associated with microtubules and kinesin-I (KHC and KLC), but not kinesin-II, in dendrites of hippocampal neurons. Immunoprecipitation of kinase-I subunits showed beta-actin mRNA, but not vinculin mRNA, associated in a zipcode-dependent manner. Yeast two-hybrid revealed a new, phylogenetically conserved kLC-like protein enriched in beta-actin RNA granules that localized to dendrites and growth cones of hippocampal neurons. Domain mapping revealed among plants, and suggest a wider distribution in nature (supported by DGAPA-UNAM IN215106-3).

The Epigenome in Health and Disease Is Addressed by Modified Codes of “Non-Coding” Small RNA Bioaptamers: Not a State, but Patterns of Processes in Transition and Turnover

J. H. Wissler; ARC Cons-Institute for Applied Research & Didactics, Bad Nauheim, Germany

OBJECTIVE: Usually, the epigenome is considered as collection of biochemical chromatin/histone/DNA modifications indexing genetic information [review: Jenuwein, Science 297:2215-2218,2002; Lederberg, TheScientist 15:6,2001]. Hence, many epigenetic [non-Mendelian] phenotype alterations [EPA] basic to health and [e.g. conformational] disease may escape consideration. Aimed at understanding of control by RNA/RNP, epigenetic regulator proteins [ERP] were investigated. METHODS were developed for isolation of homologous domains with many other ERP [FEBS J. 217:291-306,2005; Spermatogenesis in the water fern Marsilea vestita is a rapid process that relies on mRNA and proteins stored in the dry microspore. The microspore consists of one cell, which when placed in water, undergoes nine division cycles to produce 7 somatic cells and 32 spermatids. After the divisions are completed, each spermatid undergoes a complex differentiation process, which includes nuclear elongation, cell coating, cytoskeletal formation and ciliogenesis. Mago nashi is a highly conserved protein and a component of the exon-on exon junction complex (EJC) for pre-mRNA splicing. It becomes associated with other EJC components and pre-mRNA to function in the nonsense-mediated mRNA decay pathway, enhancing translation and transport/localization of mRNAs for axis formation. In M. vestita, Mv-mago is important in early development establishing cytoplasmic domains that underlie cell fate specification and control of the planes of cell divisions. The morphology of RNAi-mago treated sperms combined with the localizations of proteins involved in spemogenesis (centrin, a-tubulin) and transcripts encoding proteins involved in RNA processing (Mv-elF4AIII, Mv-Prp19) show that cell fate specification is disrupted after knockdowns of Mv-mago. Even with mild knockdowns where division patterns are normal, anti-centrin antibody reveals anomalous basal body-like staining in sterile cells late in development. We suspect that Mv-mago affects the translation and distribution of cytoskeletal or motor proteins. Not surprisingly, knockdowns of the EJC components Mv-Y14 and Mv-elF4AIII closely resemble developmental anomalies observed with Mv- Mago dsRNA. Mv-mago protein becomes localized in dots in the cytoplasm of mainly spermogenetic cells at the end of the division cycles, up to the release of the gametes. Newly translated Mv-mago, Mv-Y14 and Mv-elF4AIII are essential for mago-dot formation. Mago-dots may be EJCs and appear to be essential for gamete development. [Supported by NSF grant MCB 0234423 to SMW].

Nuclear Pore Dynamics during Fungal Open Mitosis

U. Theisen,1 A. Straube,2 G. Stemberg1; Organismissche Interaktionen, Max-Planck-Institut für Mikrobiologie, Marburg, Germany, University of Edinburgh, Edinburgh, United Kingdom

OBJECTIVE: Nuclear pores are dynamic organelles required for nuclear import and export of proteins and mRNAs. In this study, we investigated the dynamics of nuclear pores using the yeast model system, S. cerevisiae. Our results showed that the assembly and disassembly of nuclear pores is regulated by the actin cytoskeleton. We also found that the nucleus is a dynamic organelle that can change its shape and position in response to changes in the cytoplasm. The nucleus is also a site of DNA repair and gene expression, and its dynamics play a role in the regulation of these processes.

LEMDomain Proteins and Nuclear Lamina Function: Loss of Drosophila MAN1 Causes Tissue-specific Defects

B. S. Pinto,1 S. R. Wilkinson,1 L. L. Wallra, P. K. Geyer, Biochemistry, University of Iowa, Iowa City, IA.

Distinct transcriptional territories are established in the nucleus through connections between chromatin and proteins in the nuclear lamina, a protein network that lines the inner nuclear membrane. One class of lamina proteins is the LEM domain family, which have a conserved domain that interacts with chromatin. LEM domain proteins are involved in the formation of the nuclear lamina, which plays a key role in gene expression and chromatin organization. The potential of the nuclear lamina to regulate gene expression is mediated by the LEM domain proteins, which form complexes with other proteins to regulate gene expression and chromatin organization. The LEM domain proteins are also involved in the formation of nuclear pore complexes, which are important for nuclear import and export of proteins and mRNAs.
increased the peripheral incidence of a Lacl-GFP visualized euclaxic LaclO locus. That neither well-characterized NETs such as emerin, LBR or LAP2 nor the other novel NETs tested had any influence on the distribution of these GFP-chromatin proteins serves as an internal control for the specificity of these NET functions. Thus it appears that some of these novel NETs can have a profound influence on chromatin architecture.

1168 Essential Role of Drosophila Lamin C in Nuclear Integrity and Chromatin Organization

B. V. Gurudatta, L. S. Shashidhara, V. K. Parmaik; Centre for Cellular and Molecular Biology, Hyderabad, India

Nuclear lamins are components of a filamentous network underlying the inner nuclear membrane termed the nuclear lamina. Lamins are important determinants of nuclear architecture and are also involved in vital functions of the nucleus such as replication, transcription and apoptosis. There are two kinds of lamins, B-type lamins that are expressed in all cells, and A-type lamins, which are differentially expressed during development. Mutations in the human lamin A gene cause a group of highly debilitating diseases called laminopathies. In order to understand the developmental role of A-type lamins, we have carried out a detailed genetic analysis of Drosophila lamin C (lamC) - a bona fide orthologue of vertebrate A-type lamins. We have generated lamC-specific alleles using P-element excisions and also made lamC RNAi transgenic lines. Mitotic clones with lamC excision allele or lamC RNAi were cell lethal, supporting the role of lamC in cell survival. The RNAi-mediated knock-down of lamin C in all cell types caused early lethality. The tissue-specific down-regulation of Lamin C resulted in a variety of phenotypes in wings, legs, thorax and eyes. The UAS-GAL4 mediated over-expression of Lamin C in various tissues resulted in the disruption of nuclear envelope organization and eventually manifested as developmental defects in muscles, wings and thorax. Perturbation in Lamin C expression affected lamina-chromatin interactions since the lamC excision alleles suppressed position effect variegation both at centromeric and telomeric sites, supporting a role for Lamin C in heterochromatic gene silencing. Heterochromatin protein 1 was either depleted (by lamC RNAi) or mis-localized (by over-expressed Lamin C) from its chromosomal sites. In summary, we provide evidence that Drosophila Lamin C is essential for nuclear integrity during development and is specifically required for chromatin organization.

1169 The Small Yeast Outer Nuclear Membrane Protein Apq12 Functions in Nuclear Pore Complex Biogenesis

J. J. Scarcelli,1 C. A. Hodge,1 C. N. Cole;1 Biochemistry, Dartmouth Medical School, Hanover, NH, 1Biochemistry and Genetics, Dartmouth Medical School, Hanover, NH

All transport of macromolecules between the nucleus and the cytoplasm occurs through nuclear pore complexes (NPCs), very large macromolecular assemblies embedded within the nuclear envelope and constructed using multiple copies of approximately 30 proteins, called nucleoporins. While the structure, organization, and function of various components of the NPC has been the focus of many studies, relatively little is known about NPC biogenesis. Here we report on Apq12p, a new player in this process. Apq12p was originally linked to mRNA processing and transport because apq12Δ cells accumulate mRNA with elongated poly(A) tails in their nuclei. Apq12p is a trans-membrane protein located in the outer nuclear envelope and endoplasmic reticulum. We find that cells lacking APQ12 display defects in the localization of a subset of nucleoporins, particularly those located asymmetrically at the cytoplasmic filament of the NPC. The cytoplasmic filament nucleoporins are the ones most important for mRNA export, so the defects observed in mRNA biogenesis and export are likely indirect consequences of aberrant NPCS. Electron microscopy reveals that deletion of APQ12 causes cessation of formation of membranous “studs” located around the nuclear envelope, as well as other defects in nuclear envelope morphology. In the absence of Apq12p, NPCs can be seen that are associated with the inner but not the outer nuclear envelope. Deletion of APQ12 leads to synthetic growth defects when combined with mutations in genes encoding several nucleoporins believed to provide structure to the NPC, as well as the integral membrane proteins POM152, POM34, and NDC1. We also show that the C-terminal truncation of Apq12p, which is predicted to be on the cytoplasmic side of the nuclear membrane, is required for function. The finding that inhibition of translation prevents mislocalization of GFP-tagged nucleoporins in apq12Δ cells strongly supports the idea that Apq12p plays a role in NPC biogenesis.

1170 Targeting Protein for Xklp2 (TPX2) Interacts with Both Lamins and Chromatin and Prevents Chromatin Decondensation in Xenopus Egg Extracts

L. O'Brien, C. Wiese; Biochemistry, UW-Madison, Madison, WI

The nuclear envelope, which separates a cell’s genetic material from the cytoplasm, disassembles at the onset of mitosis in most metazoans to allow assembly of the mitotic spindle. Reassembly of a functional nucleus after mitosis involves rebuilding the nuclear envelope around the decondensing chromosomes and continued nuclear growth. We recently described an essential role for the mitotic spindle assembly factor, TPX2, in nuclear reformation after mitosis (O'Brien and Wiese, 2006. J CB 173:685). The nuclear envelope, which separates a cell’s genetic material from the cytoplasm, disassembles at the onset of mitosis in most metazoans to allow assembly of the mitotic spindle.

1171 The Role of the Nuclear Envelope in Controlling the Migration and Anchorage of the Nucleus

D. A. Starr, M. D. Matthew, R. Rillo, M. Meyeron, D. M. Drainow; Center for Genetics and Development, University of California-Davis, Davis, CA

The position of the nucleus within the cell is important to a wide variety of eukaryotes. For example, budding yeast must move the nucleus to the bud neck, mammalian skeletal muscles must specialize nuclei at the neuromuscular junction, and in the developing human brain nuclei migrate towards the cortex. Defects in these processes have severe developmental defects and can lead to muscular dystrophy or lisencephaly. In order to position the nucleus, the cell must specify the outer nuclear membrane from the ER and transfer force across the nuclear envelope from the cytoskeleton to the nuclear matrix. Here we describe a mechanism where the C. elegans proteins UNC-83 and UNC-84 accomplish both of these important tasks. Digitonin extraction experiments suggest that UNC-84 is an inner nuclear membrane protein and UNC-83 is specific to the outer nuclear membrane. UNC-84 recruits UNC-83 to the outer nuclear membrane. We show by genetic methods in C. elegans and by a membrane bound yeast two hybrid assay that the SUN domain of UNC-84 directly interacts with the KASH domain of UNC-83 in the perinuclear space. Furthermore, both the SUN domain and the KASH domain are essential for nuclear migration in vivo. We have also undertaken a deletion analysis of the nucleoporin domain of UNC-83 and show that the C-terminal region is dispensable, and that the N-terminus is essential for nuclear migration. Finally, we have purified a His-tagged version of the SUN domain and are analyzing the KASH/SUN interaction in vitro. These data support the model that KASH and SUN proteins bridge the nuclear envelope, connecting the nuclear lamina to chromoskeletal components. This mechanism appears conserved across eukaryotes and is the first proposed mechanism to target proteins specifically to the outer nuclear membrane.

1173 C. elegans BAF and Its Kinase VRK Partake Directly in Postmitotic Nuclear Envelope Assembly

M. Gorjancic,2 E. Klerks,2 V. Galy,1 R. Santarella,1 C. Lopez-Iglesias,1 P. Askjaer,3,4 I. W. Mattaj3;1 European Molecular Biology Laboratory, Heidelberg, Germany, 3Institute for Research in Biomedicine, Barcelona, Spain, 2University of Barcelona, Barcelona, Spain

The nuclear envelope (NE) of eukaryotic cells provides an essential barrier that separates the genome from the cytoplasm. During mitotic prophase the NE disassembles to enable the chromosome segregation and in anaphase and telophase it reassemblies around the chromatin. We are studying Barrier-to-autointegration factor (BAF) that is an essential and highly conserved controller we found that BAF is directly involved in NE formation. With a series of temperature-shift experiments on Caenorhabditis elegans embryos either carrying a temperature sensitive point mutation in the chromosome segregation and in anaphase and telophase it reassemblies around the chromatin. We are studying Barrier-to-autointegration factor (BAF) that is an essential and highly conserved

2006 ASCB Annual Meeting Abstracts
Changes in Nup214 Domain Topology in Response to Chemical Effectors
S. M. Paullö, M. A. Powers, K. S. Ullman, B. Fahrenkrog1, M. E. Mueller Institute for Structural Biology, University of Basel, Basel, Switzerland, 2Department of Cell Biology, Emory University School of Medicine, Atlanta, GA, 3Department of Pharmacological Sciences, University of British Columbia, Vancouver, BC, Canada
Nuclear pore complexes (NPCs) span the nuclear envelope (NE) and provide major gateways for diffusion of small molecules, as well as signal-mediated transport of proteins, RNAs and RNP complexes across the nucleus. Approximately 30 different nucleoporins assemble the NPC, from which around one third are characterized by the presence of distinct polyglutamine motifs. Recent studies have identified critical amino acid residues within the RRM that are required for DNA binding. Data will also be presented on the potential role of the RRM in RNA binding and RNA metabolism.

Dissection of Vertebrate Nup53 Function through Domain Localization and Interaction Mapping
L. A. Hawryluk-Gara, R. W. Wozniak; Cell Biology, University of Alberta, Edmonton, AB, Canada
Nuclear pore complexes (NPCs) work in conjunction with soluble transport factors termed karyopherins to facilitate movement of macromolecules across the nuclear envelope (NE). The NPC is an evolutionarily conserved structure comprised of ~30 proteins termed nucleoporins (nups) that are present in multiple copies and organized into sub-complexes of interacting nups. In an effort to further understand how NPCs are formed and the mechanisms that control nuclear transport, we have examined the function of an essential vertebrate nucleoporin, Nup53. In these studies, we have investigated the role of various domains of Nup53 in mediating its assembly into the NPC and its interactions with neighboring nups. A series of N- and C-terminal truncations were examined by fluorescence microscopy to define domains necessary for NPC localization. In addition, in vitro binding studies were performed to map the domains of Nup53 necessary for its interactions with binding partners, namely the nucleoporins Nup93, Nup205, Nup155, and Ndc1. We showed that Nup53 interacts with these nups through a C-terminal domain where Nup155, Nup93, and Ndc1 interact with mutually exclusive domains. In line with our domain analysis of Nup53, we have initiated studies to examine the function of the RNA recognition motif (RRM) motif present within a central region of Nup53. We have observed a direct interaction between Nup53 and both single- and double-stranded DNA. Furthermore, mutational analysis identified critical amino acid residues within the RRM that are required for DNA binding. Data will also be presented on the potential role of the RRM in RNA binding and RNA metabolism.

Nuclear Size Control in Fission Yeast
F. R. Neumann, P. Nurse; The Rockefeller University, New York, NY
Many eukaryotic cells maintain a constant ratio between the volume of the nucleus and the cytoplasm. This requires a well orchestrated interplay between many processes which can influence nuclear and cell size, such as membrane biosynthesis, nucleo-cytoplasmic transport, and the cell cycle and growth machinery. Fission yeast is a good organism for studying nuclear envelope homeostasis due to the simple geometry of the cell and the nucleus. In metazoans, developmental changes, nuclear envelope breakdown during mitosis and the presence nuclear lamins add another layer of complexity to the control of nuclear envelope shape and size. We first describe nuclear growth during the cell cycle and further characterize how different cell size, growth conditions, DNA content, affect the nucleo-cytoplasmic ratio (N/C). Time-lapse studies reveal that the N/C volume ratio is kept at a constant throughout all stages of the cell cycle. This suggests that there is a rapid expansion of the nuclear envelope during mitosis, similar to budding yeast. Genetic and physical perturbations of this equilibrium show that nuclear growth is stopped at a high N/C ratio until cell size reaches a threshold upon which the nucleus and the cell will grow at the same rate. Taking advantage of the extensive repertoire of cell cycle and size mutants in fission yeast, we find that the N/C ratio is conserved over a 10-fold difference in cell sizes. In agreement with the cell cycle studies we find that cells arrested in G1 phase or G2 phase of the cell cycle have a conserved N/C ratio. Further increase of DNA content in diploid cells or in an endoreduplicating condition further undermines the strong conserved correlation between the size of the nucleus and the cell. Future experiments are aimed at elucidating the molecular mechanisms of this remarkable conservancy.

Mitic Remodeling of the Nuclear Envelope
D. R. Mackay, S. Elgort, A. J. Prunuske, K. S. Ullman; Huntsman Cancer Institute, University of Utah, Salt Lake City, UT
Remodeling and disassembly of the nuclear envelope during mitosis has been acknowledged as an important event in the metazoan cell cycle for over a century; however, the mechanisms by which this occurs and is coordinated with other mitotic events are still poorly understood. Recent studies in Xenopus egg extracts have demonstrated that the zinc-finger domains of two components of the nuclear pore complex, Nup214 and Nup358/RanBP2, interact with the COP1 customer complex and that this interaction is required for efficient nuclear disassembly, thus uncovering a previously unexplored function for the nuclear pore in this process. This mechanism appears to be conserved in mammalian cells, as overexpression of the Nup153 zinc-finger domain results in a two-fold increase in the number of mitotic cells in prophase concomitant with a decrease in the number of cells in metaphase, consistent with a delay in mitotic progression resulting from disrupted nuclear disassembly. To further understand the role of Nup153 in nuclear disassembly and how this process is coordinated with other mitotic events, we are taking a multifaceted approach using both RNAi and dominant negative strategies to disrupt Nup153 in somatic cells. Interestingly, we have found that mitotic arrest resulting from spindle stress is perturbed when Nup153 levels are decreased in HeLa cells, suggesting that these cells are either not progressing into mitosis or that the spindle stress checkpoint is not activated properly. A combination of FACs analysis and live imaging methods are currently being used to distinguish between these two possibilities. This work promises to provide new insight into the mechanism of nuclear remodeling and how it is coordinated with other cell cycle events.

The Role of Dyanin 3 in the Tests
K. S. Vaid1, J. A. Gutmann2, N. Babyk1, W. Deng2, M. A. McNiven1, M. Nohchi1, B. B. Finlay2, A. W. Vogel1, C. Lau1, S. Elgort1, 1Cellular and Physiological Sciences, University of British Columbia, Vancouver, BC, Canada, 2Michael Smith Laboratories, University of British Columbia, Vancouver, BC, Canada, 3Biochemistry and Molecular Biology, Mayo Clinic, Rochester, MN, 4Structural Analysis, National Cardiovascular Center Research Institute, Osaka, Japan
We report here that dyanmin 3 is the testis specific isoform of the vertebrate nuclear envelopeoporin Nup53. The nuclear pore complex is a major gatekeeper for diffusion of small molecules, as well as signal-mediated transport of proteins, RNAs and RNP complexes across the nuclear envelope. Approximately 30 different nucleoporins assemble the NPC, from which around one third are characterized by the presence of distinct polyglutamine motifs. Recent studies have identified critical amino acid residues within the RRM that are required for DNA binding. Data will also be presented on the potential role of the RRM in RNA binding and RNA metabolism.

Using a Chemical Genetic Approach to Protein Kinase A (PKA) as a Novel Tool to Investigate Male Fertility
D. J. Morgan, M. Weissenhaus, D. F. Babcock, C. Zhang, K. M. Slebk1, G. S. McKnight1, 1Pharmacology, University of Washington School of Medicine, Seattle, WA, 2Biophysics and Biophysics, University of Washington School of Medicine, Seattle, WA, 3Cellular and Molecular Biology, University of California, San Francisco, San Francisco, CA
We generated a novel strain of mice that expresses a point mutation in the catalytic-alpha subunit (Ca) of PKA. The Ca432A point mutation enhances the ATP binding pocket of PKA conferring sensitivity to pharmacological inhibition through the ATP analog, 1NM-PFI. Protein homogenates containing the mutant PKA were prepared from testes as well as other tissues from Ca432A

217
The WD1 Scaffold RACK1 Is Essential throughout Development

J. L. Kadrams, M. A. Smith, S. M. Pronovost, M. C. Beckerle; Huntsman Cancer Institute and the Department of Oncological Sciences, University of Utah, Salt Lake City, UT

Primary regulator of spermatogenesis is an intrinsic genetic program involving male germ cell-specific genes. In this study, we analyzed the mouse spermatocyte UniGene library (Library 6787) containing 2155 gene-oriented transcript clusters, predicting that 230 of them are testis-specific genes, and identified 24 novel genes by computational bioinformatics tools, we found that a number of the gene products are potentially involved in various processes during spermatogenesis or fertilization. We performed transfection assay of the genes using GC-2 cells, providing information on the cellular characteristics of the gene products. Further, we generated antibodies against proteins encoded by a number of the novel genes and identified the proteins in spermatogenic cells and sperm. Taken together, we discovered the 24 authentic, novel genes with spermatogenic cell-specific expression by the integrative approach, and provide new and comprehensive information about the novel testis-specific genes by various in vitro and in silico analyses. Thus, this study establishes on a comprehensive scale a new basis for future investigation on functional characterization of the genes.

HeterotrimERIC G P R OTEIN(s) as an Src-activator in Xenopus Fertilization

T. Iwasaki, 1 K. Sato, 2, 3 Y. Kono, 3 Y. Koretomo, 4 G. Mammadova, 4 N. Yamaamoto, 5 H. A. K. M. Mahbub, 6 Y. Ueda, 6 Y. Fukami 1, 2, 7, 8 1 Research Center for Environmental Genomics, Kobe University, Kobe, Japan, 2 Department of Biology, Faculty of Science, Kobe University, Kobe, Japan, 3 The Graduate School of Science & Technology, Kobe University, Kobe, Japan, 4 A sperm induces a transient Ca2+ release, activation, and beginning of embryonic development in fertilized egg. We have reported that the Xenopus Src tyrosine kinase (xSrc) plays an important role in the egg activation signaling. xSrc, which localizes to the low-density detergent-insoluble fraction (LD-DIM or rafts) of egg plasma membrane, is activated and partially translocated to the cytosol within a few minutes after insemination. However, the mechanism of sperm-induced xSrc activation is still unrevealed. Previous studies demonstrated that microinjection of non-hydrolyzable GTP analog, GTPγS, an activator of GTP-binding proteins (G proteins), into Xenopus eggs resulted in egg activation. It was also shown that a pertussis toxin-insensitive G protein is involved in Xenopus egg activation (Kline et al. Dev Biol 1991). Another group showed that α subunits of G proteins, Gai and Gi, but not Gq, could directly interact with the kinase domain of e-Src and activate it (Ma et al. Cell 2000). We have reported that GTPγS promotes Src activation in the rafts isolated from Xenopus unfertilized eggs in vitro (Sato et al. Development 2002). These results suggest that G proteins act as an xSrc and egg activator. To assess this possibility, we tested whether GDPβS has an inhibitory effect on egg activation. GDPβS decreased the successful rate of egg activation in a dose-dependent manner. We have also shown that some signaling molecules including xSrc and Gi are present in the raft fraction prepared from unfertilized eggs. To analyze direct interaction between xSrc and G proteins, we prepared glutathione-S-transferase (GST)-fused α subunits of Xenopus G proteins. It is shown that GST-Gia, but not Gqβγ, can activate the xSrc in vitro. Our results support the hypothesis that G proteins such as Gai and Gi activate xSrc in the egg rafts at sperm-induced egg activation.

The WDI Scaffold RACK1 Is Essential throughout Drosophila Development

J. L. Kadrmas, M. A. Smith, S. M. Pronovost, M. C. Beckerle; Huntsman Cancer Institute and the Department of Oncological Sciences, University of Utah, Salt Lake City, UT

RACK1 shows that these proteins are highly conserved. Therefore, we have explored the function of RACK1 in Drosophila with 3 μM 1NM-PP1 blocked the increase in flagellar beat frequency that was caused by bicarbonate administration during capacitation. In contrast, the beat frequency of wildtype sperm increased from 2.6 Hz to 5.2 Hz in response to bicarbonate and was unaffected by 1NM-PP1. We conclude that the Drosophila mutant RACK1 is sensitive to inhibition by 1NM-PP1 in vitro and that tissue specific expression of this mutation will allow cell-type specific pharmacological inhibition of PKA in vivo to study the physiological roles of PKA. Supported by NIH grants: GM32875 (G.S.M.), HD12629 (D.F.B.), HL07312 (D.J.M.)
Within the mutant oocytes, egg chambers appear morphologically normal but mature eggs are not laid. Stage 14 eggs eventually accumulate within the ovarioles, with few early stage egg chambers present despite proper maintenance of germ-line stem cell populations. Our analysis highlights the critical importance of RACK1 in developing tissues.

1187 Highly Conserved Cysteines in the “VM Domain” of sV23 Are Essential for Eggshell Assembly in Drosophila

T. Wu, G. L. Waring; Biological Sciences, Marquette University, Milwaukee, WI

Extracellular matrices are complex molecular networks that not only provide mechanical support, but serve as reservoirs for bioactive molecules that control cell growth and differentiation. We are using the Drosophila eggshell, a specialized extracellular matrix amenable to biochemical, genetic, and morphological analyses, to study molecular mechanisms and motifs that are used to regulate its assembly in vivo. The oocyte proximal vitelline membrane (vm) layer consists of a small number of abundant proteins that possess a highly conserved 38 amino acid sequence termed the “vm domain”. Within the “vm domain” are 3 precisely spaced cysteines (CX3CX3CX3). To investigate their role in eggshell assembly we created a series of cysteine to serine substitution mutations in sV23, a major vitelline membrane protein. To assess the effects of the mutations we introduced each mutant transgene into an sV23 protein null female sterile mutant (fs(2)QJ42). Functional sV23 transgenes rescue the sterility and defective eggshells of fs(2)QJ42 females. A functional eggshell failed to assemble when the sV23 transgene had substitutions at either all three, or two of the three positions. Although sV23 accumulation was negligible in the triple cysteine mutant, sV23 accumulated at levels compatible with function in the double mutants. In wild type eggshells sV23 becomes incorporated into a large disulfide linked network during the terminal stages of oogenesis (12-14). In the double cysteine mutants sV23 formed small oligomeric disulfide linked complexes that failed to remain integrated in the eggshell correlated with the removal of its hydrophobic N-terminal segment via a normal, regulated cleavage event. While other proteins with “vm domains” were incorporated into large disulfide networks, their subsequent insolubilization via the formation of non-reducible cross-links was impaired, suggesting interdependence between the assembly of sV23 and other “vm domain” containing protein networks.

1188 Release of Calcium by Phosphatidic Acid in Xenopus Oocytes and Eggs

B. J. Stith,1 J. Juergens,1 J. Stafford,1 J. Snyder,1 M. Wood,2 D. Petcoff2; 1Biology, University of Colorado Denver, Denver, CO, 2Biology, Metropolitan State College, Denver, CO

The current model for fertilization in Xenopus laevis is that sperm activates Src tyrosine kinase which activates phospholipase C (PLC)γ (work by K-J Sato and others) to increase inositol 4,5-bisphosphate (IP2) and intracellular calcium. We have provided evidence that the missing step between sperm and Src activation is activation of phospholipase D1β2 which catalyzes the breakdown of phosphatidylcholine to phosphatic acid (PA): inhibiting the PA increase at fertilization inhibited IVB induction (but not sperm entry into the egg or the DAG mass increase), addition of 400 μM PA increased IP3 mass whereas herbimycin A, a tyrosine kinase inhibitor commonly used to inhibit Src, blocked PA elevation of IP3. PA also raised intracellular calcium whereas 2APB, an IP3 receptor blocker, inhibited calcium release. We now report that herbimycin A inhibited the PA- induced in vitro release of calcium from a preparation consisting of plasma membrane, cortex and cortical cytoplasm (PMC). Inhibited calcium release of PA action was obtained with 4 μM herbimycin, 50% inhibition with 2 μM herbimycin and 0% inhibition with 0.5 μM herbimycin (20 min preincubation). As an alternate method of intracellular calcium measurement in whole cells, we recorded the membrane potential of Xenopus oocytes as depolarization has been shown to be a measure of intracellular calcium. 400 μM PA-induced membrane depolarization (calcium release) that was inhibited by preincubation with herbimycin. PA addition shortly after a previous release of intracellular calcium by LPA (during the LPA refractory period) did not elicit a second release of calcium. This suggests that PA releases calcium specifically from intracellular stores used by LPA (e.g., IP3)- not through some nonspecific or alternate calcium release paths. As a control, ionomycin, which induces a nonspecific release of calcium, did induce a membrane depolarization when the ionophore was added at an equivalent time after LPA.

1189 Identification and Distribution of Carbohydrates on the Surface of Gametes in the Zebra Mussel Dreissena polymorpha and the Oyster Crassostrea virginica

L. C. Fallis,1 K. M. Kendro-McAnlis,1 J. W. Lynn,2 M. J. Misamore1; 1Biology, Texas Christian University, Fort Worth, TX, 2Biological Sciences, Louisiana State University, Baton Rouge, LA

Carbohydrates play a critical role in many cell-cell adhesions, including sperm-egg binding. The objective of this study is to identify carbohydrates associated with the surfaces of eggs and sperm and map their distribution during fertilization using two species of bivalve, the freshwater zebra mussel Dreissena polymorpha and the eastern oyster Crassostrea virginica as models. Both species are broadcast spawners with external fertilization. We used several lectins to characterize surface carbohydrates including: WGA, Con A, LCA, and GSII. Initial studies have found C. virginica and D. polymorpha have similar carbohydrate distributions such that the entire surface of eggs of both species labeled with WGA, Con A, and LCA. WGA also labeled the entire surface of sperm in both species. Con A, LCA, and GSII labeled only the lateral region of acrosome in acrosome-reacted sperm in both zebra mussels and oysters. GSII was the only lectin that specifically labeled the sperm acrosome but not the egg. During fertilization in D. polymorpha, GSII labels the acrosome in unbound, acrosome-reacted sperm and is localized to the binding site in sperm bound to the egg. Following incorporation of fertilizing sperm, the GSII labeling remains as a patch on the egg surface. Once an egg is fertilized, nonfertilizing bound sperm are detached from the egg surface at approximately 15 min postinsemination. The majority of the GSII labeling leaves with the detaching sperm. These studies suggest a role for N-acetylgalactosamine in initial sperm-egg interactions.

1190 The Role of Mos in Sea Urchin Fertilization and Early Mitotic Cell Cycles

M. M. Roux, K. R. Fotlz; MCDB and Marine Science Institute, University of California Santa Barbara, Santa Barbara, CA

The mitogen activated protein kinase (MAPK) cascade plays a crucial role in oocyte maturation, fertilization and early development. In eggs, this signaling module consists of MEKK (Mos), MEK and an ERK1/2 like MAP kinase, but its precise role in regulating the transition from arrested egg to the first mitotic cell cycle is unclear. The purple sea urchin Strongylocentrotus purpuratus is a unique model organism, spawning eggs that are fully mature and arrested at haploid pronuclear stage, making it possible to investigate regulation of MAPK signaling at fertilization specifically with respect to mitotic cell cycle progression and without the complication of meiotic completion. Of particular interest is the MEKK Mos. This kinase’s role in meiotic maturation has been extensively studied, but its role post fertilization and during mitosis remains controversial and elusive. We have identified the gene and cloned the cDNA encoding the S. purpuratus Mos ortholog (SpMos). The SpMos gene is a single exon containing a 1257bp open reading frame encoding a protein of ~48 kDa. SpMos mRNA and protein are expressed in sea urchin eggs and early embryos and expression of full length SpMos in Xenopus blastomeres causes cell cycle arrest, confirming that SpMos functions as a canonical Mos protein. Interestingly, SpMos has a unique N terminus extending 90 amino acids past the Xenopus Mos N-terminal domain and lacking the canonical phosphorylation site that regulates Mos protein degradation. SpMos lacking this extended N-terminus also causes Xenopus embryos arrest, suggesting that the N-terminus is not required for the arrest function. Experiments are under way to determine the potential functional role of the N-terminal domain (possibly in regulating degradation or activity) and to investigate the requirement of SpMos for normal cell cycle progression at fertilization in sea urchin zygotes.

1191 Milton Controls the Early Acquisition of Mitochondria by Drosophila Oocytes

R. T. Con, A. C. Spradling; Dept. of Embryology, Carnegie Institution/HHMI, Baltimore, MD

Mitochondria in many species enter the young oocyte en mass from interconnected germ cells to generate the large aggregate known as the Balbiani body, or mitochondrial cloud. Organelles and germ plasm components frequently associate with this structure. Balbiani body mitochondria are thought to populate the germ line, ensuring that their genomes will be inherited preferentially. We find that miton, a gene whose product was previously shown to associate with Kinesin and mediate axonal transport of mitochondria, is needed to form a normal Balbiani body. In addition, germ cells mutant for some mito or Kinesin heavy chain (Khc) alleles transport mitochondria to the oocyte prematurely and excessively, without disturbing Balbiani body- associated components. Our observations show that the majority of mitochondria by competitive bidirectional transport along microtubules and this is mediated by the Milton adaptor. These experiments provide a molecular explanation for Balbiani body formation and, surprisingly, show that viable, fertile offspring can be obtained from eggs in which the normal program of mitochondrial acquisition has been severely perturbed.
Cell shape changes, central to cellular function and development, require coordinated spatial regulation to redirect changes in cell form. Phosphoinositide phosphates (PIPs), phosphorylated derivatives of phosphaatylinositol, are highly spatially regulated lipids known to localize signaling events and cellular processes. The many lipid kinases and phosphatases that target specific PIPs therefore are crucial to cellular spatial-temporal regulation. Phosphoinositols are a large family of phosphoinositide 3-phosphate (PI(3)P) lipids implicated in human developmental myopathy and neuropathy diseases. However, little is known about the cellular roles and regulation of different Myotubularin phosphatases, or their specific functional PIP substrates, in mammalian myogenesis. Using RNAi in Drosophila cell culture, we identified myotubularin (mtm), one of six predicted in flies as important for cellular elongation. Characterization of the mtm RNAi defect in Kc167 blood cells suggests that regulation of PI(3)P-dependent membrane homeostasis is important to mediate cell shape change. We have generated loss and gain-of-function tmn mutant Drosophila to investigate roles for phosphoinositide regulation and endolysosomal function in developmental programs for cellular elongation. Using RNAi hairpins to knockdown mtm in vivo, we discovered that mtm is essential for proper development and survival past the pupal stage. We are currently characterizing defects leading to mtm RNAi induced lethality by assessing molecular markers of endolysosomal membrane compartments (Rab7-GFP and Rab5-GFP for endosomes; Lamp-GFP for lysosomes; FYVE-GFP and Aig1-GFP for PI(3)P and PI(3,5)P2, respectively) and cellular morphogenesis (actin-GFP and tubulin-GFP for cytoskeletal structure). To address specific roles for mtm and other encoded myotubularins we have determined ubiquitous mtm developmental expression by RT-PCR and in situ hybridization. We are currently localizing Mtm protein using antibodies and Mtm-GFP expression to assess spatial regulation of PI(3)P and PI(3,5)P2. A functional analysis of phosphoinositide regulators is an important first step towards understanding the dynamic subcellular pathways that orchestrate cell shape changes.
Ca++-dependent Phosphorylation of Ets-2 in Mechanotransduction Pathways in Cranial Suture Morphogenesis

J. Chen, J. Huang, C. Chew, K. H. Wenger, J. C. Yu, S. Huang, J. Huang, J. L. Borke; Biological Science & Technology, I-Shou University, Kaohsiung, Taiwan, 1Genesis Biotech Inc., Functional Discovery Unit, Taipei, Taiwan, 2Department of Biochemistry, Medical College of Georgia, Augusta, GA, 3Promega, Regensburg, Germany, 4Max-Planck-Institute for Molecular Medicine and Genetics, Medical College of Georgia, Augusta, GA, 5Orthopaedic Surgery, Medical College of Georgia, Augusta, GA, 6Surgery, Medical College of Georgia, Augusta, GA, 7College of Dental Medicine, Kaohsiung Medical University, Kaohsiung, Taiwan, 8Oral Biology and Maxillofacial Pathology/Graduate Studies, Medical College of Georgia, Augusta, GA

Ets-1 is expressed in proliferating preosteoblastic cells, while Ets-2 is expressed in mature and differentiating osteoblasts. Ets proteins bind to DNA sequences in the promoter regions of target genes important for osteogenesis. We study the effects of mechanical strain on cells of the cranial sutures and associated bone. Our studies show that mechanical loading of sutures in organ culture produces a transient and reversible increase in cell Ca++. Our hypothesis is that mechanical loading of cranial sutures may be linked through Ets to changes in osteoblast gene expression. Loading may be derived from internal forces as the brain grows. The goal of our study is to determine if mechanical loading of cranial sutures is linked through the Ca++- dependent phosphorylation of Ets-2 in cranial bone gene expression. We use electrophoretic mobility shift assays to quantify Ca++-dependent phosphorylation of Ets-1 and Ets-2 from rat cranial sutures exposed to mechanical strain at a normal (high) extracellular Ca++ concentration of 10-3M and at a low extracellular Ca++ concentration of 10-6M Ca++. Based on existing literature and preliminary data, we suspect Ets-2 is phosphorylated by CaM Kinase II in vivo. The NetPhos 2.0 server was used to predict possible CaM kinase II phosphorylation sites on Ets-2. Based on query results, a nanoprobe array scanning through the entire sequence of Ets-2 was synthesized in situ on a stable membrane using Fmoc solid phase technology. In vitro kinase reactions were performed by incubation with CaM kinase II in the presence of radioactive ATP. Incorporated phosphate, indicating a positive reaction, was detected by autoradiography and phosphorimaging. Phosphopeptides were enriched by immobilized metal affinity chelation (IMAC) for MALDI-TOF/TOF mass spectrometry. Positive results from peptide array screening form the basis for further mutational analyses of Ets-2 in the mouse calvaria fibroblasts cell line MC3T3. (NSC(Taiwan) 95-2314-B-214 -007-MY2 Chen)

Nucleoredoxin, a Thioredoxin-related Redox-regulating Protein, Inhibits Wnt/β-catenin Signaling through Dishevelled

Y. Funato, H. Miki; Division of Cancer Genomics, Institute of Medical Science, University of Tokyo, Tokyo, Japan

Wnt signaling pathway is evolutionarily conserved from nematodes to mammals. It is important in organogenesis and stem cell maintenance, and its aberrant activation leads to tumorigenesis. Dishevelled (Dvl) is an essential intermediate in Wnt signaling pathway. Dvl transduces the signal from the Wnt receptor Frizzled to downstream components, leading to the stabilization of β-catenin and subsequent activation of the transcription factor TCF/LEF. However, the mechanism of Dvl action remains largely unknown. To elucidate the role of Dvl, we search for Dvl binding partners in vivo. Here, we report that nucleoredoxin (NRX), a member of the thioredoxin (TRX) family redox-regulating protein, is a novel Dvl-interacting protein. Overexpression of NRX selectively suppresses the Wnt/β-catenin pathway, and RNA-interference (RNAi) of NRX shows TCF/LEF activation, accelerated cell proliferation, and enhancement of oncogenicity via cooperation with Mek or Ras. Also, depletion of endogenous NRX in Xenopus embryos shows abnormal development via Wnt-β-catenin pathway activation. We find that cells respond to H2O2 stimulation by activating TCF/LEF. Redox-dependent phosphorylation of the cytoplasmic domain of NRX is impaired by NRX-RNAi. In addition, association between Dvl and NRX is inhibited by H2O2 treatment. These results implicate a hitherto unknown relation between the Wnt/β-catenin pathway and redox signaling through redox-sensitive association of NRX with Dvl.

Pinch Mediates Actin Organization and B-integrin Localization and Signaling during Drosophila Embryonic Dorsal Closure

A. M. Smith, J. L. Kadrmas, S. Pronovost, M. C. Elias, M. C. Beckerle; Huntsman Cancer Institute, University of Utah, Salt Lake City, UT

The coordination of integrin-mediated signaling and adhesion with cytoskeleton dynamics and cell shape change is essential for cell motility. An excellent model for the study of cell motility is Drosophila melanogaster embryonic dorsal closure. During dorsal closure, opposing lateral sheets of epithelia migrate, meet and suture at the dorsal midline. Dorsal closure is driven by a variety of forces, including cell shape changes in both the lateral epithelium and the underlying amnioserosa. Integrin mediated signaling and adhesion, the actin cytoskeleton, and the Jun kinase pathway form the basis for further mutational analyses of Ets-2 in the mouse calvaria fibroblasts cell line MC3T3. (NSC(Taiwan) 95-2314-B-214 -007-MY2 Chen)

Murine Palate Fusion Is Blocked by Down Regulation of Twist Expression

W. Yu, K. Svoboda; Biomedical Sciences, Baylor College of Dentistry, Dallas, TX

Epithelial-mesenchymal transformation (EMT) plays an important role in the disappearance of medial epithelial cells (MEE) during fusion of secondary palate. TGF beta3 regulates the disappearance of MEE during this process. Twist protein has a major role during EMT and our previous studies demonstrated that twist protein was upregulated just prior to palatal fusion. In this study, we demonstrated that Twist protein was downregulated by increasing the expression of Twist siRNA in vitro. The palatal shelves from E13.5 CD1 mice were dissected and placed on filter paper with the medial edges in contact. They were cultured in BGJb medium with 100, 200nm siRNA in 0.004% of transfection reagent, Lipofectamine. TGF beta3 was added (10ng/ml) in 221
Biochemical Evidence for the Role of Gαo in β-catenin/Wnt Signaling
K. E. Kalie, E. Lee; Cell and Developmental Biology, Vanderbilt University, Nashville, TN

Since the Wnt co-receptor Frizzled was identified to contain 7-transmembrane spanning domains, it has been speculated that G-proteins play a role in the beta-catenin/Wnt signaling pathway. Evidence for a key role of Gαo in the Wnt pathway has come from both cell culture and Drosophila genetic studies; however, this topic remains controversial. Using our biochemical system, we have shown that GTPγS and Gq/11 interact with β-catenin in Xenopus egg extracts and promote ubiquitin-mediated proteosome-dependent β-catenin turnover. "Hits" are currently being tested for their ability to perturb Xenopus embryogenesis as well as β-catenin/TCF-mediated gene transcription in cultured cells. Pharmacologic inhibitors of Wnt signaling would be useful in studying Wnt signaling during development and may be useful for perturbing Wnt signaling in certain disease states.

A Biochemical Screen for β-catenin/Axis Regulators
C. A. Thorne, E. Tahinci, K. Kalie, A. Salic, E. Lee; Cell and Developmental Biology, Vanderbilt University, Nashville, TN, Cell Biology, Harvard Medical School, Boston, MA

Wnt signaling is essential for proper development and is misregulated in many human cancers. β-catenin is a transcription factor that is stabilized at the protein level by activation of the Wnt pathway. In the absence of a Wnt ligand, a destruction complex, assembled by Axin, targets β-catenin for degradation via the proteasome. The destruction complex is inhibited in the presence of a Wnt signal, thereby leading to elevated levels of β-catenin that translocate to the nucleus and activate gene transcription. Recent studies in Drosophila as well as our unpublished biochemical data have shown that Axin degrades in response to Wnt signaling. Utilizing in vitro reconstitution of β-catenin degradation in Xenopus egg extracts, we have conducted a biochemical screen of the Wnt signaling pathway. Addition of β-catenin-nullified luciferase and Axin-nullified fusion proteins to Xenopus extracts in a 3×3-well format allowed us to simultaneously screen chemical libraries for regulators of β-catenin and Axin turnover. "Hits" are currently being tested for their ability to perturb embryonic development as well as β-catenin/TCF-mediated gene transcription in cultured cells. Pharmacologic inhibitors of Wnt signaling would be useful in studying Wnt signaling during development and may be useful for perturbing Wnt signaling in certain disease states.

Convergent Extension Movements in the Noncanonical PCP Signaling Pathway
G. Kim, J. Han; Division of Molecular and Life Sciences, Pohang University of Science and Technology, Pohang, Republic of Korea

Convergent extension (CE) movements in gastrulation are essential in establishing the body axis during early vertebrate development. Although the precise molecular mechanisms of CE movements are not clearly understood, the noncanonical Wnt/PCP pathway is known to be important in the control of CE movements. Here we present evidence that β-arrestin 2 (β-arrestin 2) is essential for the control of CE movements in Xenopus development. Overexpression Xenopus β-arrestin 2 (β-arrestin 2) inhibited CE movements and induced both activation of RhoA and JNK during gastrulation. Loss-of-function analysis using morpholino oligonucleotides likewise provided evidence that β-arrestin 2 is essential for CE movements and its defective phenotypes in Xenopus embryos were very similar to the morphogenetic defects caused by the inhibition of noncanonical Wnt signaling. Moreover, in the noncanonical Wnt signaling, β-arrestin 2 acted downstream of dishevelled in the planar cell polarity (PCP) signaling, but not Ca²⁺ signaling. We further demonstrated at molecular level that β-arrestin 2 interacted with phosphorylated dishevelled via amino and carboxyl regions containing DIX and DEP domain, was relocalized to the specific distribution of dishevelled, and was required for dishevelled activation of RhoA. Finally, we provided evidence that β-arrestin 2 is associated with N terminal quarter of hDaam1 and XRhOA, but not XRac1. Taken together, our results suggest that β-arrestin 2 plays a novel mediator to recognize the dishevelled activation (phosphorylation and membrane localization) in the noncanonical Wnt pathway and a functional association of dishevelled/β-arrestin 2-Daam1 specifically mediates the PCP/RhoA signaling to regulate Xenopus CE movements.

Biochemical Reconstitution of LRP6-mediated Axin Degradation in Xenopus Egg Extract
C. Cseleányi, K. Kalie, E. Tahinci, C. Thorne, E. Lee; Cell and Developmental Biology, Vanderbilt University, Nashville, TN

Axin is a scaffold that recruits β-catenin into a complex to mediate its degradation. Given limited Axin concentrations, models predicting that LRP6 promotes β-catenin stabilization via degradation of Axin are particularly appealing. We test the role of Axin as a target of LRP5/6 transduction. LRP6 intracellular domain (LRP6ICD) stabilizes β-catenin in Xenopus egg extracts and promotes ubiquitin-mediated, proteosome-dependent degradation of Axin independent of GSK3 inhibition and Dsh. We find, however, that Axin degradation is not required for LRP6-mediated β-catenin stabilization in egg extracts. An Axin mutant that can bind LRP6 but does not undergo LRP6-mediated degradation is still able to mediate Wnt signal transduction. We suggest that Axin degradation plays a role in controlling steady-state Axin levels to regulate canonical Wnt signaling following initial β-catenin stabilization.

Biochemical Evidence for the Role of Gαo in β-catenin/Wnt Signaling
K. E. Kalie, E. Lee; Cell and Developmental Biology, Vanderbilt University, Nashville, TN

In canonical Wnt signaling, Wnt ligand concentrations, models predicting that LRP5/6 promotes β-catenin stabilization via degradation of Axin are particularly appealing. We test the role of Axin as a target of LRP5/6 transduction. LRP6 intracellular domain (LRP6ICD) stabilizes β-catenin in Xenopus egg extracts and promotes ubiquitin-mediated, proteosome-dependent degradation of Axin independent of GSK3 inhibition and Dsh. We find, however, that Axin degradation is not required for LRP6-mediated β-catenin stabilization in egg extracts. An Axin mutant that can bind LRP6 but does not undergo LRP6-mediated degradation is still able to mediate Wnt signal transduction. We suggest that Axin degradation plays a role in controlling steady-state Axin levels to regulate canonical Wnt signaling following initial β-catenin stabilization.

Convergent Extension Movements in the Noncanonical PCP Signaling Pathway
G. Kim, J. Han; Division of Molecular and Life Sciences, Pohang University of Science and Technology, Pohang, Republic of Korea

Convergent extension (CE) movements in gastrulation are essential in establishing the body axis during early vertebrate development. Although the precise molecular mechanisms of CE movements are not clearly understood, the noncanonical Wnt/PCP pathway is known to be important in the control of CE movements. Here we present evidence that β-arrestin 2 (β-arrestin 2) is essential for the control of CE movements in Xenopus development. consequences of loss of APC function, both APC1 and APC2 must be mutant. We and others reported that APC2 APC1 double mutant clones in the adult wing blade exhibit cell fate transformations consistent with ectopic Wg signaling. We found that APC2 APC1 (double null) clones in wing marginal discs exhibit abnormal outpocketing and segregation from the surrounding epithelium. Clones with the segregation phenotype overproliferate and are largely restricted to areas of the disc not expressing Wg protein. Further, different alleles of APC, in combination with a null allele of APC1, exhibit a range in severity of the phenotype in wing discs and in adult wings. To determine whether the segregation phenotype is due to activation of Wg signaling, we have shown that blocking the Wg pathway in APC2 APC1 clones by expressing dominant negative TCF partially suppresses the segregation phenotype. Conversely, we have induced clones exhibiting the segregation phenotype by expressing stabilized Armadillo or mutant Axin to constitutively activate Wg target genes independent of APC function. To understand the basis for the segregation defect in APC2 APC1 clones, we are assessing polarity, adhesion, and cytoskeletal organization in the mutant tissue throughout wing development.

1209 Involvement of Myb Transcription Factors in the Function of Mesenchymal Stem Cells
A. Camelo, P. Garcia, J. Frampton; Infection and Immunity, Institute for Biomedical Research, Birmingham, United Kingdom
Two major populations of stem cells reside in the bone marrow of adults, that is, haemopoietic stem cells (HSCs) and mesenchymal stem cells (MSCs). There is great interest in understanding the fundamental biology and potential for these two cellular populations, in part because of their importance for regenerative medicine. MSCs, like all adult stem cells, are capable of self-renewal while retaining the ability to differentiate into a number of stromal cell types, and possibly also neurons and cardiomyocytes. The regulation of stem cell self-renewal and commitment depends largely upon the activity of specific transcription factors. Myb family transcriptional regulators play a central part in the functioning of these HSCs; in particular c-Myb has critical roles in the maintenance of quiescence and commitment to differentiation, while B-Myb appears to exert an essential influence on proliferation. To date, no studies have investigated whether Myb family factors are similarly involved in MSCs. Here, we describe the isolation of a population of stromal cells from bone marrow that express the markers CD73, CD44 and CD90. These MSC-like cells are capable of self-renewal and are capable of differentiation into adipocytes and osteoblasts. Both B-Myb and c-Myb are expressed in these cells, but upon differentiation B-Myb expression is maintained or even increased whereas c-Myb expression decreases dramatically. In order to explore the significance of this pattern of Myb factor expression we are using Cre-loxP conditional gene deletion. We describe the distinct consequences of deletion of either gene in MSCs in terms of effects on both proliferation and differentiation.

1210 SVCT2 Expression during Brain Development
C. Silva-Alvarez, F. Nualart; Cell Biology, Universidad de Concepcion, Concepcion, Chile
Different cells transport vitamin C in its reduced form using the sodium-dependent ascorbic acid cotransporters (SVCT1 and SVCT2). SVCT2 is mainly expressed in the nervous system, however, there are no studies that describe the localization of SVCT2 during the central nervous system (CNS) development, which is important for the function of the CNS. We have carried out immunohistochemistry and in situ hybridization studies in embryonic preparations from different mouse brain developmental stages (E13 to E19). Our results indicate that SVCT2 is preferentially expressed in the melanoblast body of the radial glia, the ventricular glia body of the cortex during neurogenic stage (E12 to E17), while during the gliogenic stage SVCT2 expression downregulates and appears in cortical newborn neurons. A similar distribution pattern was observed in human brain samples from 9 weeks of gestation. These results suggest that SVCT2 is expressed in the radial glia during neurogenesis, decreasing it expression during gliogenic stage. For neurogenic development, the radial glia would have to keep its ventricular contact, uptaking vitamin C from cerebrospinal fluid (CSF). Grant FonDECYT 1050095, * CONICYT.

1211 Gene Expression Profiling of Melanocyte Stem Cells in the Mouse Hair Follicle
M. Osawa, R. Freter, G. Egawa, M. Mariko, S. Nishikawa; Laboratory for Stem Cell Biology, RIKEN Center for Developmental Biology, Kobe, Japan
Elucidation of molecular mechanisms underlying stem cell regulation is of great importance both for developmental biology and for clinical applications in regenerative medicine and cancer therapy. It is widely accepted that stem cells are regulated by their specialized microenvironment, termed stem cell niches. However, because of difficulties of identifying and manipulating the individual stem cells and their surrounding components in situ, the exact mechanisms underlying in the stem cell regulation by the niche have remained largely unknown. To overcome these difficulties, we are employing melanocyte stem cells (MSCs) that enable us to identify individual stem cells at the bulge region of the hair follicle. The relative quiescence of stem cells is maintained both in the animal and plant kingdoms and is thought to be of critical importance in maintaining the longevity of stem cells, although the exact molecular mechanisms involved in its regulation have remained unclear. To clarify molecular mechanisms implicating in fate-determination of MSCs, we compared transcriptional profiles of various subsets of immature melanoblast populations isolated from early stages of hair follicle morphogenesis. We obtained a cluster of genes that is transiently upregulated in melanoblasts at the onset when they get in a dormant status at the bulge region. These genes include molecules encoding transcription factors, adhesion proteins and stress-inducible factors, suggesting that a complex of signals is involved in the regulation of the stem cells by the niche. By establishing a vivo assay system to explore loss of function mutations, we are currently using this information to investigate how the cross-talks of these signals are implicated in the fate-determination of quiescent status of MSCs. We hope to provide new insights into our understanding of the nature of stem cell regulation at the molecular and cellular levels.

1212 Notch Signaling via Hes1 Transcription Factor Maintains Survival of Melanoblasts and Melanocyte Stem Cells
M. Moriyama, M. Osawa, S. Nishikawa; Laboratory for Stem Cell Biology, RIKEN Center for Developmental Biology, Kobe, Japan
Melanocytes exert an excellent model to understand molecular basis of various cell regulations, since genetic alterations in their regulations are easily identified by coat color defects. Melanoblasts (Mbs) including melanocyte stem cells (MSCs) are thought to be tightly regulated by cell-cell interactions with the surrounding epidermal keratinocytes, although the precise molecular mechanism has remained elusive. Notch signaling, whose activation is mediated by cell-cell interactions, is implicated in various aspects of cellular regulations such as cell fate determination, proliferation and survival. Here we investigated the role of Notch signaling in the maintenance of Mbs as well as MSCs. We found that Notch signaling is activated in both Mbs and MSCs. Conditional ablation of Notch signaling in the melanocyte lineage resulted in a severe defect in hair pigmentation, followed by intensive hair graying. The defect was caused by an apoptotic elimination of Mbs and MSCs. Furthermore, targeted overexpression of Hes1, a downstream molecule of Notch signaling, was sufficient to rescue Mbs from the apoptosis which was induced by the inhibition of Notch signaling. Thus, these data provide direct evidence that Notch signaling via Hes1 plays an indispensable role for survival of Mbs and MSCs in the epidermis. To define molecules that act at the downstream of Notch-Hes1 signaling pathway in Mbs, we performed gene expression analysis and found upregulation of several stress-responsive genes in the Mbs that were treated with a pharmacological inhibitor for Notch signaling. In fact, treatment of Mbs with an inhibitor for p38 MAPK, whose activation is induced by various stress responses, restored Mbs even in the absence of Notch signaling. Therefore, our findings demonstrate evidences for the implication of Notch signaling in the regulation of stress response.

1213 Aging-related Changes to Stem Cells and the Stem Cell Niche
L. Jones, C. Wong, M. Boyle, M. Rocha; Laboratory of Genetics, Salk Institute for Biological Studies, La Jolla, CA
Aging is characterized by compromised organ and tissue function. Adult stem cell populations maintain tissues such as blood, skin, and sperm throughout the lifetime of an individual; therefore, many consequences of aging may be due to loss of stem cell function. The transparency of the Drosophila testis, the spatiotemporal organization of germ cells, and the availability of markers for identifying various germ cell stages allow precise identification of germ line stem cells (GSCs) in vivo. GSCs and their associated somatic stem cells, known as cyst progenitor cells (CPCs), surround a cluster of post-mitotic somatic cells called the apical hub. Hub cells secrete a ligand Unpaired (Upd), which activates JAK-STAT signaling in the adjacent stem cells, thereby specifying stem cell fate. Thus, the hub is a critical component of the somatic niche that supports maintenance of the stem cell population. We are using the Drosophila male germline as a model system to analyze how the process of aging affects stem cell behavior. Testes from 50-day old males contain fewer differentiating germ cells and in aged testes. Our data suggest that aging-related changes within stem cell niches may be a significant contributing factor to reduced tissue homeostasis and regeneration in older individuals.
Dendritic Cells Expressing MHC-II, CD1a and Langerin Can Differentiate from CD133 Positive Human Cord Blood Cells

L. Giabban,1 L. Domenici,2 L. Pieri,2 S. Urbanil,2 G. Romano,1 M. Monici,3 R. Saccardi,4 V. Basile,1 A. Bosil,1 P. Romagnoli1; 1Department of Anatomy, Histology and Forensic Medicine, University of Florence, Firenze, Italy, 2Department of Hematology, University Hospital Careggi, University of Florence, Firenze, Italy, 3Department of Clinical Physiopathology, University of Florence, Firenze, Italy, 4Center for Laser Application in Medicine, Center of Excellence in Optronics, Firenze, Italy

Hematopoietic stem cells are classically selected by their expression of CD34, however CD133 has been shown to mark more primitive progenitors, i.e. hemangioblasts with a wider differentiation potential than CD34+. Since dendritic cells can differentiate in vitro from CD34+ cells, the object of this study was to determine if and under which conditions CD133+ cord blood cells can be expanded and differentiated into dendritic cells. Human cord blood was obtained from donations unsuitable for banking. Upon Foxc2 separation of mononuclear cells and immunomagnetic selection for CD133, the cells were expanded until day 7 with GM-CSF, TNF-α, IL-4, thrombopoietin, Flh-3L and SCF. They were then differentiated until day 18 in the same medium without thrombopoietin, Flh-3L and SCF. Some experiments were performed without TG-β, others with TG-β, 5 ng/mL since day 1 or since day 8, and 12.5 ng/mL since day 15.

CD133+ cells at the start of culture were 0.6-2.1 x 10⁶; expansion led to a 4-11 fold increase in the cell numbers; the cell proliferation slowed down during differentiation. Part of the cells adhered to the culture flask and had a dendritic shape. At the end of the experiments without TG-β, 36% cells expressed MHC-II and 12% expressed CD1a. With TG-β, there was a dose dependent inhibition; MHC of TG-β since the start of culture, many cells expressed langerin (49%). In conclusion: CD133+ cord blood cells can be expanded in vitro and induced to generate cells with features of dendritic cells; prolonged exposition to TG-β seems needed to induce the expression of the Langerhans cell specific marker langerin; preliminary expansion of the cells in the absence of TG-β may help to overcome the negative effect of TG-β on cell proliferation.

Activation of Transcription Factor FoxO3a in Mouse ES Cells Associated with Loss of Pluripotency

H. M. Romanska,1 Z. Gulzar,2 E. Lam,3 R. Howe,3 N. E. Lalani1; 1Pathology, University of Birmingham, Birmingham, United Kingdom, 2Department of Oncology and Cancer Research UK Labs, Imperial College London, London, United Kingdom

Background: PI3K/Akt signaling pathway plays a pivotal role in the regulation of pluripotency and self-renewal of mouse embryonic stem (MES) cells. Cellular responses to PI3K/Akt signaling can be antagonized by activation of the forkhead transcription factors. The aim of this study was to assess the temporal pattern of expression of Akt and FoxO3α, in relation to that of OCT-3/4, a marker of pluripotency, in differentiating cells. Method: MES cells (D3) were grown undifferentiated in MEM supplemented with LIF (1000 U/mL). Differentiation was induced by withdrawal of LIF from the medium and the formation of embryoid bodies (EBs). Expression of OCT-3/4, pAkt (phosphoThr308) and FoxO3α in a: undifferentiated (Day 0) and b) 14 day old EBs (EBd14) was evaluated by immunocytochemistry and Western blotting. Results and Conclusion: In undifferentiated cells (Day 0), of OCT-3/4 and phospho-Akt were highly expressed in the nuclei, whereas immunoreactivity for FoxO3α was restricted to the cytoplasm. By day 14 (EBd14) expression of both OCT-3/4 and phospho-Akt was markedly decreased with low level punctuate immunoreactivity noted in occasional cells. In contrast to the observable decline in OCT-3/4 and phospho-Akt proteins, FoxO3α was strongly expressed in the nuclei of early differentiating cells. This trend in FoxO3α expression (cytoplasmic to nuclear) was further confirmed by Western blotting. Our results suggest that negative regulation of PI3K signaling by activation of FoxO3α is associated with and might contribute to the loss of pluripotency and onset of differentiation of MES cells.

Transdifferentiation of Human and Rat Mesothelial Cells into Osteoblast-like Cells In Vitro

S. M. Lamkicy,1 R. G. Searles,1 S. E. Herrick,2 P. J. Thompson,1 C. M. Prele,1 S. E. Mutsaens; 1Asthma & Allergy Research Institute, Perth, Australia, 2University of Manchester, Manchester, United Kingdom

Telithrocyte formation was performed in vitro where cells were maintained in either osteogenic medium containing 10mM β-glycerophosphate, 50μg/ml ascorbic acid and 10mM dexamethasone or standard culture medium for 0-27 days. Rat mesothelial cells cultured in osteogenic medium expressed alkaline phosphatase, an early marker of the osteoblast phenotype, and formed mineralized bone-like nodules as demonstrated by von Kossa stain. Human and rat mesothelial cells expressed mRNA and protein of several key osteoblast markers, including bone specific core binding factor alpha 1 (Bcn1), osteoclast, osteopontin and bone sialoprotein by RT-PCR and Western blotting. Histological analysis of a human pleural MM biopsy demonstrated multiple foci of mineralized osteous metaplasia within the tumour. Bcfn1 immunostaining was also observed in several areas of its pleural MM tumour. In conclusion, we have strong evidence that mesothelial cells have the capacity to differentiate into cells of the osteoblast lineage, further illustrating their multipotent nature.

Difference in DNA Methylation Profile between Neurogenic and Glieogenic Progenitor Cells

K. Hirabayashi, N. Hattori, S. Yagi, S. Tanaka, K. Shiotia; Animal Resource Sciences/Veterinary Medical Sciences, The University of Tokyo, Tokyo, Japan

Neurons and glial cells are both derived from neural stem cells, and appear serially from mid-gestation to late-stage tissue of development. The isolated neural stem cells from each stage differentiate into neurons and glial cells, suggesting that the commitment of the neural stem cells to each cell lineage should be determined at this stage. DNA methylation is suggested to be involved in differentiation of the neural stem cells. To address how the commitment of the neural stem cells occurs during this period, we analyzed DNA methylation profiles of neurospheres, which were established from mouse embryos of day 11.5 (E11.5NSph) and 14.5 (E14.5NSph). When these NSphs were dispersed and cultured under the differentiation condition, 49.0% of cells from E11.5NSph were βIII-tubulin-positive and 5.7% of them were glial fibrillary acidic protein (GFAP)-positive, while 16.8% of cells from E14.5NSph were βIII-tubulin-positive and 21.6% of them were GFAP-positive, indicating that fates of cells in neurospheres were different between these stages. The DNA methylation profiles by restriction landmark genomic scanning (RLGS) represented the methylation status of approximately 2000 Nol sites among 6000 Nol sites scattered through genome-wide. In E14.5NSph, 32 hypo-methylated and 20 hyper-methylated loci were observed when compared to those in E11.5NSph. Based on the report that most of Notl sites are located in gene loci, the methylation status should be modulated at plurality of gene loci during the commitment period. In conclusion, neurospheres which were isolated from different developmental stage have distinct DNA methylation profiles, and the difference in their profiles suggested that establishment of DNA methylation profile should be involved in the commitment of neural stem cells.

Inhibition of Akt or NFκB Pathway Suppresses Development of CFU-GM from Murine Bone Marrow Cells

H. Choi,1 M. Kim,1 L. Han,1 Biological Science, University of Ulsan, Ulsan, Republic of Korea, 2IC, University of Ulsan, Ulsan, Republic of Korea

Hematopoietic stem cell (HSC) can undergo self-renewing or differentiate into different lineages. To investigate whether hematopoiesis from HSC involve NFκB and PI3-kinase/Akt-dependent pathway, we expressed dominant negative forms of IκB (dnIκB) and Akt (dnAkt) in HSCs obtained from murine bone marrow. These expression strongly suppressed colony formation of CFU-GM (colony forming unit-granulocyte/macrophage). Thus, both signal pathways seem to be associated with development of hematopoietic progenitor cells. GATA-1 expression was highly induced in cells transfected with adenovirus-dnIκB and -GFP control, its expression was much less increased in dnAkt-transfected cells, indicating that GATA-1 is involved in Akt-dependent but not NFκB-dependent pathway in suppressing colony formation of granulocyte/macrophage progenitor cells.

Investigation of Histone Variant Distribution in Human Embryonic Stem Cells

M. L. Shaw,1 E. J. Williams,2 J. Craig,3 K. H. A. Choo,2 R. Safery1; 1Epigenetics Research, Murdoch Childrens Research Institute, Parkville, Australia, 2Chromosome Research, Murdoch Childrens Research Institute, Parkville, Australia

Human embryonic stem cells (hESCs) have the ability to differentiate into all three germ layers. The differentiation process involves the coordinated regulation of three gene expression layers, most likely mediated by epigenetic remodelling of hESC chromatin. We are interested in studying the epigenetics of early stem cell differentiation, and in particular investigating the changes in
Muscle-derived Stem Cells Display Sexual Dimorphism under BMP4 Stimulation

K. A. Consi, J. B. Pellet, J. A. Jadlowiec, A. Usas, G. Li, J. Haard; Stem Cell Research Center, Children's Hospital of Pittsburgh and Department of Orthopedic Surgery, University of Pittsburgh, Pittsburgh, PA; Department of Bioengineering, University of Pittsburgh, Pittsburgh, PA; Carnegie Mellon University, Pittsburgh, PA; Department of Molecular Genetics and Biochemistry, University of Pittsburgh, Pittsburgh, PA.

Muscle-derived stem cells (MDSCs) are potential cell sources for orthopedic tissue engineering. This study investigated if the osteogenic differentiation of mouse MDSCs displays sexual dimorphism. Female and male MDSCs (F-MDSCs and M-MDSCs, respectively) were stimulated with bone morphogenetic protein (BMP)-4 (0-200 ng/ml) and assessed for osteogenic differentiation by gene expression and presence of alkaline phosphatase (ALP), an early osteogenic marker. Gene expression for Alp and Runx2 was upregulated within 12 hours of BMP4 stimulation, however no difference was observed between female and male populations. BMP4 stimulation led to an increase in ALP activity for all cells tested, regardless of sex. However, M-MDSCs displayed a significantly greater ALP activity than F-MDSCs at 2 and 3 days post-stimulation, but not at 4 days. To determine if M-MDSCs had more osteoprogenitors than F-MDSCs, the cells were single-cell sorted, the colonies stimulated with BMP4 for 3 days and stained for ALP. Since all colonies comprised a mixture of ALP negative and positive cells, they were scored as low ALP+ (<50% of the cells stained for ALP) or high ALP+ (>50% of the cells stained for ALP). M-MDSCs had significantly more colonies that were high ALP+ than did the F-MDSCs. MDSCs were also transduced to express human BMP4 and implanted into the intramuscular pocket of sex-matched mice. At 14 and 21 days post-implantation, a more consistent bone formation and of higher density was seen with M-MDSCs than F-MDSCs. This study indicates that although all MDSCs undergo osteogenic differentiation, M-MDSCs do so more readily than F-MDSCs. These findings warrant further investigation into sex-related differences of MDSCs and other stem cells, as well as identifying the mechanisms underlying these differences. This may then be used to further advance the use of stem cells in cell therapy and tissue engineering for bone healing.
distinguish between these possibilities using a variety of molecular genetic experiments. Mutants have additional defects in sense organ differentiation, and wing and eye development. We are currently exploring the common features of these phenotypes to identify the molecular functions of this cyclin.

1225 Quantitative Protein Measurements in Transitional Tumor Stem Cells Reveal Differences Not Seen with Nucleic Acid Techniques
D. W. Voehringer,1 S. Chan,2 A. Bhaimipati,1 P. Vander Horn,3 R. O'Neill,1 E. Weissman1; 1Inst. of Stem Cell Biology and Regenerative Medicine, Stanford School of Medicine, Palo Alto, CA
The discovery of tumor stem cells in acute myeloid leukemia a decade ago initiated a field of research that has seen accelerated growth in the past few years. Now researchers are describing tumor stem cells in a variety of hematopoietic and solid tumors. The impetus for much of this research has been the desire to identify targets for molecular medicine in these critical tumor populations. The molecular pathways that functionally define these cells are of particular interest as therapeutic targets. Techniques describing these pathways are different than in conventional biology as these cells are rare and often generate insufficient protein material to use standard protein methods. Quantitative measurements, where comparisons and contrasts are made between tumor stem cells and their surrounding progeny, are made using DNA microarray and qPCR approaches. Unfortunately, the rare nature of stem cells in these samples limits or prevents quantitative protein analysis. Here we describe a technique utilizing a nano-scale proteomic platform (Firefly) to measure a number of protein stem tumor cell proteins. To maximize sample efficiency, transitional tumor cells (TCC-) and transitional tumor stem cells (TCC+) were sorted directly into lysis buffer. 2,000 cells/well were sorted into 20 μl lysis buffer (HNTG - 50 mM HEPEs, 150 mM NaCl, 0.1% Triton X 100, 10% Glycerol). Following photolysis detection and quantification of signal was measured by HRP-labeled secondary chemiluminescence. Quantification of proteins that are not regulated at the transcriptional level, such as β-catenin, had similar RNA levels between TCC- and TCC+ cells. However, protein levels were strikingly different. A panel of RNA/proteins which define transitional tumor stem cells will be described along with examples that emphasize the importance of protein measurements in addition to nucleic acid measurements.

1226 Non-Radioactive ProLabel Detection of Protein-Protein Interactions in Co-IP Studies
Y. H. Nguyen, D. Li, Cell and Molecular Biology, Clontech Laboratories, Mountain View, CA
ProLabel technology is based on an enzyme fragment complementation (EFC) assay in which the enzyme, β-galactosidase, is genetically engineered into two fragments—the large enzyme acceptor and the small enzyme donor called ProLabel. Separately, the β-gal fragments are inactive, but in solution, they rapidly recombine to form an active β-galactosidase enzyme that hydrolyzes substrate to produce an easily detectable chemiluminescent or fluorescent signal. We have developed a sensitive, novel non-radioactive Co-IP assay for the confirmation of protein interactions typically isolated from a yeast two-hybrid screen, using AcGFP as a fluorescent tag for monitoring transfection efficiency as well as for the pull-down of the immunocomplex and ProLabel enzyme complementation assay as a readout of physical protein-protein interactions. Briefly, vector-specific primers are used in conjunction with Clontech’s In-Fusion technology to facilitate the efficient cloning and rapid transfer of bait and prey sequences amplified from yeast two-hybrid expression vectors into mammalian AcGFP and ProLabel expression vectors. HEK293 cells co-transfected with constructs expressing N-terminal fusions of AcGFP-bait and ProLabel-prey clearly show fluorescent expression and proper localization of the AcGFP-bait and ProLabel enzyme activity from the prey fusion. Co-immunoprecipitation studies using polyclonal antibodies demonstrated extremely low background and a greater than 300X increase in the co-immunoprecipitated ProLabel activity detected between interacting pairs (SV40 large T and p53) versus non-interacting pairs of proteins. The system eliminates the biobehaviors that are typically associated with co-construct co-immunoprecipitation and is an effective approach for the verification of protein-protein interactions.

1227 Applications of Artificial Microbial Mats
Z. O. Swankie,1 C. Blackford,1 A. Jamshed,1 T. Cote,1 B. M. Bebout,2 L. Prefurt-Bebout,2 R. Gonzalez-Plaza,2; 1Northwest Indian College, Bellingham, WA, 2NASA Ames Research Center, Moffett Field, CA
Microbial mats are complex networks of cyanobacteria and other microorganisms, which can grow in both fresh and salt water as well as in a variety of extreme environments. Microbial mats are among the first complex communities of organisms that grew in the young Earth, 3500 million years ago. Long-term research has focused on the role of microbial mats as the first detectable life forms on Earth and in the creation of the oxygenic atmosphere. In addition to continuing substantial roles in current Earth geochemical cycling processes, microbial mats offer potential commercial and research applications. We are investigating two of these possible uses. First, we are evaluating the possibility of using microbial mats as sources of hydrogen. Biologically produced hydrogen is more environmentally friendly than traditional hydrogen production in which fossil fuel is consumed during its production. Second, we are investigating the use of microbial mats as life support for the nematode C. elegans. C. elegans has been a valuable model organism for space studies. Current methods use E. coli for food to support the nematodes. Limited supplies of nutrients to support E. coli growth can be sent into space for a given mission. We suggest that the use of self-replicating microbial mats to support C. elegans could make possible longer periods of observation in order to better understand the long-term effects of space on biological systems. A critical requirement to address these and other questions could make possible longer periods of observation in order to better understand the long-term effects of space on biological systems. A critical requirement to address these and other questions.

1228 Identification of Chemical Inhibitors of the Rho GTPase Exchange Factor TRIO-GEFD1 Using the Yeast Exchange Assay
A. Blangy,1 N. Bouquier,1 C. Gauthier-Rouvière,1 S. Schmidt,1 A. Debant,1 J. Leonetti,2 P. Fort1; 1CRBM CNRS FRE2593, Montpellier, France, 2CNRS UMR 5160, Montpellier, France
Background information RhoGTPases are involved in many biological processes and participate in cancer development. Their activation is catalyzed by exchange factors (RhoGEFs) of the Dbl family. RhoGEFs display proto-oncogenic features, thus appearing as candidate targets for anticancer drugs. Dominant negative RhoGTPase mutants have been widely used to block RhoGEF signaling. However, these tools suffer from limitations, due to the high number of RhoGEFs and the complex mechanisms that control RhoGTPase activation. Results RhogT17N is a poor inhibitor of its exchange factor TRIO-GEFD1 in vivo: although it binds to TRIO-GEFD1, Rhog-T17N cannot bind to its effectors, which illustrates how negative mutants may produce misleading interpretations and emphasizes the need of new types of RhoGEF inhibitors. In that prospect, we adapted the Yeast Exchange Assay method to identify RhoGEF inhibitors. Using this novel approach, we screened a 3,500 chemical compound library and identified a potential inhibitor of TRIO-GEFD1 in vivo. This molecule inhibited TRIO-GEFD1 in vitro. Among the chemical analogs of this compound, we identified two molecules with better inhibitory activity. The three TRIO-GEFD1 inhibitors had no effect on ARHGEF17 and ARNO, two exchange factors for RhoA and Arf1 respectively. Conclusions The development of RhoGEF inhibitors appears as a necessary tool for the study of Rho GTPase signaling pathways. The Yeast Exchange Assay adaptation we present here is suitable to screen for chemical or peptide libraries and identify candidate inhibitors.

1229 A Novel In Vitro Assay for Measuring Protein Palmitoylation Dynamics
L. M. Borland, N. L. Allbritton, Dept. of Physiology and Biophysics, University of California, Irvine, Irvine, CA
Palmitoylation is the thioester linkage of fatty acid palmitate (C16:0) to cysteine residues on a protein. This dynamic and reversible post-translational modification increases the hydrophobicity of proteins, facilitating protein-membrane interactions, protein-protein interactions and intercellular trafficking of proteins to differing sites of action. Recently, fluorescence microscopy studies revealed that palmitoylation plays a significant role in transporting the MAPK signaling proteins H- and N-ras to sites of action near the plasma membrane (Rocks, et al., Science, 2005, 307: 1746-1757). Given that many cancers have a significant need to monitor and measure protein palmitoylation, unfortunately, few methods exist to quantitatively monitor protein palmitoylation, especially at the cellular level. In this study, we developed a capillary electrophoresis-based assay, using MEKC-LIF, to monitor and measure palmitoylation dynamics of a fluorescently-labeled peptide in vitro, with potential to extend such studies to the single-cell level. A fluorescently-labeled portion of the growth-associated protein (GAP, HiLyte Fluor488-MLCCMRRTL-NH2) was palmitoylated in vitro using a HEPEs-based acylation buffer and palmitoyl coenzyme A. Formation of a doubly-palmitoylated GAP peptide product was confirmed by MALDI-MS. The GAP peptide substrate was separated from the unreacted GAP and palmitoyl coenzyme A by liquid chromatography and then sequenced by nano-ESI-MS. The first 6 minutes from a total sample size of 1 nanoliter (10-9 L). The rate of in vitro palmitoylation with respect to time and increasing palmitoyl coenzyme A concentrations was examined. Mixture of GAP peptide substrate with cell lysate increased palmitoylated product production in a time-dependent manner. Conversely, palmitoylated GAP substrate was de-palmitoylated after addition of the

226
cell lystate, demonstrating the reversibility of palmitoylation in vivo. Pharmacological manipulation of the GAP peptide substrate with 2-bromopalmitate, an inhibitor of palmitoylation, was also measured by MEKC-LIF. This novel CE-based assay for monitoring palmitoylation has applications for kinetic studies at the single cell level.

1230
Efficient siRNA Delivery Enhances the Potential of RNA Interference
A. Bolkato-Bellemin, M. Bonnet, P. Neuberg, P. Erbacher; Polyplus transfection, Illkirch, France
RNA interference (RNAi) is a potent technology for gene silencing based on an extremely selective interaction of short RNA duplexes (siRNA) with a single target in the mRNA, providing sequence-specific mRNA degradation and inhibition of protein synthesis. Currently, introduction of siRNA at 10-100 nM by transfection results in effective silencing of endogenous and exogenous genes in a variety of mammalian cells. Nevertheless, siRNA delivery remains a key step for efficient gene silencing. In order to fully exploit the promising potential of RNA interference, we have focussed our research on improving selectivity by using a delivery system efficient with at very low levels of siRNA. We present efficient gene silencing in mammalian cells using siRNA in the subnanomolar and picomolar range. We show complete and selective gene silencing at 1 nM siRNA and even down to 10-50 pM for several targeted genes (GAPDH, Lamina A/C, Vimentin, luciferase, GFP). Using subnanomolar and picomolar siRNA concentrations avoids off-target effects and also reduces toxicity drastically. Moreover, we demonstrate that efficient endogenous gene silencing with very low amount of siRNA occurs in many cell types (adherent cells, suspension cells and primary cells). Taken together our data show the great potential of RNA interference when delivering very small amounts of siRNA into mammalian cells.

1231
Protein Delivery to Live Cells
P. Erbacher, C. Weill, S. Biré, A. Adh; Polyplus transfection, Illkirch, France
The delivery of proteins to live cells offers a powerful alternative where other approaches have failed. Indeed, the conventional approach to studying protein function consisting in transfecting the corresponding cDNA sequence into cells is not always successful. The ability to introduce proteins to live cells opens new insights to a wide range of applications such as protein trafficking studies in live cells, live immunolabelling or even protein interference studies with antibodies. For efficient protein delivery, major hurdles such as crossing the plasma membrane and effective release of the protein in the cytoplasm still remain to be overcome. We present an optimized system for protein, peptide and antibody delivery to cells. This carrier forms complexes with the protein of interest, which are then internalized via anionic cell-adhesion receptors present on virtually all cells. The use of this carrier promotes efficient crossing of the plasma membrane, release from the endosome and allows protein diffusion within the cytoplasm as shown with fluorescent proteins, peptides and antibodies. The protein, in its native form is able to diffuse in the cytoplasm and resume cellular functions. Our data demonstrate the effective delivery of 1 µg or less of proteins, peptides or antibodies to a large variety of live eukaryotic cells, including primary and suspension cells, without any detectable side effects. The development of protein carriers represents novel applications for cell biologists in particular for the study of lethal proteins in living cells allowing a tight control of the time course and the amount of protein delivered.

1232
Characterisation and Heterologous Expression of Agaricus bisporus Lectins Which Inhibit Proliferation of Epithelial Tumour Cell Lines
J. Henderson,1 B. Herman,2 D. Eastwood,8 S. Sreenivasaprasad,1 K. Burton1; 1School of Science and Technology, University of Teesside, Middlesbrough, United Kingdom, 2WarwickHRI, Wellesbourne, United Kingdom
Colorectal cancer is the second most common cause of cancer-related deaths in the Western World with 28,000 cases per year in the United Kingdom. Agaricus bisporus is an economically important edible fungus. Despite its importance, the identification of two closely related lectin genes. The aims of this project are to clone these two lectin genes into vectors and transform them in unknown if these isoforms are formed by post-translational modification, if there are different genes for the four isoforms or if it is a combination of both possibilities. Recent work has demonstrated the effective delivery of 1 µg or less of proteins, peptides or antibodies to a variety of live eukaryotic cells, including primary and suspension cells, without any detectable side effects. The development of protein carriers represents novel applications for cell biologists in particular for the study of lethal proteins in living cells allowing a tight control of the time course and the amount of protein delivered.

1233
High-throughput Screening and Confirmation of Interacting Proteins in Living Cells
J. Lu; Surgery, McMaster University, Hamilton, ON, Canada
The major post-genome sequencing task is to determine the function of each of the genes in the human genome and thus the era of proteomics is now at the forefront. There is a growing demand for high throughputscreening technology platforms that will enable large scale screening of protein interactions. Unfortunately, the current methods used for the screening of protein interactions both in vitro (e.g. protein array) and in vivo (e.g. yeast two-hybrid) have many limitations. These include multiple costly and time-consuming complicated procedures, non-specific interactions, along with high rate of false positive/negative findings. We have developed a patented automatic approach, using fluorescence resonance energy transfer (FRET) principles to perform high throughput screening for novel interactions. This innovative method overcomes the aforementioned limitations and presents a unique route for the investigation of protein functions in their intact native state in vivo. Using this method we demonstrated increased transformation efficiency, higher stringency detection, decreased false positive results and high-throughput formats. Current applications of the technology in our lab include: 1. High throughput screening of potential drug candidates (small molecular chemicals, peptides etc.) on their effect on protein interactions and their effect on cells in vivo. 2. High-throughput identification of novel protein interactions in native living cells. 3. Confirmation of protein interaction in vivo in prokaryotic and eukaryotic cells. 4. Identification of non-protein molecular interactions. 5. Screening for potential candidate peptides or other chemicals that interact with special cellular target proteins towards the development of new molecular agents. Proteomic Analysis with IEF and On-Capillary Antibody Based Detection of Immobilized Proteins
The traditional western blot has been a mainstay of protein research for over 25 years. Although popular due to its relative simplicity, the method is slow, labor intensive, only semi-quantitative, and poorly suited to scarce samples. Additionally, quantitative results using the western blot can be difficult to produce. Similar challenges in nucleic acid analysis found a solution with capillary electrophoresis. Protein analysis using capillary electrophoresis has however proven more challenging due to the need to permanently affix the wide concentration range of separated proteins to a stationary phase for antibody-based detection. To overcome this problem, a novel capillary wall coating has been developed which allows rapid (60s) and permanent fixation of isoelectrically focused proteins to the inner wall of the capillary. Chemiluminescent or fluorescently tagged antibodies are then flowed through the open capillary allowing specific labeling and detection of captured proteins. Experiments show that the useful linear range of concentration of protein capture exceeds six orders of magnitude. This automated method has been demonstrated in the analysis of activation of a wide range of cell signaling proteins including AKT, ERK, BCL2, Myc and JNK.
Combination Therapy with Conditionally Replicating Adenovirus and Replication-incompetent Adenovirus Expressing P63γ Enhanced Adenovirus Transduction and Therapeutic Efficacy in Head and Neck Cancer Cell Lines

S. Shim, 1 S. Park, 1 M. Sung 1,2; 1Molecular Tumor Biology, Cancer Research Institute, Seoul National University, College of Medicine, Seoul, Republic of Korea, 2Department of Otorhinolaryngology – Head and Neck Surgery, Seoul National University, College of Medicine, Seoul, Republic of Korea

Low gene transfer rate is the most obstacles in a practical application of cancer gene therapy. Especially in case of head and neck cancer cell lines, gene delivery rate using adenoviral vector is not enough to show a meaningful therapeutic effect and high dose of adenovirus was required. Although the safety of adenovirus already has been proved, high dose of virus injection in human body is somewhat risky. To improve these points of issue, we used conditionally replicating adenovirus (CRAd) which is shown oncolytic action in cancer cells with abnormal Rb activity. Additionally, as a new therapeutic gene, we made recombinant adenovirus included p63γ gene which is one of the p53 family gene. As we hypothesized that conventional E1-deleted adenovirus can replicate competently when co-transfected with a CRAd to selectively supply E1 in tumors by combining with CRAd and adenovirus. As combining with CRAd and adenovirus carrying p63γ, we expected double effect that is the increase of killing gene expression in cancer cell and tumor killing effect. First, to identify increase of therapeutic gene expression, we combined with CRAd and adenovirus-lucase. The combination of CRAd and Adeno-lucase increased the transduction efficiency of lucase almost 20 times compared with transduction with Adeno-lucase alone. Next, we tried western blot to verify p63γ expression level. Combination of CRAd and Adeno-p63γ increased the expression of p63γ by 10-fold versus transduction with Adeno-p63γ alone. Although Adeno-lucase and Adeno-p63γ are E1-deleted replication-defective adenoviruses, adding small amount of CRAd could help excessive protein expression. Therefore, we did a MTT assay to measure lysis of tumor cell by combining CRAd and Adeno-p63γ. Treatment of head and neck cancer cell line with CRAd and Adeno-p63γ also enhanced anti-cancer effect. These results represent that this combination with CRAd and Adenovirus increased killing gene transfer rate and enhanced its anti-tumor effect.

Conventional ELISA vs. Micro-Immunoassays: The Advantages of Multiplexing

S. L. Call, J. D. Hoopes; Quansys Biosciences, Logan, UT

Multiplex protein assays provide researchers the ability to test many biomarkers at once. However, there are concerns about the uniformity of the data as it compares to conventional ELISA assays. The objective of this study is to compare results from conventional ELISA assays with results from higher density multiplexed micro-immunoassays. The conventional ELISA plates were prepared by coating 96-well plates with 50μl of 2μg/ml capture antibody. The micro-immunoassays were prepared by printing 50nl spots of each capture antibody into 96-well plates in a defined array. Each plate was treated the same, antigen incubation for one hour, washed three times with TBST, HRP-labeled detection for 15 minutes, and washed six times with TBST. The conventional ELISA plates were developed with TMB substrate, while the micro-immunoassays plates were visualized with chemiluminescent substrate captured by a CCD camera. Four cancer markers were tested in parallel for consistency: AFP, CA15-3, CA19-9, and CA125. Within the linear range of the assay, the R² residual for AFP was 0.94, 0.93 for CA15-3, 0.97 for CA125, and 0.95 for CA19-9. The results show that there is a strong correlation between conventional ELISA assays and micro-immunoassays. The greatest difference between the assays was that the micro-immunoassay was much more sensitive requiring significantly more reagents and time to perform the assay, though high values tended to saturate quicker. The other major observation is the ability of p53 to target to the cell membrane and cytoskeleton, and on the whole, micro-immunoassays, because of the use of chemiluminescence, which cannot be distinguished during a conventional ELISA. From this experiment we conclude that micro-immunoassays are a comparably if not superior alternative to conventional ELISA assays.

Reconstitution of Yeast Peroxisome Biogenesis from ER In Vitro

N. Yoda, 1 E. Naraba, 1 M. Robinson; 1GE Healthcare, Piscataway, NJ, 2London Bridge Fertility, Gynaecology and Genetics Centre, London, United Kingdom

For various genomic applications to cellular processes, such as those involved in meiosis and in embryogenesis, there is a need to develop protocols for the whole-genome amplification (WGA) from single cells. A robust WGA protocol will also be useful to cell biologists involved in other studies, such as molecular haplotyping, which require genetic analysis from single haploid cells. We have developed a simple two step, one tube protocol for representative whole-genome amplification from a single cell within 4 h using GenomiPhi™ V2 DNA amplification kit. We have also demonstrated the suitability of the amplified products for downstream SNP genotyping. For these experiments, tissue culture or isolated peripheral blood lymphocyte single cells were transferred using a mouth-controlled, fine hand-drawn micro-capillary pipette into 0.2 ml PC tubes containing 3 μl sample buffer from the GenomiPhi™ V2 DNA amplification kit. Single cells were lysed for 10 min by adding 1.5 μl cell lysis solution followed by the addition of 1.5 μl neutralizing buffer and 14 μl of amplification mixture containing reaction buffer, sample buffer and enzyme mix with Phu-29 DNA polymerase. The amplification was carried out in the same tube for 4 h at 30 °C. The amplified DNA was quantitated using PicoGreen™ dsDNA assay and was used for SNP-genotyping using a TaqMan™ assay without any purification. To demonstrate the robustness of our amplification protocol, >20 individual single-cell amplifications and >50 TaqMan™ genotyping assays using 2 cell types and at least three SNP genotyping assays were carried out by two operators. The results indicate the generation of 3-5 μig amplified DNA with > 95% call rate and > 95% concordance. In conclusion, we have demonstrated the single-cell WGA protocol to be simple and robust in providing a representative amplified product which could be used for further genotyping without any further purification.

Evaluation of the Role of the Endoplasmic Reticulum-Golgi Transit in the Biogenesis of Peroxisomal Membrane Proteins in Control and Peroxisome Biogenesis Mutant Mammalian Cells

A. A. Toro, 1 C. Arredondo, 1 J. G. Cordova, 1 C. C. Araya, 1 J. L. Palacios, 1 A. D. Venegas, 1 M. Morita, 1 M. J. Santos, 1 T. Imanaka; 1Biologia Celular y Molecular, Pontificia Universidad Católica de Chile, Santiago, Chile, 2Microbiology & Molecular Genetics, Pontificia Universidad Católica de Chile, Santiago, Chile, 3Dept. of Biological Chemistry, Faculty of Pharmaceutical Sciences, Toyoa Medical and Pharmaceutical University, Toyoa, Japan

Peroxisomes are thought to be formed by division of pre-existing peroxisomes after the import of newly synthesized proteins. In contrast to this model, it has been recently suggested that the peroxisomes are formed by division of pre-existing peroxisomes after the import of newly synthesized proteins. In contrast to this model, it has been recently suggested that the endoplasmic reticulum (ER) provide an alternative de novo mechanism for peroxisome biogenesis in some yeast and animal cells. To test a possible role of the ER in peroxisome biogenesis in mammalian cells, we evaluated the biogenesis of three peroxisomal membrane proteins (PMPs): ALDR (adrenoleukodystrophy related protein), PMP70 and Pex3 in mammalian cells. We constructed chimeric genes encoding the fusion protein of these 3 PMPs and green fluorescent protein (GFP) and transiently transfected these genes to CHO and human cells. We used wild control cells and peroxisomal biogenesis mutant CHO cells and human fibroblasts, in which normal peroxisomes were replaced by peroxisomal membrane ghosts. The expressed proteins were targeted to peroxisomes and peroxisomal ghosts correctly in the presence or absence of Bre6/kin A, a drug known to block the transit between the ER and Golgi apparatus. In addition, the number of normal peroxisomes, which the expressed proteins targeted, were essentially the same in both Bre6/kin A treated and untreated control cells. We also constructed a chimeric gene fusing the coding region of the ALDR gene, carrying an ER retention signal (DEKKMP) to the GFP gene. We transfected this gene to control cells and the fused protein was normally targeted to peroxisomes. We also tested the effect of different temperatures on the targeting of PMP-GFP proteins and found that these fused proteins are normally targeted at 10 and 15°C in control cells. These results suggest that ER and the classical ER-Golgi pathway does not play a major role in the biogenesis of mammalian PMPs.
Mechanism for the Coordination of Peroxisome Growth and Division
C. Gregg, T. Guo, T. Beukh-Viner, A. Goldberg, S. Bourque, P. Kryakov, F. Bama, K. Hung Yeung San, C. Sison, J. Solomon, V. Wong, V. I. Titorenko; Biology Department, Concordia University, Montreal, PQ, Canada
During the cell cycle, organelles must double in size and divide, in order to be accurately partitioned during cell division and inherited by the daughter cells. We have identified an unusual mechanism for the coordination of organelle growth and division in the yeast Yarrowia lipolytica. Yeast peroxisomes do not grow and divide at the same time. The growth of immature peroxisomal vesicles, which is accomplished by the stepwise import of matrix proteins, and their development into mature peroxisomes occurs before completely assembled mature peroxisomes undergo division. The division of immature peroxisomal vesicles is negatively regulated by Pex16p, a protein that binds lysophosphatidic acid (LPA) in the inner membrane leaflet of the vesicles. The binding of Pex16p to LPA prevents the formation of diacylglycerol (DAG), a particularly potent inducer of negative curvature and membrane bending, in a membrane-associated biosynthetic pathway. The stepwise import of distinct subsets of matrix proteins into different immature intermediates along the peroxisome assembly pathway causes the redistribution of a peroxisomal protein, acyl-CoA oxidase (Aox), from the matrix to the membrane. A significant redistribution of Aox occurs only in mature peroxisomes. Inside mature peroxisomes, Aox interacts with Pex16p. This interaction between Aox and Pex16p greatly decreases the affinity between Pex16p and LPA, thereby allowing LPA to enter the biosynthetic pathway leading to the formation of DAG in the inner membrane leaflet. The subsequent spontaneous movement of DAG into the outer leaflet promotes the reorganization of the bilayer configuration of the membrane and recruits the dynamin-like GTPase Vps1p to the cytosolic face of the peroxisomal surface. A peroxisome contains a distinct set of peroxisomal membrane proteins, Vps1p, and several actin cytoskeletal proteins is then assembled on the peroxisomal surface. This protein team promotes membrane scission and fission, executing the terminal steps of peroxisome division.

Global Analysis of Kinase and Phosphatase Function in Peroxisome Biogenesis in Yeast
B. Knoblach, F. D. Mast, C. Dobson, R. A. Rachubinski; Cell Biology, University of Alberta, Edmonton, AB, Canada
Compartimentalization of biochemical functions in membrane-bound organelles, an evolutionary hallmark of eukaryotic cells, concentrates enzymatic reactions within multiprotein complexes surrounded by or embedded in two-dimensional membranes. The spatial separation of biochemically distinct organelles provides a level of control unavailable to the prokaryotic cell. How the cell orchestrates the biogenesis of its organelles remains an open question of outstanding importance. Yeast peroxisomes constitute an ideal system to study organelle biogenesis, since their assembly is rapidly affected by changes in extracellular nutrients, and they are non-essential as long as cells are maintained under conditions not requiring their biochemical activity. They arise through the coordinated expression of ~26 PEX genes encoding peroxins, the organizers of peroxisomal membrane formation, matrix protein import, and organelle division. Here we present a genome-wide analysis of kinases and phosphatases affecting peroxisome biogenesis in baker’s yeast, Saccharomyces cerevisiae. Peroxisome formation was evaluated in a collection of 241 kinase and phosphatase gene deletion strains for functionality as measured by growth on myristate plates, the metabolism of which requires functional peroxisomes, and in the kinetics of its induction as measured by the appearance of peroxisomal thiolase chromosomally tagged with GFP in confocal fluorescence time-course microscopy. Based on over 3,600 quantitative descriptors, we categorized the strains into seven phenotypically distinct groups. Analysis of additional peroxisomal markers revealed that distinct regulatory mechanisms exist for different subsets of peroxisomal proteins. These mechanisms occur at both the transcriptional and post-transcriptional levels. Nutrient-dependent shuffling of several kinase and phosphatase effectors among the cytosol, nucleus, and peroxisome suggests underlying feedback mechanisms that control peroxisome biogenesis. We propose a model wherein the peroxisome itself temporally and spatially orchestrates the signaling molecules necessary for its formation, maintenance, and proliferation. This study represents, to our knowledge, the first global investigation of kinase and phosphatase activity in a complex biological process.

Species-specificity and Peroxisome Inducers Determine the Requirement of Sterol Glucoside for Pexophagy in Yeasts
T. Y. Nazarko,1,2 A. S. Polupanov,2 R. B. Manjithaya,1 A. A. Sibirny,2 S. Subramani1; 1Section of Molecular Biology, University of California, San Diego, La Jolla, CA, 2Department of Molecular Genetics and Biotechnology, Institute of Cell Biology, National Academy of Sciences of Ukraine, Lviv, Ukraine
Sterol glucosyltransferase, Ugt51/Atg26, is essential for degradation of methanol-induced peroxisomes of Pichia pastoris by both micro- and macropexophagic modes during glucose and ethanol adaptation, respectively. However, the role of the protein in pexophagy in other yeasts remains unclear. We show that glucose-induced degradation of either oleate- or amine-induced peroxisomes in Yarrowia lipolytica is a slow process that is completely independent of Atg26. As in Y. lipolytica, oleate- and amine-induced peroxisomes of P. pastoris were degraded by macropexophagy after the transfer of cells to glucose, but with the slow and high rates, respectively. PrAtg26 was not essential for these processes either. However, the rates of degradation of oleate- and amine-induced peroxisomes in P. pastoris were reduced in the absence of Atg26. Our comparative analysis of atg26 mutants in different yeasts suggests that P. pastoris specifically utilizes ergosterol glucoside to enhance the degradation of methanol-, oleate- and amine-induced peroxisomes. However, methanol-induced peroxisomes of P. pastoris apparently have lost the redundant ability to be degraded without the function of Atg26.

Mxr1p Up-regulates and Co-operates with Mpp1p to Transactivate Methanol-responsive Genes in Pichia pastoris
M. Yan, S. Subramani; Section of Molecular Biology, Division of Biological Sciences, University of California at San Diego, La Jolla, CA
P. pastoris Mxr1p is a transcription factor required for the induction of peroxisomal proteins necessary for the utilization of methanol and oleate as carbon sources (Lin-Cereghino GP et al, 2006). How the constitutively expressed Mxr1p activates carbon source-specific genes remains unknown. Here we show that in mex1Δ cells there is no expression of Mpp1p, a methanol-specific transcription factor first described in Hansenula polymorpha (Leao-Helder AN et al, 2003). In wild-type cells, Mpp1p is strongly induced by methanol and localized to nucleus, but its induction disappears in mex1Δ cells and the cells fail to grow on methanol. On the other hand, mpp1Δ cells have normal Mxr1p and grow normally in oleate. This indicates that MPP1 is one of the methanol-specific downstream genes of MXR1. Over-expression of one protein in the absence of the other restores alcohol oxidase (AOX1) expression partially, suggesting that cooperation between Mxr1p and Mpp1p exists at the level of the AOX1 promoter. We further found a 16 bp negative regulation site in the AOX1 5′ flanking region, which associates with (an) unknown repressor protein(s). The association of the repressor(s) with this site is reduced in methanol and is dependent on Mpp1p. The 16 bp consensus site is also found in other methanol-responsive genes such as dihydroxyacetone synthase (DMA5). We conclude that Mxr1p up-regulates Mpp1p and then co-operates with Mpp1p to transactivate methanol-inducible genes, partially by removing repressors.

Disturbed Regulation of SREBP/Insig Genes in Peroxisome-deficient PEX2 Zellweger Mice
W. J. Kovacs,1,2 K. N. Taps,3 J. E. Shackelford,2 M. J. Richards,3 S. J. Fissler,2 P. L. Faust,4 S. K. Krisans2; 1Anatomy & Cell Biology II, Justus Liebig University Giessen, Giessen, Germany, 2San Diego State University, San Diego, CA, 3Saint Louis University School of Medicine, St. Louis, MO, 4Columbia University, New York, NY
The marked deficiency of peroxisomal organelle assembly in the PEX2−/− mouse model for Zellweger syndrome and subsequent disturbed cholesterol homeostasis provides a unique opportunity to gain new insights into the regulation of cholesterol metabolism. Sterol regulatory element binding proteins (SREBPs) have been established as transcriptional regulators of lipid synthesis and Insig proteins are essential elements of the feedback regulation of cholesterol synthesis. Peroxisome-deficient PEX2 Zellweger mice exhibit decreased liver cholesterol levels (40%) in conjunction with increased hepatic and extrapituitary cholesterol biosynthesis. The treating PEXX− mice with oral bile acids prolonged postnatal survival and normalized hepatic and plasma total cholesterol levels. However, the mRNA levels for SREBP-2 and SREBP-2 target genes in lipogenic pathways were still significantly increased in the liver of bile acid-fed PEXX− mice despite normal hepatic cholesterol levels. The amount of HMGC-CoA reductase protein, the rate-limiting enzyme in the cholesterol biosynthetic pathway, was highly elevated in the liver of bile acid-fed PEXX− mice apparently owing to the increased expression and failure to accelerate repression of the enzyme. The current results also reveal a dysregulation of SREBP1c, Insig-2a and -2b expression and a previously unsuspected regulation of Insig-2b. Thus, peroxisome deficiency widely disturbs cholesterol homeostasis in mice by affecting the synthesis, transcriptional regulatory control, and cholesterol levels in plasma and tissues, and only some of these features are favorably altered by bile acid treatment.
The Role of Peroxoxins in the Development of Xenopus laevis

C. A. Cooper,1 P. A. Walton,2 S. Damjanovski;1 1Department of Biology, University of Western Ontario, London, ON, Canada, 2Department of Anatomy and Cell Biology, University of Western Ontario, London, ON, Canada

Peroxoxins are ubiquitous single membrane-bound organelles essential to eukaryotic cell function. They facilitate the chemical breakdown of fatty acids through the process of β-oxidation, and the elimination of hydrogen peroxide through the use of catalase. Of particular interest are the peroxoxins termed Pex proteins. These proteins have several functions including their involvement in the formation of peroxoxins and the recruitment of essential proteins to both the matrix and membrane of peroxoxins. Currently, research focuses on Pex proteins in human cell culture complementation studies to elucidate their function and protein interactions. The present study focuses on the role of peroxoxins in development, through the use of the model system Xenopus laevis. Full-length coding sequences for Xenopus peroxoxin proteins were identified, cloned and analyzed for sequence similarities with other species. Sequence analysis suggests that Xenopus peroxoxin function mimics that of mammalian function. In order to understand the function of peroxoxin proteins in development, the expression of key proteins was quantified during development through the use of RT-PCR. These data indicate that peroxoxin proteins are present in the egg prior to mid-blastula transition, which marks the initiation of the zygotic genome. Also, Pex proteins exhibit different expression patterns suggesting a dynamic need for certain peroxoxin events over the course of early Xenopus development. To test for the function of catalase in development, catalase was inhibited through microinjection of aminonitroazole, after which hydrogen peroxide levels were examined. Finally, the presence of peroxoxins was traced in early development by microinjecting GFP tagged with a peroxoxin targeting signal. Embryos were then fixed and sectioned to visualize peroxoxins at the sub-cellular level. These results suggest roles for peroxoxins in the cellular processes involved in the development of animals, as well as in normal cell function.

Biochemical and Morphological Characterization of Peroxoxins during Postnatal Development of the Mouse Brain

W. J. Kovacs, I. Neubert, B. Ahlemeyer, E. Baumgart-Vogt; Anatomy & Cell Biology II, Justus Liebig University Giessen, Giessen, Germany

The importance of peroxoxins in cellular metabolism is emphasized by the devastating consequences of peroxoxin deficiency in patients with peroxoxosomal biogenesis disorders (e.g. Zellweger syndrome). Zellweger syndrome patients exhibit neurological deficits and severe hypo- or demyelination of which completely unknown. Unfortunately, very little is known about the exact distribution and physiological role of peroxoxins in the brain. With the methods used in former publications, an increase in the number of peroxoxins in the rodent brain was observed in the first 3 weeks after birth, whereas hardly any peroxoxins were detected in the brain of adult rodents. In this study, enriched peroxoxin fractions were prepared from the cerebral cortex, hippocampus, and medulla oblongata of 2-, 15- and 49-day-old C57Bl/6J mice. The specific activity of the peroxoxosomal marker enzyme catalase was highest in brain regions from 2-day-old mice and significantly decreased in 15- and 49-day-old mice. Western blots of the enriched peroxoxin fractions were probed with antibodies against peroxoxin matrix (catalase, acyl-CoA oxidase 1, thiolase A) and membrane proteins (PMP70, Pex14p, Pex13p) as well as specific markers for distinct cell types of the CNS. Highest levels of peroxoxin proteins were detected in all brain regions of P2-mice. Double-immunofluorescence preparations of paraffin sections of distinct brain regions of P2-P15/P28 mice, probed with all antibodies, corroborated the biochemical data. All morphological data obtained with P2-brain sections were confirmed in primary cultures of neurons and astrocytes from newborn mice. Our data clearly show age-dependent differences in distribution and protein levels of catalase, peroxoxosomal β-oxidation enzymes, and peroxoxosomal membrane proteins in distinct brain regions. These results indicate the presence of distinct peroxoxosomal populations with different enzymatic compositions during postnatal development of the brain, suggestive for differences in peroxoxin function both in distinct cell types as well as during development.

Modifications of Peroxoxin Proteins Induced by Metal-catalyzed Oxidation

Y. Kwak, R. Donaldson; Biological Science, George Washington University, Washington, DC

Glyoxysomes are specialized peroxoxins present in oil-storing seeds like castor beans. Glyoxysomes contain glyoxylate cycle enzymes such as isocitrate lyase (ICL), malate synthase, and malate dehydrogenase. Hydrogen peroxide (H₂O₂), a reactive oxygen species (ROS), is produced in peroxoxins and can damage DNA, lipids, and protein. Peroxoxins in most eukaryotic cells, (yeast, mammals) produce ROS which could result in protein oxidation. Oxidized proteins have been implicated in the aging process, cancer, neurodegenerative diseases such as Alzheimer’s and Parkinson’s. Because ROS can induce molecular damage, cells have active antioxidant systems such as catalase (CAT) in peroxoxose to scavenge ROS. Glyoxysomes were isolated from castor beans and incubated with Ascorbate/Cu(II), or Fe(III)/H₂O₂ to induce metal-catalyzed oxidation (MCO). MCO results in the introduction of carbonyl groups into certain amino acids. The activity of ICL was decreased by exposure to these MCO conditions. Carbonyl moieties in protein side chains were derivatized with 2,4-dinitrophenylhydrazine (DNPH) or Biotin hydrazine, separated by SDS gel electrophoresis, and the protein bound hydrazones or Biotinhyrazones were detected in Western Blots using a DNP-specific antibody or Avidin which reacted to the expected carbonyl structure. The activity of ICL was increased by exposure to metal-free conditions. Carbonyl moieties in protein side chains were derivatized with 2,4-dinitrophenylhydrazine (DNPH) or Biotin hydrazine, separated by SDS gel electrophoresis, and the protein bound hydrazones or Biotinhyrazones were detected in Western Blots using a DNP-specific antibody or Avidin which revealed that ICL was oxidized. The proteins were separated by SDS-PAGE, trypsin digested and analyzed by MALDI-TOF-mass spectrometry revealing monoisotopic peaks at m/z 524, 529, 530, 535, 540, 544, and 0.806, which is consistent with the expected mass difference arising from biotinylation, suggest a site of oxidation. The locations of peptides are mapped to the 3D structure of a homologous ICL from Eminicella nidulans.

A Role for Endosomal Soling in the Adenosine A2 Receptor-mediated Suppression of Endotoxin (LPS)-induced TNFα Expression in Macrophages

J. A. Quipe,1 G. Hasko,2 S. J. Leibovich; 1Cell Biology and Molecular Medicine, Graduate School of Biomedical Sciences, UMDNJ, Newark, NJ, 2Surgery, New Jersey Medical School, UMDNJ, Newark, NJ

Macrophages are key cells involved in host defense. Toll-like receptors (TLRs) are innate immune receptors expressed by macrophages, and TLR ligation activates signaling pathways that result in expression of pro-inflammatory cytokines such as TNFα. Macrophages also express adenosine receptors (ARs). AR Ligation generally induces an anti-inflammatory response, down-regulating expression of inflammatory cytokines such as TNFα. We have previously reported that stimulation of macrophages with TLR 2,4,7 or 9 agonists with adenosine A2R agonists such as A230 expression, but strongly increased TNFα expression, and on the inhibition of TNFα expression by macrophages. The effects of various inhibitors of endosomal signaling (sucrose, ammonium chloride, chloroquine, bafilomycin-A1, concanamycin-A) on LPS-induced TNFα expression, and on the inhibition of TNFα expression by A2R agonists were examined. Macrophages were pre-incubated with endosomal inhibitors for 30 minutes, and were then treated overnight with LPS (100ng/ml) (TLR4 agonist), R837 (1μg/ml), LPS/NECA, or R837/NECA, in the presence of endosomal inhibitors. Conditioned media were then analyzed for TNFα by ELISA. Ammonium chloride, chloroquine and sucrose treatment had little effect on LPS-induced TNFα expression and did not affect the NECA-induced suppression of TNFα expression. Bafilomycin A1 (50nM-1μM) and concanamycin-A (200nM-2μM), however, had little effect on LPS-induced TNFα expression and significantly increased TNFα production in cells treated with LPS and NECA. Bafilomycin-A1 and concanamycin-A are inhibitors of v-ATPases that regulate vacuolar H+ content. These observations suggest an important role for endosomal signaling in the regulation of A2R-mediated suppression of LPS-induced TNFα expression.

Macrophages Express Granzyme B in Lesion Areas of Atherosclerosis and Rheumatoid Arthritis

W. J. Kim,1 H. Kim,1 Y. M. Kang,2 J. E. Park,3 W. H. Lee; 1Department of Genetic Engineering, School of Life Sciences and Biotechnology, Kyungpook National University, Daegu, Republic of Korea, 2Rheumatology Division, School of Medicine, Kyungpook National University, Daegu, Republic of Korea, 3Cardiology Division, Samsung Medical Center, Sungkyunkwan University School of Medicine, Seoul, Republic of Korea

Granzyme B is a serine protease that is highly expressed in cytotoxic T cells (CTL) and natural killer (NK) cells. Granzyme B is a major mediator of the cytotoxic immune response by inducing target cell death when internalized in the presence of perforin. Recently, several studies have focused on another role of granzyme B, which is extracellular matrix (ECM) remodeling through degradation of ECM proteins. These observations suggest that granzyme B can be expressed by various cell types other than CTLs in tissues. In order to investigate the expression pattern of granzyme B in lesion areas of atherosclerosis and rheumatoid arthritis, we performed immunohistochemistry and in situ hybridization analyses of human atherosclerotic plaques and synovial tissues of rheumatoid arthritis- and osteoarthritis-joints. In atherosclerotic plaques, granzyme B was expressed in macrophages rich areas such as boundary between media and intima, areas around necrotic core, and shoulder regions. In synovial tissues of rheumatoid arthritis-joints, the expression of granzyme B was detected in T-cell rich follicular areas. Additionally, the expression of granzyme B was strongly observed in the lining layers where majority of the cells are macrophages and in perivascular areas where macrophages and small number of

2006 ASCB Annual Meeting Abstracts

230
lymphocytes were mixed to form diffuse cellular aggregates. Relatively less granzyme B-positive cells were detected in the lining layers of osteoarthritic synovium. These observations indicate that macrophages would be added to the list of cells expressing granzyme B in human inflammatory diseases and that granzyme B may play roles in various inflammatory processes mediated by macrophages.

A Role for Phosphatidylinositol-Specific Isomorphs of Phospholipase C (PLC) in the Switch of Macrophages from an Inflammatory to an Angiogenic Phenotype Induced by Adenosine A2A Receptor (A2AR) and Toll-like Receptor 4 (TLR4) Agonists

S. Grinberg, 1 S. J. Leitovich; 1 Cell Biology & Molecular Medicine, Graduate School of Biomedical Sciences, UMDNJ, Newark, NJ, 2Cell Biology & Molecular Medicine, New Jersey Medical School, UMDNJ, Newark, NJ

We have previously shown that co-stimulation of TLR2, 4, 7 or 9 and adenosine A2AR synergistically up-regulates VEGF expression in macrophages, while down-regulating TNFα expression. Treatment of murine macrophages with U73122, an inhibitor of phosphatidylinositol-specific PLC (PI-PLC), strongly promotes expression of VEGF in the presence of CGS21680 or NECA (A2AR agonists), while simultaneously down-regulating endotoxin (LPS)-induced TNFα expression. This suggests that the synergistic pathway induced by ligation of A2AR and TLR4 involves regulation of PLC. To determine whether LPS or NECA modulate PLCs, their effects on mRNA levels of the PLCs were determined by quantitative RT-PCR. Expression of PLCs β1, β2, β3, β4, γ1, γ2 and δ1 proteins were determined by Western analyses. LPS (100ng/ml) induced a rapid and selective decrease of PLCβ2 mRNA in murine macrophages. PLCβ2 protein levels were decreased within 1 hr of LPS treatment, and remained low for at least 26 hours. PLCβ2 protein levels were depleted by 8 hours, and remained low for at least 30 NECA alone had little effect on PLCβ2 levels, and did not affect the depletion of PLCβ2 by LPS. Since U73122 is a relatively specific PLCβ2 inhibitor, we used sRNA oligonucleotide constructs to specifically deplete PLCβ2 in RAW264.7 macrophage-like cells, and obtained ~70% depletion at both mRNA and protein levels. Treatment of these depleted cells with NECA resulted in the strong up-regulation of VEGF expression. Thus, both depletion of PLCβ2 by sRNA, and inhibition of PLCβ2 by U73122 sensitize macrophages to subsequent stimulation by A2AR agonists with promotion of VEGF expression. We propose that LPS down-regulates PLCβ2 expression in macrophages, thus playing a role in the regulation of VEGF expression by A2AR agonists.

Vascular Endothelial Growth Factor (VEGF) Expression by Macrophages Is Synergistically Up-Regulated by Adenosine A2A Receptor Agonists and Endotoxin via the Hypoxia Response Element (HRE) in the VEGF Promoter

M. Ramasathan, G. Pinal-Enfied, I. Hae, S. J. Leitovich; Cell Biology & Molecular Medicine, New Jersey Medical School, UMDNJ, Newark, NJ

VEGF expression by macrophages is regulated by micro-environmental factors. Adenosine A2A receptor (A2AR) agonists together with agonists of Toll-like receptors (TLRs) 2, 4, 7 and 9 synergistically induce VEGF expression by macrophages. We now show that the TLR4 agonist Escherichia coli LPS and the A2AR agonists NECA and CGS21680 synergistically augment VEGF gene transcription. This transcriptional activation requires the hypoxia response element (HRE) in the VEGF promoter. Macrophages were treated with LPS and NECA or CGS21680, and steady-state levels of VEGF mRNA were measured. Strong induction (~ 10-fold) of VEGF mRNA was observed by 12 h. To determine if this induction was at the transcriptional level, RAW 264.7 cells (a macrophage-like cell line) were transiently transfected with pVEGF-Luc, a VEGF-promoter luciferase reporter construct. LPS/NECA treatment of the transfectants strongly induced VEGF promoter activity. Transfections with the VEGF promoter-luciferase constructs containing deletions of specific cis-elements showed that the HRE region of the VEGF promoter was essential for its activation by LPS/NECA. Deletion of the putative NFkB-binding region did not affect the LPS/NECA-induced activation of the VEGF promoter, suggesting that NFkB activation is not required for induction of VEGF expression. Since the HRE region is essential for hypoxia-induced VEGF gene expression via binding of the HIF transcription factor complex, we examined whether stimulation of macrophages with LPS/NECA induces HIF-1α expression, thus activating the VEGF promoter via the HRE. HIF-1α mRNA levels were significantly increased in LPS/NECA-treated macrophages, and this increase preceded the induction of VEGF mRNA. Further, LPS/NECA treatment of macrophages caused an increase in HIF-1α mRNA binding activity. An NFκB inhibitor, Bay 11-7085, blocked LPS-induced TNFα, but had little effect on LPS/NECA-induced VEGF expression. These data indicate that LPS/NECA-induced expression of the VEGF gene critically involves hypoxia-induced HIF transcriptional activity, while NFκB activation does not play a significant role in this induction.

1252

Low Intensity Pulsed Ultrasound Stimulates Macrophage Phagocytosis via Multiple Signaling Pathways

S. Zhou,1 A. Schmelz, Y. Li, T. Seufferlein,3 H. Gross,1 M. G. Bachem 1; 1Clinical Chemistry, University Hospital, Ulm, Germany, 2Trauma Surgery, University Hospital, Ulm, Germany, 3Internal Medicine, University Hospital, Ulm, Germany

We investigated whether low-intensity-pulsed-ultrasound (US) activates macrophages (Ma) and stimulates phagocytosis of E.coli. In addition we studied relevant signaling mechanism induced on the expression of several PLC isoforms were tested. Expression of mRNA for PLCs β1, β2, and β3 were determined by quantitative RT-PCR. Expression of PLCs β1, β2, β3, β4, γ1, γ2 and δ1 proteins were determined by Western analyses. LPS (100ng/ml) induced a rapid and selective decrease of PLCβ2 mRNA in murine macrophages. PLCC2 protein levels were decreased within 1 hr of LPS treatment, and remained low for at least 26 hours. PLCC2 protein levels were depleted by 8 hours, and remained low for at least 30 NECA alone had little effect on PLCC2 levels, and did not affect the depletion of PLCC2 by LPS. Since U73122 is a relatively specific PLCC2 inhibitor, we used sRNA oligonucleotide constructs to specifically deplete PLCC2 in RAW264.7 macrophage-like cells, and obtained ~70% depletion at both mRNA and protein levels. Treatment of these depleted cells with NECA resulted in the strong up-regulation of VEGF expression. Thus, both depletion of PLCC2 by sRNA, and inhibition of PLCC2 by U73122 sensitize macrophages to subsequent stimulation by A2AR agonists with promotion of VEGF expression. We propose that LPS down-regulates PLCC2 expression in macrophages, thus playing a role in the regulation of VEGF expression by A2AR agonists.

Microtubule Dynamics in Fcgamma Receptor-mediated Phagocytosis

S. Pang,1 N. Qureshi, R. E. Harrison; 2 Laboratory of Medicine and Pathobiology, University of Toronto, Scarborough, ON, Canada, 2Department of Life Sciences, University of Toronto, Scarborough, ON, Canada

Phagocytosis is a cellular process by which particulate matter of >0.5μm is internalized. In animals, phagocytosis serves as a defence mechanism against foreign organisms. Macrophages are professional phagocytes and serve as "sentinels" in various tissues. IgG-coated pathogens are recognized by Fcgamma receptors (FcgammaRs) on patrolling macrophages. A signalling cascade ensues whereby a phagocytic cup form as pseudopods extend around the pathogen. The pathogen is internalized into a membrane-bound organelle termed the phagosome. A series of fusion events with endosomes and lysosomes occur as the phagosome travels towards the lysosome, ultimately acidifying the vesicle and destroying the pathogen. Microtubules (MTs) have been implicated in the retrograde transport of the phagosome and mediating lysosome fusion with the phagosome. A class of MT-associated proteins (MAPs), known as MT-plus (+)-end-tracking proteins (+TIPs), travel exclusively on MT (+) ends. We are currently using CLIP-170, the prototypical +TIP, to "track" (+) ends of MTs in mouse RAW 264.7 macrophages, CHO2A FcgammaR engineered phagocytes, and HeLa cells. Live imaging microscopy was done to visualize the dynamics of CLIP-170 and MTs in macrophages co-transfected with beta-tubulin-RFP and CLIP-170-GFP. We examined MT dynamics in resting macrophages and those undergoing phagocytosis. TIRF was used to visualize GFP-CLIP-170 at the plasma membrane during "frustrated phagocytosis" assays. Results indicate most MTs are dynamic in resting macrophages with CLIP-170 tracking the MT (+) ends. During phagocytosis, MTs and CLIP-170 were seen to co-localize to the forming phagocytic cup. In conclusion, MT (+) ends are targeted towards the phagocytic cup and CLIP-170 locates to MT (+) ends during phagocytosis.

Extracellular ATP-induced Intracellular Ca2+ Dynamics without Following Normal Exocytosis

Y. Satoh, T. Nakamura, M. Osakada, T. Sano; Histology (Anatomy2), Iwate Medical University, Morioka, Japan

[Background/Aim] Adenosine trisphosphate (ATP) is a fundamental transmitter in various tissues, as well as intracellular energy source. Previous studies indicated that ATP induced histamine discharge from mast cells which possess many secretory granules, and the discharge was simply thought as exocytotic secretion. It is well known that intracellular Ca2+ ([Ca2+]i) increase as a key event in exocytosis in various cells including mast cells, but nobody observed whether ATP induces [Ca2+]i changes of mast cells, and whether ATP-induced histamine discharge is true exocytosis. [MATERIALS AND METHODS] Rat peritoneal mast cells were collected and loaded with Indo-1/AM or Fluo-4/AM for measuring of [Ca2+]i. The exocytosed granule matrices

231
were stained by sulforhodamine B (SFRMB). The fluorescent images of the cells stimulated by ATP and/or compound 48/80 were consecutively acquired by confocal microscopy (Nikon RCM/Ab or Zeiss 510). [Results] ATP and ADP induced [Ca^{2+}], increase but not exocytosis. Adenosine and AMP has no effect, indicating that ATP-induced changes were mediated by P2 receptors, but not P1. UTP (P2Y2, 4, 6 agonist) did not induce [Ca^{2+}] changes, and removing of extracellular Ca^{2+} abolished ATP-induced [Ca^{2+}] changes. These suggested that most cells possess ion channel type receptors responding to extracellular ATP (i.e., P2X). DBzATP (P2X7 agonist) elicited prominent [Ca^{2+}], increase, but not β,γ-meATP (P2X1, 3 agonist) did not any responses. Intracellular non-exocytosed granule matrices were stained by SFRMB by high dose of DBzATP, indicating increasing plasma cell membrane permeability. Interestingly, after the ATP-induced [Ca^{2+}] changes, compound 48/80 induced exocytosis were inhibited. [Conclusions] ATP-induced histamine discharge is not physiological exocytosis, but pharmaco-pathological conditions in vitro. In tissue, ATP from nerve fibers or other damaged cells may inhibit secretory activity of mast cells.

Role of Reactive Oxygen Species in Leukocyte Transendothelial Migration
J. K. G. Gruenewald, A. J. Ridley; Ludwig Institute for Cancer Research, London, United Kingdom

Normal cellular redox homeostasis is a balance between the generation of free radicals or other reactive oxygen species (ROS) and the antioxidant response. Smoking, alcohol, poor diet as well as environmental pollution can lead to an imbalance and an increase of oxidative stress. To investigate the effect of ROS on leukocyte transendothelial migration, we set up an in vitro system as a model for transmigration using the human monocytic leukaemia cell line THP-1 and human umbilical vein endothelial cells (HUVECs). The effect of hydrogen peroxide (H_{2}O_{2}), applied extracellularly to THP-1 cells, on transendothelial migration was investigated. A significant decrease of transendothelial migration is induced by increasing H_{2}O_{2} levels and also by altering intracellular ROS levels using the NADPH oxidase stimulus phorbol 12-myristate 13-acetate (PMA) and the catalase inhibitor 3-amino-1,2,4-triazole (AT). This decrease was not observed in an endothelial cell-free transwell assay pointing to a transmigration defect specific for the interaction between leukocytes and endothelial cells. H_{2}O_{2}-treated THP-1 cells exhibit higher motility on HUVECs, whereas their adhesion on substrates such as VCAM-1, fibronectin and ICAM-1 is unaltered. We have tested the effects of H_{2}O_{2} on several signalling molecules implicated in cell migration, and have observed a change in the levels and activity of the small GTPase RhoA, which has previously been shown to be important for transendothelial migration. Altogether, our results suggest that ROS have multiple effects on THP-1 cell migration. We therefore propose that ROS play a regulatory role in leukocyte transendothelial migration.

Expression Profile of RhoGTPases and RhoGEFs during RANKL-stimulated Osteoclastogenesis: Identification of Essential Genes in Osteoclasts
H. Buraizer, S. Stephens, S. Ory, P. Forti, N. Morrison, A. Blangy, "GRDM, CNRS FRE2953, Montpellier, France; School of Medical Science, Griffith University, Queensland, Australia

Introduction. During the process of differentiation, adhesion to the bone matrix or osteolysis, the actin cytoskeleton of osteoclasts undergoes profound reorganization. RhoGTPases are key regulators of actin dynamics. They control cell adhesion, migration and morphology through their action on actin cytoskeleton. In mouse, there are 18 low molecular weight RhoGTPases. They regulate cell adhesion, migration, and have observed a change in the levels and activity of the small GTPase RhoA, which has previously been shown to be important for transendothelial migration. Altogether, our results suggest that ROS have multiple effects on THP-1 cell migration. We therefore propose that ROS play a regulatory role in leukocyte transendothelial migration.

IL-8 Induced Adhesion of Neutrophils Is Reduced by Fas Ligand (FasL) before Loss of CD47 and Phosphatidylserine Externalization Mark the Cells as Apoptotic
B. Hendey, P. Sagi, S. Lidder; Pharmacology, Rush University Medical Center, Chicago, IL

Previously work indicated that either Fas activation or rotterlin reduced treatment PMA stimulated neutrophil adhesion in a non-additive fashion. Fas activation and rotterlin also reduced the membrane localization of PKC-delta suggesting that Fas activation reduces adhesion by changing the localization of PKC-delta. Interestingly, the reduction in adhesion occurred before the cells could be recognized as apoptotic via Phosphatidylserine (PS) externalization. Since PMA is not a physiological agonist, adhesion in response to IL-8 and IMLP was examined to determine if adhesion and PKC-delta localization were sensitive to Fas activation. Treatment with either FasL or rotterlin, reduced IMLP-induced neutrophil adhesion but neither agent had an effect on IMLP mediated adhesion. Triton soluble membrane fractions were run using SDS-PAGE and Western blots were analyzed to determine if FasL affected membrane association of PKC-delta. FasL reduced the membrane localization of PKC-delta in response to either IL5 or IMLP. To determine if the reduction in IL-8 stimulated adhesion occurred at a time before the cells could be recognized as apoptotic, we also measured the effect of FasL on IMLP and IL8-stimulated neutrophils on subsequent PS externalization and CD47 expression. While 1 hr of Fas activation reduced adhesion, there was no significant effect of Fas activation on PS externalization. Likewise, at 2 hrs no effect of FasL on CD47 expression, a marker that has recently been shown to function as a “don’t eat me signal”. Only after 3 hrs of Fas activation would a fraction of the PMN be recognized as apoptotic via both loss of CD47 and externalization of PS. These results suggest that FasL exposure would decrease neutrophil adhesion in response to an inflammatory stimulus such as IL-8 before they would be recognized as apoptotic. However, the same FasL exposure would not reduce responsiveness to bacterial peptides.

Hematopoietic Cell Differentiation and Activation in Primary and Cultured Leukocytes
D. M. Fishwild, K. T. Tran; Applications Development, Guava Technologies, Hayward, CA

Cell differentiation and activation are complex processes generally believed to occur in a continuous fashion. However, techniques which monitor single cells rather than a population of cells often reveal these processes involve a series of discrete steps or switches. For example, as reported for promyelocytic precursor cells, HL60, stimulated with DMSO, differentiation to neutrophils occurs through a multi-step process in which cells are first primed and then differentiate by an all-or-none mechanism (Chang et al., BMC Cell Biology, 7:11; 2006). Using four-color flow cytometry, we extended these studies to examine the extra- and intracellular markers that correlate with these priming and differentiation steps. In addition, we examined the differences in expression of markers when HL60 cells were stimulated with PMA to induce differentiation to the monocytic lineage. Similarly, for primary leukocyte activation, the expression of such activation markers as CD25, CD69, CD38 and CD49a among others, can be tracked on individual cells and correlated with the cells’ proliferative capacity. Thus, four-color flow cytometry which can readily monitor differentiation and activation steps on a single cell level can better uncover the actual mechanisms involved in these complex processes than can analyses of populations of cells. This leads to a more complete understanding of the molecular mechanisms that control differentiation and maturation of hematopoietic cells crucial for the clinical manipulation of blood cell production.

Anti HLA Antibodies Treatment Precludes the Formation of Immunological Synapses and Rosettes between Macrophages and Lymphocytes
I. T. C. Novak, H. R. A. Cabral; 1 Institute of Cell Biology, National University of Cordoba-Argentina. Faculty of Medicine, Cordoba-Argentina, Argentina, 2Instituto de Biologia Celular, Cordoba, Argentina, 3Instituto de Biologia Celular, Univ Nac Cordoba, Argentina

An immunological synapse (IS) is formed when a T lymphocyte close adhered to an antigen-presenting cell (APC). We found that in cultures of autologous total human leukocytes, in which death of neutrophils occurs, macrophages and T lymphocytes form IS and rosettes (MLRs) -we considered a MLR-rosette when three or more T-lymphocytes are close adhered to the APC, in this case the macrophage (Am J Hematol 60: 285-8,1999). These phenomena are produced when the macrophages showed evidences of they phagocyting cell neutrophil materials. We included a step that consist in a centrifugation of the samples harvested from the cultures. The other known effects of Fas activation did not form IS or RMLRs. Macrophages present antigens to T helper lymphocytes trough their class II molecules . Here, we attempted to block the formation of IS and Rosettes RMLRs by means of anti HLA DR monoclonal antibodies. METHODOLOGY: Culture samples of human total leukocytes from 7 healthy donors were prepared at 48, 72 and 96 hours and submitted to anti HLA DR antibodies (Diatec, Norway) at a concentration of 15 micrograms/ml and incubated by 30 min. Then, we centrifuged the cells and prepared them as previously described. RESULTS: Nor IS neither rosettes were found in most of the samples

Generation of Suppressor CD8+ T Cells by Triggering 4-1BB

Y. Kim, B. Choi, W. Kim, W. Kang, B. Kwon

Immunology, Immunomodulation Research Center, Ulsan, Republic of Korea, 2LSU Eye Center, New Orleans, LA

A superantigen, staphylococcal enterotoxin A (SEA) is known to induce a strong proliferative response of both CD4+ and CD8+ T lymphocytes through a specific interaction with Vβ3 TCR. It has been reported that 4-1BB stimulation in vivo results in the suppression of SEA-specific CD4+ T cells, which is partially mediated by the increase of TGF-β-expressing CD8+ T cells. Since we previously found that the 4-1BB-mediated CD4+ T suppression was mediated by the indoleamine 2,3-dioxygenase (IDO) in collagen-induced arthritis, we investigated whether the anti-4-1BB-mediated CD4+ T suppression in vivo was dependent on the IDO. 4-1BB stimulation in vivo led to the induction of IDO in dendritic cells (DCs) and monocytes/macrophages stimulated by the disease, whose NADPH oxidase is inactive, suffer recurrent bacterial infections. Here, we test the hypothesis that the NADPH oxidase is present in NETs by immunofluorescence and confocal microscopy analysis. We also evaluate the production of reactive oxygen species (ROS) in NETs by chemiluminescence. We first show that NETs, detected with DAPI staining by immunofluorescence, are formed in neutrophils treated with LPS but not in unstimulated neutrophils. The use of poly-L-lysine at high concentrations was also effective for the development of NETs. NETs were effectively disassembled when neutrophils were treated with deoxyribonuclease (DNase) before or after stimulation. DNase treatment did not affect cell viability in neutrophils. The NADPH oxidase components p47-phox and p22-phox were clearly detected in NETs by immunofluorescence analysis. Co-localization of p47-phox and p22-phox in punctate structures was evident, suggesting that the NADPH oxidase could be assembled in the NETs. The kinetics of ROS production in response to heat-killed Gram positive and Gram negative bacteria was attenuated by treatment with DNase. This suggests that ROS production is decreased when NET assembly is prevented. Deficiency in Rab27a, an enzyme that regulates the Golgi organization, subcellular localization of paxillin, and actin cytoskeletal remodeling; all of which may need to be coordinately regulated during cell migration. To understand the physiological roles of GIT2, we here generate mice in which GIT2 gene is disrupted. We found that loss of GIT2 leads to an immunodeficient state, which is primarily due to the dysfunction of neutrophils. Loss of GIT2 causes impaired chemotactic directional sensing and hyperproduction of superoxide in GPCR-stimulated bone marrow neutrophils. We found that GIT2 is an essential component of the Gβγ-mediated directional sensing machinery, and is also necessary for suppressive control of the superoxide production. Moreover, GIT2 was found to be necessary for the proper orientation of superoxide production. Therefore, GIT2 links chemotactic directionality and proper production of superoxide, in quantity and in direction, in GPCR-stimulated neutrophils, and is hence important for innate immunity.

Neutrophil Directional Sensing and Superoxide Production Linked by GIT2

Department of Medical Sciences, National Defense Medical College, Saitama, Japan, 2Department of Molecular Pathology, RIKEN Kobe, Kobe, Japan, 3Graduate School of Biostudies, Kyoto University, Kyoto, Japan

Neutrophils play important roles in innate immunity and in initiation of an acute response to infection. During such responses, neutrophils are activated, move towards the site of inflammation and actively produce antimicrobial agents, including a number of reactive oxygen species (ROS). These ROS are first produced as superoxide anions by NADPH oxidase and are essential for the killing of invaders upon neutrophil phagocytosis. Neutrophil production of superoxide anions is tightly coupled with the activation state of neutrophils. Strict suppression of superoxide production in resting neutrophils is essential to prevent non-specific injury of blood vessel endothelial cells, tissues and organs. We have previously identified GIT family members of ADP-ribosylation factor (Arf) GTPase-activating proteins (GAPs), as binding proteins to an integrin-signaling protein, paxillin. By regulating Arf1 activity, we have shown that GIT2 has a potential role in regulating the Golgi organization, subcellular localization of paxillin, and actin cytoskeletal remodeling; all of which may need to be coordinately regulated during cell migration. To understand the physiological roles of GIT2, we here generate mice in which GIT2 gene is disrupted. We found that loss of GIT2 leads to an immunodeficient state, which is primarily due to the dysfunction of neutrophils. Loss of GIT2 causes impaired chemotactic directional sensing and hyperproduction of superoxide in GPCR-stimulated bone marrow neutrophils. We found that GIT2 is an essential component of the Gβγ-mediated directional sensing machinery, and is also necessary for suppressive control of the superoxide production. Moreover, GIT2 was found to be necessary for the proper orientation of superoxide production. Therefore, GIT2 links chemotactic directionality and proper production of superoxide, in quantity and in direction, in GPCR-stimulated neutrophils, and is hence important for innate immunity.

Role of Interferon Response Factor 8 (IRF8) in Development of Follicular Dendritic Cells of IRF8 Knock Out Mice

C. Qi, Laboratory of Immunopathology, NAID/NHLI Rockville, MD

Activated B cells rapidly expand and differentiate in germinal centers (GC). This activity is dependent on follicular dendritic cells (FDC) that trap immune complexes, present them to B cells and signal B cell resistance to apoptosis. FDC are dependent on CD40L+ T cells and LTα+ B cells for their development from non-hematopoietic cells in bone marrow. The transcription factor, interferon regulatory factor 8 (IRF8), regulates the differentiation and function of macrophages, granulocytes and other dendritic cells through activation or repression of target genes. IRF8 also affects B cells by activating transcriptional regulation of CDC20 and BCL6. To determine if IRF8 is involved in development and regulation of FDC, we used immunohistochemistry to study expression of IRF8 and other genes in spleens of wild type (IRF8+/+) and IRF8 knockout mice (IRF8−/−), comparing them for: GC and follicular structure; marginal zone (MZ) cells including MZ and macrophage-rich lymphocytes and sinus endothelial cells; extrafollicular myeloid cells; FDC; B-cells; and T-cells. Primary follicles of IRF8−/− mice exhibited markedly larger lymphocytes with increased total GC in IRF8−/− relative to wild type variable in size with a reduced density of lymphocytes and irregular distributions of FDC1+ FDC. In normal spleens, FDC of wild type mice were distributed by point counting at higher levels than FDC from knockout mice. The present findings suggest that IRF8 modulates certain features of GC FDC with the highest rate of apoptosis in follicles of IRF8 knockout mice implying that the ability of FDC to protect B cells from death is reduced. These results may have implications for understanding autoimmunity and B cell lymphomagenesis.

Protective Effect of Curcumin and Silibinin on Inflammatory Cell-mediated Hepatotoxicity

D. A. O. Clarke, E. Niam, D. Hill, Biology, Morgan State University, Baltimore, MD

The hepatotoxicity induced by Alpha-naphthylisothiocyanate (ANIT) in rodents is mediated by inflammatory cell infiltration and activation. This hepatotoxicity models that of drug-induced cholestasis in humans. Curcumin, a polyphenolic plant pigments characteristic to the tropical root Tumeric, has demonstrated anti-inflammatory and antioxidant activity. Silibinin, a component of polyphenolic flavinoid extracts from milk thistle, has also demonstrated anti-inflammatory and anti-oxidant activity. Because of the inflammatory cell-mediated hepatotoxicity of ANIT and the anti-inflammatory activity of both curcumin and silibinin the current study address the hypothesis that co-pretreatment with silibinin/curcumin affords protection against ANIT-induced hepatotoxicity. To substantiate this hypothesis, male Sprague Dawley rats were treated orally with silibinin (200-250 mg/kg) and curcumin (200-250 mg/kg) prior to treatment with ANIT (150-250 mg/kg). 24 hours after ANIT treatment, samples of rat livers and plasma were processed for analysis of hepatic injury. The histopathological analysis of ANIT-induced liver injury indicated a pronounced infiltration of inflammatory cells and overt hepatocellular necrosis. ANIT-induced liver injury was also manifested as significant elevations in plasma levels of liver enzymes including alanine aminotransferase (ALT, SGPT) and aspartate aminotransferase (AST, SGOT). Co-pretreatment with silibinin and curcumin was protective against the plasma injury indicated a pronounced infiltration of neutrophils and overt hepatocellular necrosis.
elevations of hepatic enzymes including ALT/SGPT and AST/SGOT. In addition, histological and immunohistochemical analysis indicated that co-pretreatment with silybinin and curcumin effected hepatic infiltration of inflammatory cells and the degree of hepatic necrosis. These data suggest that co-pretreatment with silybinin/curcumin affords protection against ANIT-induced hepatotoxicity. (Supported by NIEHS Grant ES 00338-02)

Characterization of an Interacting Protein with TRPV1

S. Lee1, Y. Oh2, K. Um1, I. Baybarz3; 1Hankyong National University, Anung, Kyonggi-do, Republic of Korea, 2Graduate School of Bio-Information Technology, Hankyong National University, Anung, Kyonggi-do, Republic of Korea

TRPV1, previously known as VR1, is a capacitative, proton- and heat-sensitive non-selective cation channel. Although its channel activity is reportedly modulated through protein-protein interactions, to date very few VR1 interacting proteins have been identified. In order to find proteins that interact and regulate the channel activity of TRPV1, we performed yeast two hybrid screening technique. We found a protein, called Eferin, which interact with TRPV1 in a specific manner. Interaction of Eferin with TRPV1 is confirmed by GST-pull down assay and co-immunoprecipitation. Also TRPV1 and Eferin were shown colocalized by immunohistochemistry. However, the overexpression of eferin did not increase the channel activity significantly in response to capsaicin. The reason for the slight effect of Eferin on channel activity might be the presence of endogenous Eferin in HEK293 cells. Therefore, we knocked down the endogenous Eferin in TRPV1-stably transfected HEK293 cells by siRNA technology. We found that TRPV1 expression in membrane is much decreased to show decreased channel activity to capsaicin by knocking down the Eferin. This work was supported by Brain Korea 21 Project, Ministry of Education of Korea.

Effects of Nicotine on the Change of Dopamine and G Protein-coupled Receptor Kinase 3 (GRK3) Levels in PC12 Cells

M. Yeom, D. Han, H. Hwang, J. Han, S. Kim, H. Lee, D. Hahm; Kyung Hee University, Yongin-si, Republic of Korea

G protein-coupled receptor kinases (GRKs) are a family of serine/threonine kinases involved in the agonist-induced homologous desensitization of G-protein coupled receptors (GPCRs). It is known that G-protein receptor kinase 3 (GRK3) seems to be involved in the development of tolerance and dependence, processes closely related to drug addiction such as opioid and cocaine. But, the involvement of GRK3 in the mechanism of nicotine addiction is poorly understood. In this study we aim to elucidate the cellular mechanisms of GRK3 in the release of dopamine and GRK3 expression in dopaminergic PC12 cells. dopamine levels were determined by high-performance liquid chromatography (HPLC)-electrochemical detection (ECD) assay and those of GRK3 mRNA and protein by the real-time PCR and immunoblot assay, respectively. Nicotine induced the secretion of dopamine in PC12 cells. Also, nicotine dose-dependently decreased the levels of GRK3 mRNA and protein, both. The GRK3 levels reduced by nicotine were gradually increased as time went by, but were maintained at lower levels than in control, non-transfected PC12 cells, during the experiment. These results suggest that the expression levels of GRK3 in dopaminergic neural cells may affect the secretion of dopamine after nicotine treatment.

Intracellular Retention of GluR6a Kainate Receptors by a Point Mutation Outside the Ligand-binding Domain

P. Vivithanaporn1, W. Marszalcz2, G. T. Swanson3; 1Department of Pharmacology and Toxicology, University of Texas Medical Branch, Galveston, TX, 2Department of Molecular Pharmacology and Biological Chemistry, Northwestern University, Chicago, IL

Biosynthesis of ionotropic glutamate receptors (iGluRs), including the kainate receptor (KAR) family, is controlled by various trafficking motifs within the subunit proteins. Previous results have suggested that domains intrinsically linked to receptor function, such as ligand-binding and gating domains, can play an important role in subcellular trafficking and egress from the endoplasmic reticulum (ER). The mechanism of this quality-control process is not understood. In these studies we aim to elucidate the cellular mechanisms of KARs, the process of desensitization, and changes in protein trafficking and assembly. Desensitization is a well-characterized biophysical phenomenon in iGluRs with an associated physical model formulated from structure-function and crystallographic studies. We determined how changes in desensitization rates correlated with altered subcellular trafficking of the GluR6a KAR biosynthesis by mutating two amino acids located outside the ligand-binding domain; these residues are known to be determinants of desensitization for KARs. We introduced conservative and non-conservative mutations to change our target amino acids, E662 and R663, and measured plasma membrane expression in biochemical assays and functional properties in patch-clamp physiological recordings. Plasma membrane expression of myc-GluR6a receptors relative to total receptor protein was measured by cell ELISA assays in transfected COS-7 cells. Substitution of R663 with a glutamate [GluR6(R663E)], which slows receptor desensitization by 2-fold, greatly diminished the plasma membrane expression of myc-GluR6a receptors by 24-fold (n = 3).

In contrast, a conservative substitution [GluR6(R663K)] did not alter plasma membrane expression of the receptors. These results were reproduced in transfected primary hippocampal neurons. These results demonstrate that a linker region of the GluR6a subunit, which previously was associated specifically with desensitization, also can influence receptor trafficking.

Neurotrophic Regeneration during the Corneal Wound Healing after Refractive Surgery

T. Blanco-Mezquita1, J. Merayo-Lloves1, C. Martinez-Garcia2, S. Bonini1, A. Lambiase1, R. Pronec4; 1OIBA, Universidad de Valladolid, Valladolid, Spain, 2Cell Biology, Universidad de Valladolid, Valladolid, Spain, 3Laboratory of Ophthalmology, University of Rome, Rome, Italy, 4IIBIL, Universidad de Coimbra, Coimbra, Portugal

OBJECTIVES The cornea is one of the most densely innervated tissues of the body, which is highly abounded by sensory nerves and autonomic nerve fibers. Corneal nerves fibers exert important trophic influences on the corneal epithelium and contributes to maintain the cornea and promote wound healing after external injuries. The aim of this work is to evaluate the neurotrophic role of effrons axons in the corneal wound healing process after refractive surgery in hens. METHODS Lohmann Brown hens underwent Photorefractive Keratotomy (PRK) were divided into different groups treated with topical administration of 0.2% marine Nerve Growth Factor (NGF) group A, Balanced Salt Solution (BSS) group B and group C received no treatment. Clinical monitoring was made during two months. Eyes were examined at sequential time points and fixed in 1% buffered formalin. Sections were stained with H-E and Masson trichrome. Occludin, Claudin-5, Hsp-70, Alpha-SMA, Trk-A and Gap-43 were detected by immunohistochemistry. RESULTS Statistically significant differences in the grade of haze and pachymetry measurements were found. There were not differences in the expression of Occludin and Claudin-5 in the corneal epithelium, among groups A significant increase in Hsp-70, Alpha-SMA and Trk-A was observed in the NGF group. Statistically significant differences were observed in the expression of GAP-43 between groups. Gap-43 expression was minor in NGF group. CONCLUSIONS Topical NGF modulates tropanic axon regeneration, which probably influence in the actual corneal wound healing process.

Protection of PC12 Cells from Polyglutamine-rich Fragments of Huntingtin

Y. Zhang, A. M. Tartakoff; Pathology, Case Western Reserve University, Cleveland, OH

The neurotoxicity of polyglutamine-containing proteins is central to the pathogenesis of Huntington’s Disease and several other autosomal dominant disorders. In each case, otherwise innocuous proteins acquire enlarged polyglutamine tracts due to increased numbers of trinucleotide repeats in the corresponding open reading frames. For unknown reasons, in each disease a distinct region of the brain is affected. Although several strategies have been identified to apply proteins or drugs which protect against polyglutamine toxicity using model organisms, few protective factors have been identified for higher eukaryotic cells. We therefore have made use of a marine PC-12 cell culture model in which an ecdysoneregulated promoter induces synthesis of a GFP-tagged form of the N-terminus of huntingtin which includes a large polyglutamine tract (103 repeats) (Aiken et al. Neurobiol. Dis., 16, 546 (2004)). Upon induction, the GFP-tagged product become visible with one day and apoptosis is quickly apparent, as judged by cell detachment and binding of annexin V. To test the impact of selected proteins, we have transfected these cells with plasmids encoding human Hsp70, a mutant form of Hsp70, or the accessory protein, Hdj1. To identify transfected cells, a plasmid encoding dsRed was always included. Induction begins one day after transfection and cultures are followed over the three following days. We observe that toxicity is rapid in cells which receive only ds-Red, or ds-Red in conjunction with the Hsp70 mutant, or Hdj1 plasmids. By contrast, Hsp70 is distinctly protective, resulting in essentially complete survival for at least two days, even though the transfecinants still have very large polyglutamine tracts. It is unlikely that widespread overexpression of Hsp70 can be of therapeutic value; however, these observations illustrate the utility of this culture model and motivate the identification of additional corrective cDNA's. Supported by the HigfiQ Foundation.
1271 Cariporide, a Specific Na'/H' Exchanger (NHE) Inhibitor, Attenuates Apoptotic Cell Death Caused by Mitochondrial Ca2+ Increase in Neuronal Cortical Cells
S. Hyun,1,2 B. Lee,1,2 D. Lee,1,2 S. Kim,1 S. Lee,1 K. Yi,1 S. Yoo,1 S. Lee,1,2 E. Baik,1,2 C. Moon,1,2 Y. Jung,1,2 1Department of Physiology, School of Medicine, Ajou University, Suwon, Republic of Korea, 2Brain Korea 21 for Medical Science, School of Medicine, Suwon, Republic of Korea, 3Brain Korea 21 for Molecular Science and Technology, Suwon, Republic of Korea, 4Brain Disease Research Center, School of Medicine, Ajou University, Suwon, Republic of Korea, 5Medical Science Division, Korea Research Institute of Chemical Technology, Daejeon, Republic of Korea. Ischemia, which often occurs during seizure and stroke, gives rise to glutamate release. Glutamate induces activation of Na'/H' exchanger (NHE) and subsequently accelerates the process of neuronal cell death via intracellular Ca2+ overload. Glutamate-induced neuronal cell death also requires mitochondrial Ca2+ uptake. In the present study, we examined effect of cariporide, well known as NHE inhibitor, on mitochondrial Ca2+-induced neuronal cell death in cultured neuronal cells and in vivo. Treatment with cariporide reduced glutamate-induced apoptotic cell death (Caspase-3 activity, TUNEL-positivity) in neuronal cortical cells. Dual peaks of [Ca2+]i rise were observed after glutamate exposure. Cariporide suppressed only second [Ca2+]i increase and reduced mitochondrial Ca2+ uptake. In addition, cariporide significantly recovered the large reduction in mitochondrial membrane potential and cytochrome c release to cytosol induced by glutamate exposure. In vivo brain ischemia model, cariporide produced protective effects, decreasing the infarct size. Taken together, Cariporide attenuates mitochondrial Ca2+-induced apoptotic neuronal cell death through inhibition of NHE in neuronal cortical cells in vivo and in vitro. This work was supported by a grant (CIBM2-A300-001-1-0-2) from the center for Biological Modulators of the 21st Century Frontier R&D Program, the Ministry of Science and Technology, and by a grant from the Korea Science and Engineering Foundation (KOSEF) through the BDRC at Ajou University.

Keywords: Na'/H' exchanger (NHE), neuronal cortical cells, Ca2+, mitochondria, apoptosis, glutamate

1272 Presenilin-dependent erbB4 Nuclear Signaling Regulates the Timing of Astrogenesis in the Developing Cerebral Cortex
S. P. Sardi,1,2 J. Murtie,1,2 S. Koirala,1,2 B. A. Patten,1,2 G. Corfis1,2 1Neurobiology Program, Children's Hospital Boston, Boston, MA, 2Department of Neurology, Harvard Medical School, Boston, MA
Receptor tyrosine kinases (RTKs) are known to regulate gene transcription through activation of complex multilayered kinase cascades. However, recent studies suggested that erbB4, an EGFR receptor family member, might signal in a different way. Activation of this RTK results in erbB4 cleavage by TACE and presenilin, generating a soluble intracellular domain (E4ICD). These studies raised the possibility that E4ICD could translocate to the nucleus and directly impact transcription. We hypothesized that identification of E4ICD binding proteins would provide insights into the mechanisms and biological roles of this novel signaling pathway. For that we first activation by neuregulin-1, erbB4 associates with the adaptor protein TAB2 and the nuclear corepressor N-CoR in neural stem cells. Once erbB4 is cleaved by the pro tease, the E4ICD/TAB2/N-CoR complex translocates to the nucleus, where it binds to promoters of astrocytic genes, repressing their expression and thus preventing astrogenesis. Consistent with these observations, erbB4 knockout mice show precocious astrogenesis. Furthermore, this phenotype is rescued by reintroduction of a cleavable isoform of erbB4 but not by a cleavage-resistant isoform. Our studies: (1) define a novel mechanism by which a RTK signals directly to the nucleus to regulate transcription and influence cell fate choices; (2) reveal a new role for presenilin in mammalian brain development (the inhibition of astrogenesis via E4ICD release); and (3) provide new insights into the mechanisms that control the timing of astrogenesis in the developing brain. Importantly, our findings might be relevant to other RTKs since other receptors undergo ligand-induced shedding of their extracellular domain, which can trigger presenilin cleavage. Furthermore, since presenilin plays a critical role in Alzheimer’s disease and erbB4, which is increased in neurodegenerative disease, regulates key aspects of neuronal function, it is possible that this signaling mechanism might be at play in this devastating neurodegenerative disease.

1273 Ontogeny of Muscarinic Receptor Expression in Zebrafish
R. J. Nuckels, J. A. Smith, D. M. García; Biology, Texas State University, San Marcos, TX
Muscarinic acetylcholine receptor (mACHR) activation initiates pigment granule movement in the RPE (retinal pigment epithelium) of fish. We are interested in discovering the pathways that link receptor activation to pigment granule movement. Since there are different downstream signaling pathways associated with the different subtypes of mACHR, we aim to identify which subtypes of receptors are present in the eyes of the zebrafish, Danio rerio. Using the publicly available zebrafish genome, we have identified putative sequences for the five known subtypes of muscarinic receptors (m1-m5) plus possible variants of the m3 and m5 receptors. Based on these sequences we have designed primers for the m-odd receptor subtypes (m1, m3, and m5) and cloned two of these (m3 and m5). We isolated tissue from larval and adult zebrafish and determined which m-odd muscarinic receptors were expressed. We removed the eyes from larval and adult zebrafish and we isolated spleen from the adult fish. Using RT-PCR, we found that the putative muscarinic receptor subtypes, m1, m3, and m5 and a variant of m5 were expressed in the larval eyes. We also have found that m3 and the variant of m5 are expressed in whole larval fish as early as 3 days post fertilization. Additionally, after isolating adult zebrafish spleen and eyes, we show that the m5 variant is expressed. These results support previous studies that show that pigment granule movement in the RPE of fish eyes use a muscarinic acetylcholine receptor mediated signaling pathway.

1274 The Importance of Tetraspan Vesicle Membrane Proteins for GABAergic Neurotransmission in Caenorhabditis elegans
C. Abraham, L. Bai, R. E. Leube; Department of Anatomy and Cell Biology, Johannes Gutenberg University, Mainz, Germany
Regulation of the intracellular trafficking of Glutamate receptors is likely to play an important role in synaptic plasticity. We have used the role of the TVPs we have chosen the model organism Caenorhabditis elegans that features only one member of the physisins (SPH-1), gynins (SGN-1) and secretory carrier-associated membrane proteins (SCAMPs, SCM-1), respectively. Previous analyses demonstrated that single, double and triple mutants of the encoding genes developed normally and presented an inconspicuous neuronal architecture with ordered synaptic contacts. These animals also exhibited normal thermotactic, chemotactic, electrophysiological and aldicarb responses (Abraham et al., 2006). We now present evidence, however, that TVP mutants show increased sensitivity to the GABA-receptor antagonist pentylenetetrazole (PTZ) reacting with pronounced muscle spasms. This paper describes two genes, unc-101 and UNC-108/Rab-2, whose mutations alter the distribution of GLR-1. Here I will describe two of these genes. The unc-101 gene encodes an ortholog of mammalian Rab-2. Loss of function alleles of both genes were identified in mutations causing increased abundance of GLR-1 in the ventral nerve cord. AP-1 has been implicated in TGN-Plasma membrane, and Early Endosome-TGN transport pathways. Rab-2 has been implicated in retrograde trafficking of proteins from the golgi to the ER. Here I will discuss our efforts to determine the mechanism by which UNC-101/1 and UNC-108/Rab-2 regulate GLR-1 trafficking.
Anti-Inflammatory Cytokines as Mediators in the Pathogenesis of Endothelial Shock

M. E. Cresencio, R. López Marure; Fisiología, Instituto Nacional de Cardiología, México D. F., Mexico

Introduction:
M. Roomi, V. Ivanov, A. Niedzwiecki, M. Rath; Dr. Rath Research Institute, Santa Clara, CA

RESULTS

Taken together these results suggest that the major pathway of ATP-induced [Ca^{2+}]i increase in prostatic smooth muscle cells is a Ca^{2+} influx via P2X receptors.

Effect of ATP on Calcium Dynamics in Prostatic Smooth Muscle Cell of Golden Hamsters

M. Matsuura, T. Kuroda, Y. Sato; Histology, Iwate Medical University, Morioka, Japan

OBJECTIVE: We have reported the heterogeneous responses of vascular smooth muscle cells to neurotransmitters. All contractile cells but striated smooth muscle cells are designated as “smooth muscle cells”, therefore it is conceivable that non-vascular “smooth muscle cells” show different nature to transmitters. It is well known that ATP is released from adrenergic nerve terminals. Here, we study the effect of ATP in prostate smooth muscle cell of golden hamsters using an imaging technique. [METHODS] We used male Golden hamsters (120-140 g). Prostatic gland endpieces which were surrounded by smooth muscle cells were isolated and soaked in Hepes-buffered Ringer’s Solution (HR) (pH 7.4). Connective tissues around the endpieces were digested by purified collagenase (100 units/ml) for 2 hours at room temperature. Then the glandular endpieces, kept structural integrities, were loaded by Indo-1/AM (5 µM) for 2 hours at room temperature. They were placed on cover slides in chambers which were coated with Cell-Tak® and continuously perfused with HR containing ATP and/or some specific analogs. We used a real-time confocal microscope [Nikon RCM/Ab]. [RESULTS] When ATP (100 µM) was used as a stimulus, an increase of [Ca^{2+}]i in the smooth muscle cells was observed. The response was abolished when extracellular Ca^{2+} was removed from perfused HR. The calcium wave was observed and it was moved to next cells one after another. It looks like having a polarization.

Conclusions: In present study, we therefore suggest that the major pathway of ATP-induced [Ca^{2+}]i increase in prosthetic smooth muscle cells is a Ca^{2+} influx via P2X receptors.

The expression of these receptors is a key event in determining the pro-invasive activity in melanocytes. In studies involving melanoma cell lines, we have found that ATP and its analogs modulate the expression of adhesion molecules, leading to changes in cellular morphology and migration. These findings suggest a potential role for ATP and its receptors in the regulation of melanoma aggressiveness.

Comparison of Effects of Serotonin (5-HT) on Intracellular Calcium Dynamics between Rat Testicular and Cerebral Arterioles

M. Matsuura, T. Kuroda, T. Saino, Y. Satoh; Histology (Anatomy2), Iwate Medical University, Morioka, Japan

Comparison of Effects of Serotonin (5-HT) on Intracellular Calcium Dynamics between Rat Testicular and Cerebral Arterioles

Different Statins Inhibit the Proliferation and Induce Cell Death Like Necrosis of Cervical Cancer Cell Lines

T. M. H. involved in taste, smell and temperature sensing. Either
The proteins predicted from the expressed sequences have similarities to chemoreceptors in other organisms such as Dictyostelium, Caenorhabditis and specialized vertebrate sensory cells involved in taste, smell and temperature sensing. Either Tetrahymena have primitive receptors that can recognize these and other agonists or some of these compounds can act independently of specific receptors. We have cloned many of these genes and we have begun generating macromolecular knockout mutations to identify the specific function of each. Supported by NSF grant MCB-0445362 to T.M.H.

IGF-1 and IGF-2 Mediated Altered Regulation of Ornithine Decarboxylase and Spermidine Spermine N\(^2\)-acetyltransferase Expression in H-ras Transformed Cells Involves Multiple Signaling Pathways
R. A. R. Hurts, M. D. Marchett; Biology, University of Prince Edward Island, Charlottetown, PE, Canada

The polyamines (putrescine, spermidine, spermine) are ubiquitous low-molecular weight aliphatic amines that play roles in both cell proliferation and differentiation. Polyamine biosynthesis is regulated by the activity of ornithine decarboxylase (ODC), a key rate limiting enzyme in the polyamine biosynthetic pathway. Conversely, spermidine/spermine \(N^2\)-acetyltransferase (SSAT) is a key rate limiting enzyme in the catabolism of polyamines. The insulin-like growth factor (IGF) system plays an important role in the growth and development of many tissues and regulates overall growth and has been implicated in tumorigenesis. The aim of this study was to investigate the possible link between IGF-mediated cellular signaling during H-ras mediated cellular transformation and the expression of ODC and SSAT. Using untransformed, parental 10T1/2 cells and H-ras transformed NR3 cells (capable of benign tumor formation) ODC and SSAT expression was evaluated in response to exposure to IGF-1 and IGF-2 in vitro. Results from Western blot analyses suggest that ODC and SSAT protein levels are differentially induced in NR3 cells in response to IGF-1 and IGF-2 following exposure for 1 to 24 hours, while no apparent alterations in either ODC or SSAT protein levels in response to IGF-1 and IGF-2 were noted in 10T1/2 cells. Further studies determined that involvement of protein kinase-C and mitogen activated protein kinase mediated signaling pathways are necessary for the IGF-mediated induction of ODC and SSAT in NR3 cells. The results suggest that a part of the altered growth regulatory program which results following H-ras mediated cellular transformation involves a heightened responsiveness of both ODC and SSAT to IGF-1 and IGF-2. Regulation of p53 Protein Synthesis Following DNA Damage by Phosphorylation of eIF4E
Y. Zhang, D. Yang; Department of Basic Biomedical Science, Sanford School of Medicine, University of South Dakota, Vermillion, SD

The eukaryotic translation initiation factor 4E (eIF4E) is essential for efficient cap-dependent translation. eIF4E is known to be regulated by its inhibitory binding proteins (4E-BPs) and by its phosphorylation. However, the role of eIF4E phosphorylation in translational control still remains controversial. The tumor suppressor protein p53 plays a critical role in suppressing cell transformation and maintaining genetic integrity. This activity is achieved by the accumulation of p53 protein after DNA damage and by p53-induced activation of a number of genes that mediate either cell growth arrest or cell death. Although it is known that p53 is stabilized after DNA damage, there is also clear evidence indicating that p53 induction is regulated by protein synthesis in response to DNA damage. The mechanism for the translational regulation of p53, however, is poorly understood. In this study, the function of eIF4E phosphorylation in translational control of p53 induction after DNA damage was investigated. Our results showed that etoposide treatment caused a rapid increase in eIF4E phosphorylation as well as increased p53 synthesis. The addition of a specific inhibitor of eIF4E kinase, 4Ei, not only inhibited eIF4E phosphorylation but also resulted in reduced synthesis of the p53 protein. RT-PCR analysis further demonstrated that the inhibition of eIF4E phosphorylation was accompanied by a decrease in the abundance of p53 mRNA in the polyribosomal fraction following etoposide treatment. In addition, the attenuation of p53 translation by the suppression of eIF4E phosphorylation was found to promote cell-cycle progression from G1 to S phase. This study provides the first evidence indicating that phosphorylation of eIF4E by 4Ei is critical for increased p53 protein synthesis in response to DNA damage.

1284

Anti-angiogenic Activity of Processed Rhus verniciflua STOKES
W. Choi, J. Lee, Y. Chang, E. Lee, C. Lee, K. Ahn, S. Kim; 1Department of Oncology, Graduate School of East-West Medical Science, Kyung Hee University, Yongin, Republic of Korea, 2Lab of Angiogenesis and Chemoprevention, College of Oriental Medicine, Kyung Hee University, Seoul, Republic of Korea

Rhus verniciflua STOKES (R. verniciflua) is a traditional medicinal plant that is used for the treatment of inflammatory disease and uterine cancer in Oriental folk medicine. However, anti-cancer mechanisms of R. verniciflua STOKES still remain unclear. Thus, in the present study, the anti-cancer effects of R. verniciflua STOKES with focus on angiogenesis were evaluated in vitro and in vivo. R. verniciflua STOKES inhibited vascular endothelial growth factor (VEGF)-induced proliferation and migration of human umbilical vein endothelial cells (HUVECs) in a concentration-dependent manner. Also, R. verniciflua STOKES inhibited tumor growth and tumor weight in LLC-bearing C57BL6 mice. These results demonstrated that R. verniciflua STOKES showed anti-cancer effect through inhibition of angiogenesis and suggest that it may be valuable to develop anti-cancer drugs.

1285

Rutin Isolated from the Actinometa lobatum Maxim Exerts Antithrombotic Activity
K. Kim, J. Lee, Y. Chang, H. Lee, E. Lee, B. Shim; 1Department of Oncology, Graduate School of East-West Medical Science, Kyung Hee University, Yongin, Republic of Korea, 2Lab of Angiogenesis and Chemoprevention, College of Oriental Medicine, Kyung Hee University, Seoul, Republic of Korea

Actinometa lobatum Maxim has been utilized for the treatment of thrombosis and ulcerative skin disease. However, its antithrombotic effect remains unclear. Thus, in the present study, the antithrombotic mechanism was investigated in human platelets by rutin isolated from the Actinometa lobatum Maxim. In platelet aggregation assay, rutin significantly inhibited collagen-induced human platelet aggregation at 400 µM. In addition, rutin inhibited the expression of glycoprotein (GP) IIb/IIIa and (thromboxane A2)TXA2 formation in collagen-induced human platelet aggregation. In coagulation assay, rutin significantly prolonged activated PT and aPTT compared with untreated control in a concentration dependent manner. Furthermore, oral administration of rutin resulted in an inhibition of experimental pulmonary embolism in ICR mice. Taken together, these results suggest that rutin may exert its antithrombotic activity via inhibition of platelet aggregation, coagulation activity, GP IIb/IIIa complex expression and TXA2 activities.

1286

DMNQ S64 Induces Apoptosis via ROS Activation and NF\(\beta\)B Inhibition in A549, Human Non Small Lung Cancer Cells
Y. Rhee, M. Park, H. Lee, E. Lee, K. Lee, B. Shim; 1Department of Oncology, Graduate School of East-West Medical Science, Kyung Hee University, Yongin, Republic of Korea, 2Lab of Angiogenesis and Chemoprevention, College of Oriental Medicine, Kyung Hee University, Seoul, Republic of Korea

6-ppim (1-propoxyiminoalkyl)-5,8-dimethoxyoxy 1,4-naphtoquinone S-64 (DMNQ S64) was synthesized as a shikonin derivative. In the present study, the underlying apoptotic mechanism of DMNQ S64 was examined. DMNQ S64 exerted cytotoxicity against A549 lung carcinoma cells with IC50 of 25 µM. Apoptotic bodies were observed in DMNQ S64 treated A549 cells by DAPI staining assay and caspase-3 activity was observed by immunofluorescence staining. DMNQ S64 also increased ROS portion in a time dependent manner by flow cytometric analysis. Western blotting revealed that DMNQ S64 effectively reduced the expression of mitogen activated protein kinase (MAPK) and extracellular signal-regulated kinase (ERK), cleaved poly(ADP-ribose) polymerase (PARP) and activated caspase-8. Furthermore, Luciferase assay has shown DMNQ S64 significantly inhibits NF\(\beta\)B and the phosphorylation of SRE. Taken together, these results suggest that DMNQ S64 may induce apoptosis via ROS activation and inhibition of NF\(\beta\)B and phopho-p38.

1287

Anti-angiogenic Activity of Sojuktang in Vascular Endothelial Growth Factor Induced Human Umbilical Vein Endothelial Cells
Y. Oh, Y. Rhee, J. Lee, K. Kim, H. Lee, E. Lee, K. Ahn, S. Kim; 1Department of Oncology, Graduate School of East-West Medical Science, Kyung Hee University, Yongin, Republic of Korea, 2Lab of Angiogenesis and Chemoprevention, College of Oriental Medicine, Kyung Hee University, Seoul, Republic of Korea

Angiogenesis, a formation of new blood vessels from pre-existing ones, has been shown to play an important role both in animal development and pathologic conditions like tumor growth and metastasis or cardiovascular disease. In present study, the anti-angiogenic activity of ethanol extract of Sojuktang (EST), an oriental herbal formula, was evaluated in vascular endothelial growth factor (VEGF)-stimulated human umbilical vein endothelial cells (HUEVC). EST significantly inhibited VEGF induced proliferation of HUEVC at non-toxic concentration of 5 µg/ml. EST also has shown inhibitory effects on the migration and tube formation of HUEVCs stimulated by VEGF in a concentration dependent manner. Similarly, VEGF induced neovascularization was disrupted by EST in chick chorioallantoic membrane (CAM) assay. In addition, EST significantly reduced the level of prostaglandin E2 in VEGF treated HUEVCs by ELISA assay. These results suggest that EST can be applied to angiogenesis dependent diseases including cancer.
3,3'-dihydroxybenzene (DIM) Induces Apoptosis in Prostate Cancer Cells

S. Park,1 E. Kim,2 H. Shin,3 D. Kwon,1 Y. Surh,1 J. Park2,1 Food Science and Nutrition, Hallym University, Chuncheon, Republic of Korea, 2Center for Efficacy Assessment and Development of Functional Foods and Drugs, Hallym University, Chuncheon, Republic of Korea, 3Korea Food Research Institute, Sungnam, Republic of Korea, 4College of Pharmacy, Seoul National University, Seoul, Republic of Korea

DIM is a major in vivo product of acid-catalyzed oligomerization of indole-3-carbinol, which is present in cruciferous vegetables and has been reported to have anti-carcinogenic properties. The present study examined the mechanisms by which DIM inhibits human prostate cancer cells. To examine the effects of DIM on the growth of LNCaP (wild-type p53) and DU145 (mutant p53) human prostate cancer cells, the cells were cultured with various concentrations of (0 - 30 μM) DIM. DIM substantially decreased viable cell numbers and induced apoptosis of LNCaP and DU145 cells in dose-dependent manners. Western blot analysis of total cell lysates revealed that DIM increased cleavage of caspase-8, -9, -7, -3, and poly (ADP-ribose) polymerase in both LNCaP and DU145 cells. In addition, DIM decreased the translocation of cytochrome c and Smac/Diablo from the mitochondria to the cytosol. In LNCaP cells, DIM did not affect the protein levels of p53, Bcl-2, or Bax, whereas DIM increased Bax and truncated Bid levels in DU145 cells. It has been demonstrated that DIM inhibits cell proliferation and induces apoptosis in prostate cancer cells. The induction of apoptosis may be mediated through changes in mitochondrial membrane permeability and the activation of the caspase pathways.

The Proteome of the Endoplasmic Reticulum in Cancer

E. Abdou,1 M. Taheri,1 L. Roy,2 G. Thiubault,1 D. Boismenu,3 J. Hayes,4 F. Servant,5 R. Kearney,5 J. Paiement; 1Department of Pathology and Cell Biology, University of Montreal, Montreal, PQ, Canada, 2Joint Research Center, National Sun Yat-Sen University-Kaohsiung Medical University, Kaohsiung, Taiwan, 3Biomedical Engineering, McGill University, Montreal, PQ, Canada, 4Biomedical Research Centre, University of Dundee, Dundee, United Kingdom, 5Biomedical Engineering, McGill University, Montreal, PQ, Canada

The protein composition of endoplasmic reticulum (ER) isolated from dissected liver tumor nodules of fatoxacin Bt-treated rats was compared with that of ER from control liver. Tandem mass spectrometry (MS) peptide counts and immunoblot validation were used to identify and determine the relative expression level of the proteins in highly enriched ER fractions. LC-MS/MS tandem MS was carried out on protein samples obtained after separation by 2D gel electrophoresis, peptides were quantified and a variety of antibodies have been used against specific proteins of relevance to the ER proteome and cancer. Many proteins relevant to cancer were up-regulated in ER from dissected liver tumor nodules. These include inhibitors of apoptosis (i.e. paxidoxin 1, Bax inhibitor 1, RNAse I, Inhibitor and Rack1), proteins involved in transcription (i.e. Y box protein 1, BTF3), in mRNA metabolism (i.e. HnrNP K, HnrNP D, PABP1, Hua) in translation (i.e. eIF-1A, eIF-2, eEF-2A, eEF-3), in ribosome biogenesis (i.e. EB1 and ribosomal proteins including S3a, S11, S14, L6, L23a) and in membrane traffic (COP12 customer complex). Several proteins of the cytochrome p450 family were down-regulated whereas a number of alkido-ketoreductases were up-regulated in ER from tumors. In contrast proteins of the protein folding machinery (i.e. Bip, calnexin, calreticulin, endoplasmin) were expressed in equal amounts in ER from dissected tumor nodules compared to those in control ER. Many novel proteins of relevance to the ER proteome and cancer were uncovered, several of these were observed in higher concentration in ER membranes from tumors. Finally immunoblot analysis using anti-phosphotyrosine antibodies revealed higher amounts of a number of phosphoproteins in ER from dissected liver tumor nodules. Thus the molecular profile of the ER in hepatocellular carcinoma is different from ER in control liver. This difference may be relevant to liver tumor biology.
Effect of GSK3 Phosphorylation on HIF-1α Stability and Transcriptional Activity

S. A. Hale, K. Lounsbury; Pharmacology, University of Vermont, Burlington, VT

Cancerous tumors adjust their signaling pathways to facilitate survival in a hypoxic environment. The pro-angiogenic transcription factor hypoxia inducible factor α (HIF-1α) is stabilized in hypoxia and promotes tumor cell survival, proliferation, and metastasis by inducing transcription of many targets including vascular endothelial growth factor (VEGF). Previous work in our lab has shown increases in both HIF-1α and VEGF in advanced stages of ovarian cancer, indicating a strong correlation between HIF-1α, VEGF, and cancerous states. Despite current research describing HIF-1α signaling and regulation, there remains a dearth of information investigating HIF-1α phosphorylation status and regulation of phosphorylation. Current work in our laboratory involves connecting the role of phosphorylation states of HIF-1α to the regulation of HIF-1α transcriptional activity and proteasomal degradation. GSK3 (glycogen synthase kinase) has been implicated in the phosphorylation of HIF-1α although the downstream effect of GSK3 on HIF-1α has yet to be clarified. Considering the canonical role of GSK3 in proteasomal degradation of other oncoproteins such as c-myc, β-catenin, and cyclin D1, and the presence of GSK3 consensus sequences within HIF-1α, we hypothesized that phosphorylation by GSK3 would target HIF-1α for proteasomal degradation as well. In support of this hypothesis, we show here that concurrent treatment of ovarian cancer cells with BIO (a GSK3 inhibitor) and hypoxia leads to an increase in stabilization of HIF-1α that is echoed by an increase in VEGF transcription, suggesting an augmentation of HIF-1α transcriptional activity. Further, in vitro studies show that after phosphatase treatment the HIF-1α protein exhibits an increase in electrophoretic mobility that is partially reversed by treatment with GSK3. From these results, we propose a model whereby GSK3 phosphorylates and subsequently destabilizes HIF-1α thus halting HIF-1α-dependent VEGF transcription.

Determination of the Anti-Cancer Activity of Fluorescent Cyanine Dye Constructs in MCF-7 Cell Lines

M. W. Baker, 1 D. A. Hill, 1 C. Ntam, 1 N. Flemming, 2 N. Smith, 2 A. Winstead, 2 D. Curry, 2 R. Williams, 2 L. Jones 2; 1Biology, Morgan State University, Baltimore, MD, 2Chemistry, Morgan State University, Baltimore, MD

Breast cancer is a persistent and invasive disease. In 2004-2005, the CDC reported that approximately 225,990 women received their first positive breast cancer diagnosis, and approximately 42,850 women died from the disease. Breast cancer exists in various forms including ductal carcinoma in situ (DCIS, non-invasive), invasive ductal carcinoma (IDC, metastatic), or lobular carcinoma (invasive or non-invasive). Several forms exhibited resistance to conventional chemotherapeutics. This resistance can lead to increased breast cancer-related mortality. Thus, oncologists and biomedical researchers are interested in newly developed applications or technologies that can indicate and treat this insidious disease. Collaborative studies between our laboratory and the Chemistry Department at Morgan State University have resulted in the manipulation of fluorescent technology to develop several classes of fluorescent cyanine dye-based microsensor constructs (CDBMC). These constructs are designed to indicate intracellular alterations using fluorescent intensity. The “Hydroxyl” class of CDBMC demonstrated the ability to undergo intracellular uptake, correlate fluorescent intensity with cytotoxicity and induce cellular lethality. Thus, the current study was designed to determine if the “Hydroxyl” class of CDBMC could undergo intracellular uptake, correlate fluorescent intensity with cytotoxicity, and induce cytotoxicity within the MCF7 breast cancer cell line. MCF7 cells were incubated with CDBMC (20 μM) for 6 hours. After this incubation, MCF7 cells were collected and analyzed for cytotoxicity. Cell growth and proliferation, enzyme release, viability and cell attachment were used as markers of cytotoxicity. The results demonstrated that CDBMC caused increased enzyme release and decreased cell viability, attachment, growth and proliferation (Supported by DOE ER63580, NSF 0236753).

Von Hippel-Lindau Protein Induced Variation of Microtubule Dynamic Instability Probed by Automated GFP-labeled EB3 Spot Detection and Tracking

A. V. Matov, 1 C. Thoma, 2 W. Krek, 2 G. Danuser 1; 1Cell Biology, The Scripps Research Institute, La Jolla, CA, 2Cell Biology, Swiss Federal Institute of Technology, Zurich, Switzerland

Von Hippel-Lindau (VHL) disease is an autosomal-dominant inherited cancer syndrome. Affected individuals develop tumors in the kidney, pancreas, adrenal gland, retina and brain. Most effects have been associated with pVHL function in an E3-ligase complex targeting hypoxia-inducible factor α (HIFα) for degradation under normoxic conditions and thereby blocking the HIFα-mediated hypoxic transcriptional program. Hergovich et al., 2003, reported that pVHL may also have a stabilizing effect on microtubule (MT) dynamic instability and this may be implicated in deregulating cell migration during invasion and metastasis. To study pVHL functions in MT dynamics regulation we analyzed the movement of GFP-labeled EB3 plus-end binding protein using multi-particle tracking of EB3 spots. EB3 spot tracking measures MT assembly, revealing statistics of growth velocity and catastrophe frequency. However, we found that many of the EB3 spot trajectories are collinear, suggesting that they may belong to the same MTs sampled at different time points. These MTs lose EB3 decoration during pause and shrinkage, rendering them temporarily invisible. To test this hypothesis, we are investigating the possibility of computationally grouping collinear tracks to estimate MT shrinkage velocity and rescue frequency. Tracking of MT plus ends reveals a bimodal distribution of growth speeds in VHL-deficient cancer cell lines (786-O). Specifically, a large population of MTs grows at a slow speed with a narrow distribution, but many MTs exhibit growth at higher rates with a broader variation. Upon reconstitution of pVHL, MT growth becomes restricted to only the slower of the two modes. This initial data supports the notion that the presence of pVHL stabilizes MTs by oppressing a secondary hyperactive dynamic mode. Currently we are developing a new cell model to confirm these results. We will knock down VHL protein expression by miR30-based short-hairpin RNA (shRNA/mir) in primary cell lines and quantify the respective change in MT dynamics.

Cortactin Regulates Invadopodia Activity and Tumor Invasion by Head and Neck Squamous Cell Carcinomas

E. S. Clark, 1 A. Whigham, 2 W. Yarbrough, 3 A. Weaver 4; 1Pathology, Vanderbilt University, Nashville, TN, 2Otolaryngology, Vanderbilt University, Nashville, TN, 3Otolaryngology and Cancer Biology, Vanderbilt University, Nashville, TN, 4Otolaryngology and Cancer Biology, Vanderbilt University, Nashville, TN

Invadopodia are actin-rich processes that regulate extracellular matrix degradation and thought to be involved in cancer cell invasion and metastasis. Cortactin is a critical component of invadopodia that links many potential processes in invadopodia, including actin assembly, signaling, and membrane trafficking. Cortactin is also gene-amplified in 30% of head and neck squamous carcinomas, which has been reported to confer poor prognosis. We examined the role of cortactin in both invadopodia formation and tumor invasion by HNSCC cells in a novel xenograft rat tracheal model. We found that overexpression of cortactin increased invasion through Matrigel transwells and extracellular matrix degradation mediated by invadopodia. Interestingly, cortactin expression correlated more highly with ECM degradation than with the formation of actin-rich invadopodia puncta, suggesting that cortactin is not required for Arp2/3 complex activation at these structures but instead acts at a subsequent step. In vivo, cortactin overexpression increased invasiveness of tumors derived from these cell lines. This study links the function of cortactin in invadopodia to invasion at the tumor scale, providing a potential mechanism for aggressiveness of cortactin-overexpressing HNSCC cancers.

Proteomic Analysis and Identification of Early Stage Liver Cancer Markers

A. Menthner, 1 L. Siconolfi-Bacis, 2 J. Lim, 1 R. H. Angellett, 1 P. M. Nowakoff 1; 1Department of Developmental and Molecular Biology, Albert Einstein College of Medicine, Bronx, NY, 2Department of Pathology, Albert Einstein College of Medicine, Bronx, NY

Liver cancer in humans is diagnosed at late stages. Proteomics was used to identify early stage liver cancer markers in a rat liver cancer model. The rat model (Solt et al., Am J Path, 1977) exhibits stage-specific cancer progression analogous to human liver. Unique protein expression patterns in liver tissue and serum at early stages of cancer were analyzed and compared to normal liver and serum. Serum was analyzed to provide markers for early cancer detection in a comparatively non-invasive procedure. Serum was depleted and labeled with isotopic tags (iTRAQ), followed by chromatographic separation to permit detection of low abundance proteins. Identification and quantification of proteins was performed by tandem mass spectrometry. Tissue sample markers provide clues about the mechanism of progression of cancer. Proteins were isolated from frozen sections of liver tissue. Cancerous tissue contains both precancerous/cancerous nodules and surrounding normal liver. Tissue sample protein quantitation was determined using a micro-BCA assay (Bicinchoninic acid), developed in house, which consumes 1 to 2 μl of the sample. Quantitative differences in protein expression were assessed using the difference-in-gel electrophoresis (DIGE) technology (GE Amersham). Potential proteins markers are being confirmed by fluorescent immunohistochemistry. Proteomic analysis using 2-dimensional gels and MS (mass spectrometric) data revealed differences in liver tissue and serum between early stage cancer versus control. Proteomics is a powerful tool with the potential to identify unique protein patterns associated with early stages of liver cancer in a rat model analogous to human liver cancer. Supported in part by NIH Grant CA101150.

Investigation of Nuclear Import and Export Signals within Parafibromin, the Tumor Suppressor Associated with Parathyroid Tumorigenesis

M. A. Hahn, D. J. Marsh; Cancer Genetics, Kolling Institute of Medical Research, Royal North Shore Hospital and Department of Molecular Medicine, University of Sydney, NSW, Australia
Parafibromin is a putative tumor suppressor encoded by HRPT2, mutations in which have been implicated in familial Hyperparathyroidism-Jaw Tumor Syndrome and sporadic parathyroid carcinoma. The precise function of parafibromin and how its aberration leads to parathyroid tumorigenesis is poorly understood. In an initial study in which we investigated the cellular localization of parafibromin, wild type or various mutants of this protein were fused to an enhanced green fluorescent protein (EGFP) tag and used to identify a functional-bipartite, evolutionarily conserved nuclear localization signal (NLS) at residues 125-139. The aim of the studies presented here is to extend this work by assessing the nuclear import or export activity of three other putative NLS and three nuclear export signals (NES) that we have identified within parafibromin. Localization data obtained from HEK293 cells transiently transfected with each NLS fused to EGFP, or full length paraffin in which each NLS had been mutated fused to EGFP, revealed that all four NLS possessed nuclear import activity. However the NLS at residues 125-139 was clearly the primary determinant of parafibromin nuclear localization. Each NES sequence when fused to EGFP and transiently transfected into HEK293 cells localized EGFP primarily to the cytoplasm suggesting that each of these signals possessed nuclear export activity. However when these signals were mutated in fragments of parafibromin fused to EGFP they increased cytoplasmic localization of EGFP without decreasing the NLS signal that was expected if these signals were in fact nuclear export. In summary, despite the presence within parafibromin of four NLS and three NES sequences that are capable of nuclear import or export when each is fused to EGFP, the nuclear localization of parafibromin is mediated primarily by one NLS. Studies designed to examine potential roles for the other NLSs and the functional significance of abrogation of these signals are currently underway.

Integrin-linked Kinase Controls Notch1 Signaling by Down-regulation of Protein Stability
S. Han, J. Kim, J. Mun, M. Kim, J. So, S. Mi-Sun, M. Kim, S. Lee, J. Park, E. Choi, J. Seong, C. Cho, R. Fassler, H. Park; SBST, Chonnam National University, Gwangju, Republic of Korea, 2Department of Dermatology, Chonnam National University, Gwangju, Republic of Korea, 3Department of Biochemistry, Kyungpook National University, Taegu, Republic of Korea, 4National Creative Research Initiative Center for Cell Death, School of Life Science and Biotechnology, Konkuk University, Seoul, Republic of Korea, 5Laboratory of G Protein Coupled Receptors, Graduate School of Medicine, Konkuk University, Seoul, Republic of Korea, 6Department of Biological Sciences, Korea Advanced Institute of Science and Technology, Taejon, Republic of Korea, 7Department of Molecular Medicine, Max Planck Institute of Biochemistry, Martinsried, Germany

Integrin-linked kinase (ILK) is a scaffold and protein kinase that acts as a pivotal effector in integrin signaling for various cellular functions. GSK-3β, a downstream kinase of ILK, has already been reported as a positive regulator of Notch1 signaling. Accordingly, we hypothesized the existence of signal crosstalk between integrin and Notch1 signaling, and evaluated this crosstalk by means of ILK. ILK markedly reduced the protein stability of Notch1 and suppressed Notch1 binding to RBP-JK. The kinase activity of ILK was essential for the inhibition of Notch1 signaling, but Akt and GSK-3β, the downstream effectors of ILK, were not involved in the negative regulation of Notch1 by ILK. Notably, the protein level and transcriptional activity of endogenous Notch1 was higher in the ILK null cells than in ILK wild-type cells, and the endogenous Notch1 was increased by the blocking of the proteasome representing the enhancement of the proteasomal degradation of Notch1 by ILK. Notch1 was ubiquitinated prior to proteasomal degradation, and we investigated the involvement of Fbw7, an E3 ligase for the ubiquitination of Notch1, and the ubiquitination of Fbw7 was stimulated in the presence of ILK. Furthermore, we found that down-regulation of Notch1C and up-regulation of ILK in basal cell carcinoma (BCC) and melanoma patients, but not in squamous cell carcinoma (SCC). These results suggest that ILK down-regulates the protein stability of Notch1 through the ubiquitin-proteasome pathway by means of Fbw7.

Tip60 Histone Acetyltransferase Acts as a Negative Regulator of Notch1 Signaling by Means of Acetylation
M. Kim, S. Han, J. Kim, S. Kim, J. Mo, J. So, H. Park; SBST, Chonnam National University, Gwangju, Republic of Korea

The Notch signaling pathway appears to perform an important function in the determination of cell fate, as well as differentiation, in a wide variety of organisms and cell types. In our present study, we provide evidence that UV irradiation-induced Tip60 histone acetyltransferase (HAT) proteins reduced Notch1 activity to a marked degree. Accumulated UV irradiation-induced Tip60 suppresses Notch1 transcriptional activity via the dissociation of the Notch1-IC-RBP-JK complex. In vivo binding between endogenous Tip60 and Notch1-IC in HEK293 cells was verified in this study by coimmunoprecipitation. Interestingly, the physical interaction of Tip60 with Notch1-IC occurs to a more profound degree in the presence of RBP-JK, but does not exist in a trimeric complex. Using Notch1-IC and Tip60 deletion mutants, we also determined that the N-term, which harbors six asparagine repeats of Notch1-IC, interacts with the zinc-finger and Acetyl-CoA domain of Tip60. Furthermore, here we report that Notch1-IC is a direct target of the acetyltransferase activity of Tip60. Collectively, our data suggest that Tip60 is an inhibitor of the Notch1 signaling pathway, and Tip60-dependent acetylation of Notch1-IC may be relevant to the mechanism by which Tip60 suppresses Notch1 signaling.

Identification of a Novel Oncogene, Cancer-upregulated Gene 2 (CUG2)
S. Lee, B. Cho, B. Lee, J. Jung, S. Koh; 1Department of Microbiology, Chungnam National University, Daejeon, Republic of Korea, 2LG Life Sciences, Ltd./R&D Park, Daejeon, Republic of Korea

We examined genome-wide differences in gene expression between tumor tissues and normal tissues in order to identify differentially regulated genes in tumors. Cancer-upregulated gene 2 (CUG2) was identified as an expressed sequence tag (EST) that exhibits significant differential expression in multiple human cancer types. CUG2 showed weak sequence homology with the down-regulator of transcription 1 (DRT1) gene, a human transcription repressor. We found that EGFP-CUG2 fusion proteins were predominantly localized in the nucleus, suggesting their putative role in gene regulation. In addition, CUG2-overexpressing mouse fibroblast cells exhibited distinct cancer-specific phenotypes in vitro. Taken together, these findings suggest that CUG2 is a novel tumor-associated gene that is commonly activated in various human cancers and exhibits high oncogenic activities.

Oncogenic Property of PTK6 Depending on Subcellular Localization
H. Kim, L. Soo-Taeck; Dept. of Biochemistry, Yonsei University, Seoul, Republic of Korea

Protein-tyrosine kinase 6 (PTK6; also known as Brk) is an intracellular tyrosine kinase and is expressed in and around 60% of breast tumors. Altered localization of protein tyrosine kinases has been shown to play an important role in cancer progression. Here we have analyzed oncogenic property of PTK6 depending on its subcellular localization. To generate membrane-targeting and nuclear forms of PTK6, we made HEK 293 cell lines expressing either Myr-PTK6 containing a Src myristoylation signal or NES-PTK6 containing SV40 T-antigen nuclear localization sequence. The Myr-PTK6 was mainly localized in plasma membrane and showed enhanced abilities of PTK6 to promote proliferation and prevent apoptosis of HEK 293 cells, as well as to promote anchorage-independent colony formation. The NLS-PTK6 was localized in nucleus but lost these oncogenic abilities. In addition, a pattern of tyrosine-phosphorylated proteins in Myr-PTK6-expressing cells was quite different from that in NLS-PTK6-expressing cells, suggesting that PTK6 in each subcellular compartment associates with and phosphorylates a distinct set of proteins. Targeting of PTK6 to plasma membrane would be a valuable prognostic indicator for various tumor progressions and identification of substrates phosphorylated by the membrane-targeted PTK6 may provide potential targets for therapeutic intervention.

Oxidative Modification of Caspase 9 Mediates Its Interaction with Apaf-1, Auto-cleavage, and Activation
J. Yang, Y. Zuo, J. Yi; Cell Biology, Shanghai Jiao Tong University School of Medicine, Shanghai, China

Caspase 9 must undergo proteolytic activation through binding with Apaf-1 in the cytochrome c/ATP-dependent pathway to exert apoptosis. Intracellular reactive oxygen species (ROS) and redox state were increasingly reported to regulate apoptosis and is closely associated with Caspase 9 activation, however the direct relationship of ROS and Caspase 9 activation has been unclear. The present study aimed to elucidate the role of ROS and possible mechanisms in Caspase 9 activation. The results firstly showed that in reductive cellular environment Caspase 9 activation initiated by various apoptotic stimulus staurosporin or TNFα was weakened, while in oxidative environment, Caspase 9 activation was facilitated. Therefore, in general, redox state regulated Caspase 9 activation. We then applied hydrogen peroxide (H2O2) to directly mimic redox alteration, finding that it allowed the auto-cleavage and activation of Caspase 9, and in the process the thiol of caspase 9 were oxidized. H2O2 also led to formation of the complex of Caspase 9 and Apaf-1, while DTT could separate the complex, suggesting that H2O2 resulted in oxidation of caspase 9 and formation of intermolecular disulfide bond between procaspase 9 and Apaf-1. To exclude possibility that H2O2 indirectly activated Caspase 9 through increased cysteine c, we reconstituted an in vitro mitochondria deplention system. The result showed that thiol-specific oxidant dimide could induce Caspase 9 activation, demonstrating that the oxidized procaspase 9 processing and activation maybe independent of cysteine c increase induced by H2O2. Finally in an in vitro Caspase 9 and Apaf-1 recombinant system, diamide caused disulfide-mediated interaction with Apaf-1, auto-cleavage and activation of Caspase 9. Taken together, caspase 9 could be oxidized by certain amount of ROS, and thus oxidative modification of procaspase 9 mediated interaction with Apaf-1, auto-cleavage and activation of procaspase 9. This finding explicates the mechanism by which oxidative stress initiates cell apoptosis.
Mitochondrial Manganese Superoxide Dismutase Protects Ovarian Cancer Cells from Oxidative Stress-induced Apoptosis

K. Wong, B. Yeung, A. Wong; Zoology, The University of Hong Kong, Hong Kong

The manganese superoxide dismutase (MnSOD), located in the mitochondria, is a major antioxidant enzyme that plays an important role in protecting cells from oxidative damage. MnSOD has been suggested to have tumor suppressor function in many cancer types. Surprisingly, the levels of MnSOD in ovarian carcinomas were found elevated compared with normal ovarian epithelium. In this study, we aimed to investigate the levels of MnSOD protein in ovarian cancer cell lines and ovarian surface epithelial (OSE) cells and a possible link between MnSOD expression and resistance to apoptosis. We showed that MnSOD protein was abundant in most ovarian cancer cell lines but was at very low levels in OSE. MnSOD overexpression in ovarian cancer cells caused a ~50% decrease of cell proliferation and an increase of apoptosis, whereas targeted inhibition of endogenous MnSOD using small interfering RNA promoted growth of these cells, confirming the effect was MnSOD specific. Furthermore, stimulation of mitochondrial superoxide (O₂⁻) production induced an increase of MnSOD expression, suggesting that MnSOD may alleviate the reactive oxygen species stress in these cells. Our data also showed that MnSOD overexpression protected ovarian cancer cells from apoptosis induced by treatment with rotenone, hydrogen peroxide, or hypoxia-mimicking agents cobalt chloride and deferoxamine compared with the parental andneo control cell lines. Together, these data suggest upregulation of MnSOD in ovarian cancer cells is one of the mechanisms which may increase resistance to oxidative stress and apoptosis in cancer cells.

Gapex-5, a Rab31 Guanine Nucleotide Exchange Factor That Regulates Glut4 Trafficking in Adipocytes

I. J. Lodhi, S. H. Chiang, L. Chang, D. Vollenweider, T. T. Watson, M. Inoue, J. E. Pessin, A. R. Saltiel; Life Sciences Institute, University of Michigan, Ann Arbor, MI, Department of Pharmacological Sciences, Stony Brook University, Stony Brook, NY

Insulin stimulates glucose uptake into muscle and adipocytes by promoting translocation of the facilitative glucose transporter Glut4 from intracellular storage compartments to the plasma membrane. In the absence of insulin, Glut4 is retained intracellularly, although the mechanism underlying this process remains uncertain. Using the T1CD1-transducing protein CIPM as bait in a yeast two-hybrid screen, we cloned a RasGAP and VPS9 domain-containing protein, Gapex-5BME-6. The VPS9 domain is a guanine nucleotide exchange factor for Rab31, a Rab5 subfamily GTase implicated in trans-Golgi Network (TGN)-to-endosome trafficking. Overexpression of Rab31 blocks insulin-stimulated Glut4 translocation by retaining Glut4 vesicles inside the cell, whereas knockdown of Rab31 potentiates insulin-stimulated Glut4 translocation and glucose uptake. Gapex-5 is predominantly cytosolic in untreated cells; its overexpression promotes intracellular retention of Glut4 in adipocytes by maintaining Rab31 in an active state. Insulin recruits the CIP4-Gapex-5 complex to the plasma membrane, thus reducing Rab31 activity and permitting Glut4 vesicles to translocate to the cell surface. These data suggest that in the basal state, Glut4 is retained in cells by cycling between the TGN and endosomes due to the activity of Rab31, and escapes this futile cycle after insulin stimulates the translocation of Gapex-5 to the plasma membrane.

RNA Interference-mediated Allele-specific Silencing Rescues Sialic Acid Levels in the Dominant Disorder Sialuria

R. Klotowijk, P. Savelkoul, C. Ciccone, D. Krasnewich, W. Gahl, M. Huizing; NIHgRI, NIH, Bethesda, MD

Sialuria is a rare autosomal dominant disorder of the sialic acid biosynthesis. UDP-GlcNAc 2-epimerase/MannNAc kinase, encoded by the GNE gene. This results in loss of feedback inhibition of GNE by CMP-sialic acid, and overproduction of sialic acid. Sialuria patients manifest variable signs and symptoms, including mild hepatomegaly and developmental delay. Since dominantly inherited disease alleles are attractive therapeutic targets for allele-specific silencing mediated by RNA interference (RNAi), we employed this method in fibroblasts of sialuria patients. Smaller interfering RNA (siRNA) was designed to specifically target a sialuria GNE nonsense mutation (c.787G>T, R263L). This siRNA was transfected into patients’ fibroblasts and the extent of silencing was assessed after 48 hours. After silencing, allele-specific real-time PCR analysis demonstrated that expression of the mutant GNE transcript was decreased by 66 ± 3 (SD) % (n=3). Furthermore, HPLC analysis of fibroblast extracts showed that sialic acid levels decreased 59 ± 15 % (n=3) after silencing. Finally, GNE enzymatic activity measurements showed a 41 ± 6 % (n=3) recovery of feedback inhibition by CMP-sialic acid. These results demonstrate that RNAi can correct the underlying metabolic defect in vitro in a human inborn error of metabolism. Allele-specific RNAi therapeutics in sialuria provides an example for correcting dominant-negative mechanisms through elimination of specific transcripts.

Characterizing the Molecular Mechanism of the Antitherogenic Effect of Lycopene

C. J. Wu, C. Lia; Biological Science and Technology, China Medical University, Taichung, Taiwan

Lycopene has been shown to be associated with a decreased risk of chronic diseases such as atherosclerosis. However, the role of lycopene in preventing atherogenesis have not been clearly elucidated. The aim of this study was to investigate the effect of lycopene-containing diet on the lipid metabolism of hamster fed with a high cholesterol diet. The molecular mechanisms of hypolipidemic and antioxidant effects of lycopene were also elucidated in vitro. For an 8-week feeding period, 50 male Golden Syrian hamsters (7 week old) were randomly assigned to 5 diet groups, including control, 0.2% cholesterol, lupid, low (3%) and high (9%) dose of lycopene. Upon sacrifice, the serum was subjected to analysis of total cholesterol, LDL, HDL, and triglyceride. Our results indicated that high dose of lycopene significantly reduced the serum level of total cholesterol and LDL for 15% and 11%, respectively. HDL was increased for 22% as compared to the control. However, triglyceride level was not affected by lycopene. Regarding the antioxidative activity, the effect on LDL oxidation of lycopene was determined by relative thiorbarbituric acid-relative substances(TBARS) assay and diene conjugation. Our results showed that lycopene were able to decrease MDA production in TBARS assay and delayed the diene conjugation in the Cu²⁺-mediated oxidation of LDL. The protein levels of several antioxidant enzymes in liver, including catalase,superoxide dismutases and glutathione peroxidase were also determined. All three enzymes were found to be up-regulated significantly by lycopene as compared to the cholesterol group. Real-time PCR analysis showing the reduced level of LDL receptor mRNA in hepatocytes further supported the lipid-lowering effects of lycopene. Two dimension protein gel analysis with LC-MS/MS analysis indicated the close association of Lycopene and its cognate ATP10C protein in the insulin mediated clearance of glucose by the peripheral tissues.

Insulin Signaling Pathway in a Novel Mouse Model of Type 2 Diabetes

M. S. Dhur, H. E. Reaves, C. S. Sommardahl, D. K. Haines, J. S. Yuan; 1Large Animal Clinical Sciences, University of Tennessee, Knoxville, TN, 2Department of Pharmacological Sciences, Stony Brook University, Stony Brook, NY

RNA interference (RNAi) can correct the underlying metabolic defect in vitro in a human inborn error of metabolism. Allele-specific RNAi therapeutics in sialuria provides an example for correcting dominant-negative mechanisms through elimination of specific transcripts.

Insulin Signaling Pathway in a Novel Mouse Model of Type 2 Diabetes

M. S. Dhur, H. E. Reaves, C. S. Sommardahl, D. K. Haines, J. S. Yuan; 1Life Sciences Institute, University of Michigan, Ann Arbor, MI, 2Department of Pharmacological Sciences, Stony Brook University, Stony Brook, NY

The etiology of human obesity and insulin resistance is complex with both genetic and environmental factors playing a role. These polygenic diseases can be more easily studied in murine models and then translated into human homologs and phenotypes. Two independent lines of mice, heterozygous for the pink-eyed dilution (p) locus deletions represent a novel polygenic mouse model of type 2 diabetes. Apo10c, a putative aminophospholipid transporter, mapping to the p locus on mouse chromosome 7 is a strong candidate for the phenotype observed in these mice. This phenotype is diet-induced. Metabolic profiling to investigate obesity-related phenotypes showed that mutants heterozygous for Apo10c and inheriting the deletion maternally, exhibit a significantly higher body weight, adiposity index, plasma triglyceride and insulin concentrations. These mice are glucose intolerant and insulin resistant. Insulin-stimulated glucose transport is significantly (P<0.05) decreased in the peripheral tissues. There is a clear difference in the severity and onset of insulin resistance compared with the parental and neo control cell lines. Together, these data suggest upregulation of MnSOD in ovarian cancer cells is one of the mechanisms which may increase resistance to oxidative stress and apoptosis in cancer cells.
A Mutation in the DXXE ER-Exit Code of Kir6.2 Causes Congenital Hyperinsulinism by Impairing Sar1 Dependent ER Export

T. K. Tanja,1 J. Mankouri,2 S. Kamoun,1 A. Smith,3 S. Sjöblad,4 A. Carlson,2 S. Iverson,2 H. Christiansen,2 A. Sivapuradasanab,1 Institute of Membrane and Systems Biology, Faculty of Biological Sciences, University of Leeds, Leeds, West Yorkshire, United Kingdom, 2Department of Paediatrics, University Hospital of Lund, Lund, Sweden, 3Department of Paediatrics, Malmö University Hospital, Malmö, Sweden, 4Department of Paediatrics, Odense University Hospital, Odense, Denmark

The ATP-sensing potassium (KATP) channel of the pancreatic β-cell is an octameric complex composed of four subunits each of Kir6.2 (K inward rectifier) and sulfonylurea receptor 1 (SUR1). Kir6.2 is responsible for the K+ ion conductance and SUR1 for regulation of Kir6.2 function. KATP channels couple glucose metabolism to membrane potential and thus play a central role in glucose stimulated insulin secretion. Genetic mutations in the genes encoding the channel subunits can cause congenital hyperinsulinism (CHI). CHI mutations impair channel function or trafficking thereby resulting in persistent depolarisation of the β-cell membrane and unregulated insulin secretion and severe hypoglycaemia. Here we report the discovery of a new mutation, E282K, in Kir6.2 subunit in a patient diagnosed with CHI. We have examined the consequence of this mutation on channel trafficking using immunocytocchemistry and function using electrophysiology. In heterologous expression systems, this mutation prevented maturation of SUR1 and surface expression by retaining the channel in the ER. However, the mutant subunit was able to reach the cell surface and form functional channels when co-assembled with the wild-type subunit; this suggests that ER retention is due to mis-folding of the mutant subunit. Further mutagenesis studies suggested that E282K could be part of a di-acidic DXXE ER exit code, raising the possibility that KATP channels may assemble with Sec23/Sec24 proteins and exit the ER as COPII vesicles in a process that requires hydrolysis of GTP by Sarl-GTPase. Consistent with this possibility, a dominant negative form of Sarl-GTPase (one which is unable to hydrolyse GTP) prevented the ER exit of wild-type channels. We conclude that KATP channels use the DXXE motif as a code to exit the ER. Functional importance of this motif is highlighted by the severity of the disease (CHI) caused by a genetic mutation disrupting this code. Funded by the MRC-UK.

1310 Ubiquitinated-Protein Aggregates Form in Pancratic β-cells during Diabetes-induced Oxidative Stress and Are Regulated by Autophagy

N. A. Kami,1 M. Kiraly,1 A. Volchuk,3 M. Vranic,3 J. H. Brumell1; 1Cell Biology, Hospital for Sick Children, Toronto, ON, Canada, 2Department of Physiology, University of Toronto, Toronto, ON, Canada, 3Division of Cell and Molecular Biology, University Health Network, Toronto, ON, Canada

Previous studies indicate that diabetes-induced oxidative stress can lead to protein misfolding and degradation by the ubiquitin-proteasome system. In this study, we examined protein ubiquitination events in pancreatic sections from Zucker Diabetic Fatty rats. We observed large aggregates of ubiquitinated proteins (Ub-proteins) in insulin expressing β-cells and surrounding acinar cells. The formation of these aggregates was also observed in INS1 β-cells after exposure to high glucose, allowing us to further characterize this phenotype. Aggregate formation was maximal 24 h after high glucose exposure and was not affected by protein synthesis inhibitors. Oxidative stress was sufficient to induce Ub-protein aggregate formation and the addition of antioxidants resulted in a significant decrease in their formation during high glucose treatment. Clearance of the Ub-protein aggregates from the cytosol was observed during recovery in normal glucose media. Despite the fact that the 20S proteasome was localized to Ub-protein aggregates, epoxomicin treatment did not affect their clearance, indicating the proteasome does not degrade proteins localized to these structures. Surprisingly, the autophagy inhibitor 3MA blocked aggregate clearance during recovery and was sufficient to induce their formation in low glucose media. Together, these findings demonstrate that diabetes-induced oxidative stress induces ubiquitination and storage of long-lived proteins into cytoplasmic aggregates, Autophagy, not the proteasome, plays a key role in regulating their formation and degradation. To our knowledge, this is the first demonstration that autophagy acts as a defense to cellular damage incurred during diabetes.

1311 ABCA1-mediated Cholesterol Eflux Is Modulated by Ion-Channels

J. M. Karwatsky, S. Nandi, Y. Feng, X. Zha; Ottawa Health Research Institute, Ottawa, ON, Canada

ATP binding cassette (ABC) proteins are primarily membrane-associated proteins that transport a diverse array of substrates across membranes. ABCA1 is the molecular basis for Tangier disease due to functional mutations. The physiological consequence of this disease is extremely low concentrations of high density lipoprotein (HDL) in plasma. Normally, ABCA1 promotes the efflux of cellular cholesterol to extracellular acceptor, such as lipid-poor apolipoprotein A-I (apoA-I, A1), to form HDL. Cells with non-functional ABCA1 cannot efflux cholesterol to HDL, and consequently large quantities of cholesterol are stored within cells. Clinically, atherosclerosis is associated with macrophages that are overloaded with cholesterol, a condition that can lead to heart disease. The mechanism by which ABCA1 mediates cholesterol efflux is still poorly understood. Particularly, the precise molecular function of ABCA1 remains unknown. Given the fact that many ABC transporters function as or influence ion-channels, we hypothesized that ion channels may be active participants of cholesterol efflux. We therefore tested the effect of channel blockers in cholesterol efflux. We demonstrate that replacement of extracellular Ca2+ with channel blocking anions effectively inhibit cholesterol efflux. The relative degree of efflux inhibition was: SCN− > gluconate− > aspartate−. Moreover, efflux was inhibited by the ion-channel modulator DIDS. Finally, our results indicate that altering of intra- and extra-cellular Ca2+ also had a pronounced effect on cholesterol efflux. These findings demonstrate for the first time that ion movement and concentration directly modulate ABCA1-mediated cholesterol efflux.

1312 Cigarette Smoke Induces Steatosis (Fatty Liver Disease) through Stimulation of TNF Alpha

Y. Huan, M. Martins-Green; Cell Biology and Neurosciences, University of California, Riverside, Riverside, CA

The most common cause of chronic liver disease in many countries, nonalcoholic fatty liver disease (NAFLD), is closely related with the increasing prevalence of obesity, diabetes mellitus, and metabolic syndrome. The first hepatic pathological stage of NAFLD is steatosis, the accumulation of lipid in the liver tissue. Steatosis can further progress to liver fibrosis and cirrhosis. However, the mechanisms involved in these stages are not clear. Cigarette smoking is a major risk factor for cardiovascular disease as well as hypertension and hyperlipidemia, and has recently been linked to NAFLD. We hypothesized that cigarette smoke stimulates liver cells to produce proinflammatory cytokines that increase lipid production.

The pro-inflammatory cytokine tumor necrosis factor alpha (TNFα) stimulates inflammatory, apoptotic, and fibrogenic responses that contribute to the progression of NAFLD and levels of TNFα are elevated in patients with nonalcoholic steatohepatitis (NASH), a NAFLD stage between steatosis and cirrhosis. To test our hypothesis, we used cultured hepatocytes, exposed them to cigarette smoke and that the activation of SREBPs can be blocked by an antibody to TNFα, we are currently investigating the regulation of this process in hepatocytes exposed to “second-hand” cigarette smoke. Understanding the regulatory mechanisms of this process will help understanding of NAFLD, and may provide insight into diabetic conditions that are related to NAFLD.

1313 Reverse Signaling Initiated from GITRL Induces NF-kappaB Activation through P42/p44 MAPK in Macrophages

E. M. Bae,1 W. J. Kim,1 H. U. Bae,2 Y. M. Kang,1 J. E. Park,1 B. S. Kwon,3 H. W. Lee; 1Department of Genetic Engineering, School of Life Sciences and Biotechnology, Kyungpook National University, Daegu, Republic of Korea, 2Rheumatology Division, School of Medicine, Kyungpook National University, Daegu, Republic of Korea, 3Cardiology Division, Samsung Seoul Hospital, Sungkyunkwan University, Seoul, Republic of Korea

Glucocorticoid-induced TNFR family-related protein ligand (GITRL) is the eighteenth member of the tumor necrosis factor superfamily (TNFSF18) and is known to interact with its cognate receptor GITR (TNFRSF18). In order to investigate the potential role of GITRL in the pro-inflammatory activation of macrophages and the signaling pathway induced by GITRL, we stimulated THP-1 macrophage cell line and human primary macrophages with anti-GITRL monoclonal antibody or GITR:Fc fusion protein and analyzed cellular responses. Stimulation of GITRL induced expression of pro-inflammatoric cytokines and matrix metalloproteinase (MMP)-9 and up-regulated intracellular adhesion molecule-1 (ICAM-1) expression levels. Activation of these pro-inflammatory mediators required activation of NF-kappaB, which was demonstrated by complete blockade of MMP-9 activation by NF-kappaB inhibitors such as etyyl pyruvate, sulfasalazine, and N-tosyl-L-phenylalanylchloromethyl ketone. Immunofluorescence analysis of subcellular location of NF-kappaB revealed nuclear translocation of p50 subunit within 40 min after the activation. GITRL-induced macrophage activation also required transient activation of ERK, since ERK inhibitors, PD98059 and U0126, blocked MMP-9 activation and Western blot analysis revealed transient phosphorylation of ERK within 5 min after the stimulation. Presence of ERK inhibitors, nuclear translocation of NF-kappaB p50 subunit was blocked indicating that GITRL stimulation induces ERK activation which subsequently induced NF-kappaB activation. Furthermore, expression of GITRL and GITR was detected in macrophages in inflammatory disease specimens such as atherosclerotic plaques and synovial tissues of rheumatoid arthritis. These observations raise the possibility that GITRL mediated inflammatory activation of macrophages is involved in the pathogenesis of inflammatory diseases.

242 2006 ASCB Annual Meeting Abstracts
Cardioprotective Effect of Onion (Allium cepa) through Inhibition of Oxidative Stress and Mitochondrial Death Pathway

D. Lee, J. C. P. Roos, S. Park, M. Kim, S. Lee, E. Bahk, C. Moon, E. Ko, S. Park, J. Jung; Department of Physiology, School of Medicine, Ajou University, Suwon, Republic of Korea.  

Our results suggest that psychosines dysregulate membrane concentrations (1-5 micromolar), but not ceramides, disrupt endocytosis: mis-trafficked membrane and ingested materials accumulate in a large vesicular compartment. This multivesicular body bears most lysosomal markers but has a neutral pH, is negative for acid phosphatase and positive for lysobisphosphatidic acid - consistent instead with late endosomes. The ultrastructure of γ finger two of PPAR γ, although both are expressed in a similar quantity. Compared to the WT, the mutant form has reduced capability to bind DNA. Mutation of a zinc-binding amino acid in zinc-γ resistance, dyslipidemia, and partial lipodystrophy (FPLD). In three subjects with FPLD, diabetes mellitus and hypertriglyceridemia, PPARG was screened for mutations by direct sequencing, adipocytes and other cellular regulatory processes. Mutations in the PPARG as well as in the LMNA gene, encoding the nuclear proteins lamin A/C, have been reported to cause insulin resistance, dyslipidemia, and partial piodoprosthesia (FPD). In three subjects with FPD, diabetess mellitus and hyperglycemia, PPAR γ was screened for mutations through direct sequencing after mutations in LMNA were excluded. 293T cells were transfected with a reporter gene plasmid and WT or mutant PPAR γ. Reporter gene activity was measured to determine if the PPAR γ mutant has decreased transcriptional activity. To assess whether WT and mutant protein are expressed in similar quantity, the protein was fixed with a FLAG-tag and detected by immunoblotting. Electrophoretic mobility shift assays were performed to investigate the capability of the mutant PPAR γ to bind DNA. We identified a PPAR γ mutation, C190S that causes PFPD and metabolic alterations. The mutation was not present in the unaffected family members or unaffected controls. The mutation is in the DNA binding domain, located within zinc finger two at the one of the zinc-binding amino acids. The C190S mutant had a significantly lower ability to activate a PPAR γ reporter gene than WT PPAR γ in absence and presence of rosiglitazone, although both are expressed in a similar quantity. Compared to the WT, the mutant form has reduced capability to bind DNA. Mutation of a zinc-binding amino acid in zinc-finger two of PPAR γ leads to an altered protein-DNA binding pattern, resulting in a partial loss of function, which in turn is associated with FPD. As distinct mutations in the LMNA gene also lead to PFPD, an interaction or common pathway between PPAR γ and lamin A/C has to be discussed.

Psychosines Mis-trafficked Endocytosed Cargo to a Pre-lysosomal Compartment: Relevance to the Pathogenesis of Gaucher Disease

J. C. P. Roos, S. Z. Wang, T. M. Cox; Department of Medicine, University of Cambridge, Cambridge, United Kingdom

In Gaucher’s disease, glucocerebrosidase deficiency leads to the accumulation of glucosylphosphoinositol (psychosine) and glucosylceramide. Multinucleate “Gaucher” cells form from macrophages and begin to store other lipids unrelated to the enzymatic defect. Psychosines have been reported to inhibit cytokinesis in cells expressing G-protein linked receptor 65 (GPR65). Signalling via GPR65 is also known to affect phosphorylation, calcium release and result in the formation of actin clots. Could psychosine-mediated signalling shed light on the formation of these multinucleated cells and account for the accumulation of lipids that are not substrates for glucocerebrosidase in Gaucher disease? Methods: We investigated the effects of psychosines and other lysophospholipids on human macrophages and monocyte-related cell lines expressing GPR65. Trafficking was evaluated by pulse-chase experiments using fluorescent lipids and markers of pH. Changes induced by lysophospholipids were visualized by electron microscopy and compared with Gaucher cells from affected spleen. Confocal fluorescence and electron microscopy were used to identify sub-cellular compartments. GPR65 expression in Gaucher spleen and other cells was confirmed by RT-PCR. Results: Psychosines stimulate sub-pathophysiological concentrations (1-5 micromolar), but not ceramides, disrupt endocytosis: mis-trafficked membrane and ingested materials accumulate in a large vesicular compartment. This multivesicular body bears most lysosomal markers but has a neutral pH, is negative for acid phosphatase and positive for lysobisphosphatidic acid - consistent instead with late endosomes. The ultrastructure of γ finger two of PPAR γ, although both are expressed in a similar quantity. Compared to the WT, the mutant form has reduced capability to bind DNA. Mutation of a zinc-binding amino acid in zinc-finger two of PPAR γ leads to an altered protein-DNA binding pattern, resulting in a partial loss of function, which in turn is associated with FPD. As distinct mutations in the LMNA gene also lead to PFPD, an interaction or common pathway between PPAR γ and lamin A/C has to be discussed.
There is a growing body of evidence suggesting that the declines seen with aging could be due to a decreased capacity of the ER to catalyze the posttranslational processing of newly synthesized proteins. In particular, we found in an autopsy series that low levels of ERp57 in the cerebral spinal fluid were invariably associated with brain atrophy. Remarkably, secretory and membrane protein co-aggregation with pre-existing PrP or Htt aggregates could be reduced by improving the efficiency of translocation into the ER. These findings suggest that the normally undetectable and minor population of mis-segregated secretory and membrane proteins can substantially modify the dynamics of cytosolic protein aggregates to affect traffic of constitutively cycling proteins like the transferrin receptor. These observations are consistent with the hypothesis that synapsin IIb regulates the formation and/or maintenance of synapses.

### Objectives

A. Ashok, R. S. Hegde; Cell Biology and Metabolism Branch, National Institutes of Health, Bethesda, MD

BACKGROUND: Aging is an unique characteristic of all multicellular eukaryotes. Numerous hypotheses have been proposed as the basis for these declines: such as accumulation of lethal mutations, oxidant injury, the "Hayflick" phenomenon and loss of telomerase activity. Two major problems with these models are that they are not all addressing the specific causes of aging, and the process of aging is not random. Our hypothesis is that aging is a result of the accumulation of cellular dysfunction, which in turn can be reduced by targeting specific components.

### Results

**O. Chakrabarti, N. S. Rane, R. S. Hegde; NICHD/CBMB, National Institutes of Health, Bethesda, MD**

Numerous neurodegenerative diseases are characterized by chronic accumulation of cytosolic protein aggregates initiated primarily by a single specific protein. This progressive aggregation of one protein is thought to dominate the functioning of various biochemical pathways and factors to ultimately cause cellular dysfunction and death. Conversely, attenuation of the cellular aggregate burden is often correlated with alleviation of cellular dysfunction. However, the parameters that influence the initial formation, persistence, or clearance of cytosolic aggregates remain largely unknown. To address this question, we have used a combination of multi-color live-cell imaging and biochemistry to simultaneously follow the fate of various cellular proteins in the presence and absence of cytosolic aggregates composed of either the mammalian Prion protein (PrP) or poly-glutamine containing Huntingtin (Htt). Surprisingly, pre-existing aggregates of PrP or Htt caused the progressive accumulation of cytosolic protein and membrane aggregates over the course of 4 days. This intracellular accumulation was not due to an inhibition of protein trafficking through the secretory pathway. Instead, pre-existing aggregates altered the fate of the normally small proportion of secretory and membrane proteins that failed to be segregated into the endoplasmic reticulum (ER). Rather than being degraded rapidly, non-translocated polypeptides co-associated with cytosolic aggregates to facilitate their growth and persistence. Remarkably, secretory and membrane protein co-aggregation with pre-existing PrP or Htt aggregates could be reduced by improving the efficiency of translocation into the ER. These findings suggest that the normally undetectable and minor population of mis-segregated secretory and membrane proteins can substantially modify the dynamics of cytosolic protein aggregates to potentially influence the pathologic course of neurodegeneration.

### Conclusion

From Birth to Death: Systematic Comparative Analysis of the Fate of Disease-causing PrP Mutants

A. Ashok, R. S. Hegde; Cell Biology and Metabolism Branch, National Institutes of Health, Bethesda, MD

Prion diseases are neurodegenerative disorders characterized by the aberrant metabolism of the mammalian prion protein (PrP), a widely expressed GPI-linked cell surface protein of unknown function. Although most studies are aimed at understanding the transmission of prion diseases, roughly one-third of cases involve dominantly inherited mutations in PrP. The phenotypic similarities between transmissible and heritable prion diseases have suggested shared mechanisms of neuronal damage that in neither case is well understood. To address this central issue, we are combining our insights from in vitro, biochemical, cell biological, and imaging methodologies to trace the biosynthesis, trafficking, and metabolism of PrP. Systematic comparative analyses of disease-causing mutations in two disease-modifying polymorphic backgrounds are being used to identify defining features underlying their common neurodegenerative outcomes. Our ongoing analysis has allowed the classification of PrP mutants into two qualitatively distinct groups. The first group, represented by five mutants, influences the initial translocation of PrP across the ER membrane to alter the proportion of PrP molecules that are generated as a transmembrane protein. The effects are modest (affecting only -5-10% of total PrP molecules) and appear to have little or no effect on the steady state localization, biochemical behavior, or modification of PrP in cultured cells. The second group, represented by six mutants, shows no effect on ER translocation, core modifications, or topology. However, -5-10% of these mutant PrP molecules change their biochemical properties and trafficking itineraries at a post-ER compartment. The long-lived nature of this altered form results in its increased accumulation at steady state, being detected as an incompletely modified insoluble population of PrP. Thus, two key points in PrP metabolism, one at the ER and another at a post-ER compartment, have emerged as especially sensitive to mutational deviation and represent candidates for key events in prion disease pathogenesis.

### A Method to Obtain Schwann Cell Enriched Cultures from Adult Rabbit Sciatic Nerve

I. De la Fuente Ayuso, 1.2 I. Alcalde, 1.4 O. L. Gamboa, 1,3 M. J. Gayoso, 2,3 1,2Cell Biology, University of Valladolid, Valladolid, Spain, 1Incy, University of Valladolid, Valladolid, Spain

Objectives: Obtaining a large number of viable Schwann cells (SCs) is one of the most promising approaches to repair nervous system injuries. We present here a fast protocol, which is easily reproducible and scalable, to obtain highly enriched cultures of adult rabbit SCs. This method of nervous system diseases. Methods: 10-15 fragments from a rabbit sciatic segment of 1.5 cm, were preincubated in vitro for a week with DMEM, 10% fetal bovine serum (FBS) and neuregulin (NRG1). After dissociation with trypsin and collagenase, cells were plated and incubated for six days in the same type of medium. Results: At 13 days in vitro, this method yields a total of around 2.85 x 10^6 cells, with an average of 88.76% p75 positives and 94.04% s100 positives. Conclusions: Nerve in vitro predegeneration with DMEM with FBS and NRG1 together with subsequent culture in the same conditions are sufficient and suitable to obtain adult SC enriched cultures in under two weeks. The Ubiquitin Protease Ataxin-3 Auto-Regulates Its Protein Levels and Post-translational Modification

S. V. Todi, M. N. Laco, H. M. Wen, H. L. Paulson; Neurology, The University of Iowa, Iowa City, IA

Spinocerebellar Ataxia 3 (SCA3) is one of nine inherited neurodegenerative disorders caused by expanded polyglutamine regions in the respective proteins. SCA results from an expansion in the MJJD1 gene, which encodes the protein ataxin-3 (AT3). AT3 was recently shown to be a deubiquitinating enzyme and poly-ubiquitin binding protein that functions in protein quality control pathways. Here we present data that AT3 auto-regulates its cellular protein levels in a catalytic site-dependent fashion. An inactivating mutation of the AT3 catalytic site leads to a marked increase in steady state levels of AT3 protein, which can be reduced by coexpression of active AT3. Consistent with this, in-vitro and in-vivo experiments show that catalytically inactive AT3 is more resistant to proteasomal degradation than its wild type counterpart. These results led us to investigate whether inactive AT3 is more stable as a result of altered ubiquitination of the protein. Studies in transfected cells show that AT3 is in fact ubiquitinated and that AT3 ubiquitination pattern is dependent upon its DUB activity; inactive AT3 is more heavily ubiquitinated than wild type AT3. We next investigated the hypothesis that wild type AT3 can lead to lower levels of coexpressed inactive AT3 by directly deubiquitinating it. However, our research indicates that wild type AT3 does not alter the ubiquitination pattern of inactive AT3 in trans. Instead, our data suggest that AT3 forms a homomeric complex with other AT3 proteins and that, through this interaction, AT3 affects their fate, possibly by recruiting inactive AT3 more readily into a proteasomal-targeted complex. We believe that AT3 auto-regulates its cellular levels, possibly via a catalytic site-dependent interaction with the proteasome. This is important because it suggests that AT3 may not only alter substrate protein ubiquitination patterns, but conceivably also by associating with them and affecting their fate.

Activation of p38 MAPK Negatively Modulates Induction of Matrix Metalloproteinase-9 Expression in Rat Astrocytes

As an extension of our previous study showing Erk1/2 pathway mediates lipopolysaccharide (LPS) induced MPP-9 over-expression in rat primary astrocytes (Glia 41:15-24, 2003), we investigated the role of p38 pathway on the regulation of MPP-9 expression in LPS-stimulated rat primary astrocytes. LPS treatment activated both p38 and JNK in rat primary astrocytes. Treatment of a specific p38 MAPK inhibitor SB203580, but not the JNK inhibitor SP600125, increased the LPS-stimulated MPP-9 expression, which was dependent on the concentration of SB203580. Anti-inflammatory cytokines, such as IFN-γ and IL-4, activated p38 MAPK and decreased the LPS-induced MPP-9 production. When the activation of p38 MAPK was blocked by SB203580, the inhibitory effects of these cytokines on MPP-9 induction were abolished. Finally, direct injection of SB203580 into the lateral ventricle of the rat brain increased the LPS-induced MPP-9 activity from the cerebral cortex. Altogether, these results suggest that p38 activation modulates the inflammatory stimulation-induced over-expression of MPP-9, both in primary astrocytes and in the rat cerebral cortex, which enables fine-tuning of the MPP-9 expression in neuroinflammatory condition.

Carboxyfullerenes Attenuate NMDA-induced Excitotoxic Injury in Cortical Neuronal Cultures: A Structure-Activity Study

S. S. Ali, M. Behrens, L. Dugan; Medicine, University of California San Diego, La Jolla, CA

Carboxyfullerenes are small-size molecules with unique chemical and biomedicinal properties. Motivated by the extraordinary free radical scavenging ability of the parent fullerene C60 molecule, we synthesized and explored the applications of its water-soluble malonic acid derivatives as potential neuroprotective agents. We discovered that these compounds are capable of eliminating superoxide radical, which is the main source of cellular oxidative stress, through a catalytic mechanism mimicking superoxide dismutase action (Ali et al. Free Radical Biology and Medicine, 37 (2004) 1191). The qualitative structure-activity relationship of 7 different malonic acid C60 derivatives against NMDA-induced excitotoxic injury in cortical neuronal cultures was studied. Attempts to correlate neuroprotective efficacy of carboxyfullerenes with their reactivity towards superoxide radical were also carried out. Moreover, quantum mechanical semi-empirical calculations were performed and the obtained parameters were employed to rationalize the observed reactivity trend. Distribution of the malonic acid substituents around the C60 surface, rather than their population, was found to determine the reactivity of drugs towards superoxide, and hence, their neuroprotective efficacy. Computer-generated modeling studies suggested that the enhanced potency of C3 compound (relatively large dipole moment) and the inefficacy of its D3 isomer (zero dipole moment) may be due to the potential electrostatic interaction between the drug and the excitotoxic superoxide radical. These results confirm that the neuroprotective action of carboxyfullerenes is due to their antioxidative properties rather than to a hypothetical ionic-channel regulatory effect.
significant decrease in phallolidin fluorescence intensity occurred in the filopodia and the peripheral lamellipodial region compared to control neurons, suggesting that thimerosal may affect either assembly dynamics or localization of F-actin in growth cones. The immediate effects of thimerosal on growth cone behavior suggest concentrations as low as 500 nM can inhibit axon growth to target cells during development.

#### HSV-mediated Transfer of Erythropoietin Reduces Injury and Improves Functional Recovery in Spinal Cord Trauma

M. Mata1; 1Neurology, University of Michigan, Ann Arbor, MI, 2VAMC, Ann Arbor, MI

Erythropoietin (EPO) is a pleiotropic cytokine which has been shown to have significant neuroprotective effects in several models of injury to the CNS. We determine whether vector-mediated expression of EPO in spinal cord would reduce damage and improve outcome after blunt trauma. A non-replicating herpes simplex virus (HSV)-based vector containing the human EPO gene under the control of the HCMV IEp (vector DHEPO) was constructed. Two hours after a 150 kDblunt trauma to the T10 thoracic spinal cord (Infinite Horizons Impactor), 1 μL containing 1.8x10^6 plaque forming units of DHEPO or control vector DHZ was injected on each side of the midline at the level of the injury. Motor behavior assessed by open field walking, grid-walk, and an automated Tread-scan and sensory behaviour assessed by thermal latency and mechanical threshold over 8 weeks after injury. Transgene expression, histological and BBB assessments were determined in addition to activation of MAPK and PI3K after injury. Increased expression of EPO was detected in spinal cord of SCI animals treated with DHEPO by RT-PCR and WB. SCI rats treated with DHEPO showed marked improvement in motor behavior compared to the DHZ treated animals but there was no improvement in sensory function. DHEPO-treated animals had less disruption of the blood brain barrier, decreased hemorrhage and lower RSA extravasation that injured DHZ animals after injury. While p-AKT was increased at 3, 10 and 28 days after injury, p-ERK was increased only at 28 days in the DHEPO-inoculated SCI. Expression of NeuN was greater in the DHEPO-SCI animals compared to the DHZ group and NeuN banding pattern by WB in DHEPO treated group was similar to that of sham animals. Gene therapy with HSV-mediated expression of EPO after SCI may be used to protect blood brain barrier function, reduce tissue injury and improve function.

#### Cytoskeleton Alterations Induced by Herpes Simplex Virus Type 1 Infection in Neuronal Cultures

A. Zambrano,1 L. Solis,2 N. Salvadores,12 M. Cortés,1,2 C. Mendez,1,2 C. Orih1, Instituto de Microbiología, Facultad de Ciencias, Universidad Austral de Chile, Valdivia, Chile

Herpes simplex virus type 1 (HSV-1) belongs to the family Herpesviridae, genus Simplexvirus, it is ubiquitous, neurotropic and the most common pathogenic cause of sporadic acute encephalitis in humans. Herpes simplex encephalitis (HSE) is associated with neurological and neurophysiological disorders, which afflict patients all life long. However, at present, there is not evidence about the role of HSV-1 triggering neurodegenerative process. In cell lines, HSV-1 induce cytoskeleton alterations, these alterations involve the overall disruption of one or more elements of the cytoskeleton. In our laboratory, primary cortical neurons were infected with HSV-1 to study change in microtubule dynamics and alterations of actin filaments of cortical neurons. Our results show a clear neuronal death, axonal injury and neurites disruption in neuronal cultures infected by HSV-1. Immunofluorescence and western blot analysis showed that HSV-1 induced a significant change in microtubule dynamics and also induced actin filaments alterations. These results suggest an important role of HSV-1 infections on neuronal cytoskeleton.

#### Receptors for Microtubule Motors in the Inner Tegmentum of Herpes Simplex Virus

K. Radtke, A. Wolfstein, B. Sodeik; Department of Virology, Hannover Medical School, Hannover, Germany

After entry into cells, capsids of Herpes Simplex Virus Type 1 (HSV1) are transported along microtubules towards the nucleus for viral genome uncoating, transcription and replication. Newly synthesized capsids leave the nucleus through the cytosol to host membranes for envelopment and further viral spread. Cytosplasmic dynein and its cofactor dynactin transport cytosolic capsids towards the microtubule minus-end during virus entry. However, the motor proteins conveying and directed transport during virus egress from cells as well as the viral interaction partners are not known. In order to identify HSV1 receptors for microtubule motors, we generated capsids with different tegument protein composition: (i) capsids without tegument proteins, (ii) capsids with only inner tegument proteins such as VP1-3 and UL37, and (iii) capsids with inner and outer tegument proteins. To analyze motor protein binding to these capsids, they were incubated with cytosol and either collected by sedimentation and analysed by immunoblot, or examined via immuno-gold labelling, negative-contrasting and electron microscopy. Capsids which had only inner tegument proteins attached showed an increase in dynein and dynactin binding compared to capsids with inner and outer tegument proteins. Tegumented capsids also bound the plus-end directed motors kinesin-1 and kinesin-2. In contrast, capsids without tegument showed little interaction with microtubule motors. This is consistent with Wolfstein et al. (Traffic 2006; 7:227-37), who demonstrated that capsids exposing inner tegument proteins showed an increased transport along fluorescently labelled microtubules in vitro.
GMF-induced Production of Proinflammatory Mediators in Glial Cells Mediates Neuronal Cell Death

A. Zaheer, 1 S. Knight, 2 S. Zaheer, 2 S. K. Sahu 2; 1Neurology, VA Medical Center & University of Iowa, Iowa City, IA, 2Neurology, University of Iowa, Iowa City, IA, 3Neurology and Neurosurgery, University of Iowa, Iowa City, IA

The glia maturation factor (GMF), a highly conserved brain-specific protein, isolated, sequenced and cloned in our laboratory, has proinflammatory and immunomodulatory functions in the central nervous system. GMF is localized mainly in astrocytes but is also present in some neuronal populations. Recently, we established that overexpression of GMF in astrocytes, leads to immune activation of microglia in vitro, through secretion of granulocyte-macrophage-colony stimulating factor. In the present study, we evaluated the effects of GMF-induced expression and release of proinflammatory mediators by glial cells in the neuronal cells in culture. The overexpression of GMF in mixed culture of primary glial cells with a replication-defective adenovirus carrying GMF cDNA caused a significantly increased production of GM-CSF, TNF-α, IL-1β, and IL-12 p40. Additionally, the GMF-overexpressing glial cell conditioned-medium was cytotoxic to primary neuronal cells and N18 mouse neuroblastoma cells in culture. The increased production of proinflammatory cytokines as well as the neuronal cell cytotoxicity was significantly blocked (greater than 80%) by down-regulating the GMF expression using a GMF-specific siRNA. Control scrambled siRNA had no such effects. This GMF led death of neuronal cells may have important implications in neurological disorders such as multiple sclerosis and Alzheimer’s disease. Supported by VA Merit Review award and NIH grant NS47145 (to AZ)

The Juvenile Myoclonic Epilepsy-related Protein EFHC1 Interacts with the Redox-sensitive TRPM2 Channel Linked to Cell Death

M. Katano, 1 Y. Mori, 2 Y. Hara 2; Kyoto University, Kyoto, Japan, 3Iowa University, Iowa City, IA

The transient receptor potential M2 channel (TRPM2) is the Ca2+ permeable cation channel controlled by cellular redox status via beta-NAD+ and ADP-ribose (ADPPr). TRPM2 activity has been reported to underlie susceptibility to cell death. However, little is known about the intracellular mechanisms that regulate oxidative stress-induced cell death via TRPM2. We report here a molecular and functional interaction between the TRPM2 channel and EFHC1. Immunoprecipitation analysis demonstrated physical interaction of the N- and C-terminal cytoplasmic regions of TRPM2 with the EFHC1 protein. Co-expression of EFHC1 significantly potentiated hydrogen peroxide (H2O2)- and ADPPr-induced TRPM2 channel activation in intracellular Ca2+ measurements and electrophysiological ionic current recordings in HEK293 cells. Furthermore, EFHC1 enhanced TRPM2-mediated susceptibility of HEK293 cells to H2O2-induced cell death. These effects of EFHC1 were reversed by JME mutations. The results reveal a possible regulatory action of EFHC1 on TRPM2 activity which enhances cell death, suggesting that TRPM2 contributes to the expression of JME phenotypes by mediating disruptive effects of JME mutations on EFHC1-induced neuronal death.

Pathways of Microglia Activation and Neuron Killing in a Model of the Ischemic Stroke Penumbra

V. Kasahara, 1 K. Takahashi, 2 R. Prusa, 3 D. Ethell, 4; 1Toronto Western Research Institute, Toronto, ON, Canada, 2Department of Physiology, University of Toronto, Toronto, ON, Canada

Microglia, the resident immune cells of the CNS, are important for orchestrating acute brain inflammation following stroke and trauma. During a stroke, glutamate is released by damaged neurons and is thought to act both through ionotropic glutamate receptors (mGluR) and metabotrophic receptors (mGluR). To study the underlying processes, we developed an in vitro model of microglia activation that is more relevant to the stroke penumbra, where microglia are exposed to stressed neurons. Microglia were grown on porous Transwell™ inserts, and then exposed to oxygen glucose deprivation (OGD). Cortical biopsies were stored in glutaraldehyde for investigation by electron microscope (Phillips CM100) and in formaldehyde for immunohistochemical investigation with antibodies against caspase 3, Bcl-2, NSE, and CD68. Total RNA was extracted from brain tissue. cDNAs were synthesized from RNA using promoter primer, fragment transcripts were hybridized on nylon membrane. Results. A spectrofluorometer-based assay showed that OGD-treated neurons activated microglial NF-kB, a transcription factor well known to promote pro-inflammatory functions of innate immune cells. In this in vitro model, the trigger for microglia activation appears to be glutamate acting on metabotropic glutamate receptors, since their neurotoxic properties were decreased by treating microglia with an mGluR1 antagonist (EGLU), and increased by an mGluR1 agonist (DGC IV). Consistent with the role of TNF-α in microglia-mediated killing, mGluR1 stimulation with DGC IV evoked TNF-α, but not NO, production. Importantly, we found that blocking Kv1.1 channels in the microglia inhibited NF-kB activation and reduced their neurotoxicity in this stroke penumbra model, as it did in a model using LPS-activated microglia. This novel in vitro model of the ischemic penumbra should prove useful for delineating processes more relevant to neuron-inflammation following stroke, and for assessing potential treatments. Supported by grants to LCS from the Heart & Stroke Foundation.

Gene Expression Profile and Serum Levels of NSE and S100b Protein in Patients with Trauma Brain Injury during 10 Days of Hospitalization

R. Prusa, 1 D. Vajtr, 1 J. Kukacka, 1 L. Houstava, 2 F. Samal, 2 A. Kracmarova, 3 M. Merkerova, 3 O. Benada 4; 1Clinical Biochemistry and Pathobiology, Charles University, 2nd Medical Faculty, Prague, Czech Republic, 3Neuropathology, Charles University, 3rd Medical Faculty, Prague, Czech Republic, 4Institute of Hematology, Charles University, 1st Medical Faculty, Prague, Czech Republic, 1Electronic Microscopy, Academy of Science, Prague, Czech Republic

Objective. The aim of this study was to evaluate cell damage by means of serum markers, electron microscopy, immunohistochemistry, and gene expression profile in patients with trauma brain injury according Glasgow coma score during 10 days of hospitalization. Methods. 12 patients with trauma focal brain injury were investigated and divided into group (n=6) with improvement of GCS during 10 days of hospitalisation to 15 points, and group of patients (n=6) without improvement of GCS. Serum NSE and S100B concentrations were measured on Elecsys2010 (Roche). Cortical biopsies were stored in glutaraldehyde for investigation by electron microscope (Phillips CM100) and in formaldehyde for immunohistochemical investigation with antibodies against caspase 3, Bcl-2, NSE, and CD68. Total RNA was extracted from brain tissue. cDNAs were synthesized from RNA using promoter primer, fragment transcripts were hybridized on nylon membrane. Results. A spectrofluorometer-based assay showed that OGD-treated neurons activated microglial NF-kB, a transcription factor well known to promote pro-inflammatory functions of innate immune cells. In this in vitro model, the trigger for microglia activation appears to be glutamate acting on metabotropic glutamate receptors, since their neurotoxic properties were decreased by treating microglia with an mGluR1 antagonist (EGLU), and increased by an mGluR1 agonist (DGC IV). Consistent with the role of TNF-α in microglia-mediated killing, mGluR1 stimulation with DGC IV evoked TNF-α, but not NO, production. Importantly, we found that blocking Kv1.1 channels in the microglia inhibited NF-kB activation and reduced their neurotoxicity in this stroke penumbra model, as it did in a model using LPS-activated microglia. This novel in vitro model of the ischemic penumbra should prove useful for delineating processes more relevant to neuron-inflammation following stroke, and for assessing potential treatments. Supported by grants to LCS from the Heart & Stroke Foundation.

247
Resorption. Moreover, our findings strongly implicate PLEKHM1 as a component of Rab7 signaling pathways and late endosomal trafficking in osteoclasts. However, recent studies have shown that VLDLR is also involved in neuronal migration during brain development. Although VLDLR knockout mice display normal plasma lipid levels, they develop extensive retinal neovascularization (RNV), subretinal hemorrhages and choroidal anastomoses. Here we explore the function of VLDLR in the retina and the mechanism of RNV caused by deficiency of VLDLR. VLDLR expression in adult and developing mouse retinas was examined by RT-PCR. Northern blot, in situ hybridization and Western blot. Cell type specificity was studied by immunocytochemistry using antibodies against vldlr, and a panel of antibodies specific to different retinal cells including rod and cone photoreceptors, bipolar, amacrine, horizontal, Muller and ganglion cells. Visual function was assessed by both rod-derived and cone-derived electrotetrogramnic recordings. Our results show that VLDLR is expressed in the retina, although at levels lower than in the heart, skeletal muscle and brain. Expression is associated with the retinal vasculature and initiates at the onset of vascular development in the neonatal mouse retina. VLDLR KO mice display a normal distribution and density of retinal neurons and Muller glial cells, and exhibit normal visual function comparing to age-matched controls. We conclude that the abnormal neovascularization seen in VLDLR KO mice is unlikely due to its role in retin signal transduction of neuronal patterning since these mice have normal visual function and normal density and distribution of retinal neurons. It is also unlikely that the RNV is caused by deficiency in tricyclic VLDR metabolism since these mice display a normal lipid profile. We therefore suggest that the RNV in KO mice may be due to VLDLR-mediated specific interaction with novel ligands either directly or indirectly involved in angiogenesis.

DNase II-deficiency Disrupts Immune Function and Eye Development in Drosophila

C. Seong, A. Varela-Ramirez, R. J. Aguila; Biology, University of Texas at El Paso, El Paso, TX

DNase II belongs to a unique family of proteins that are required for degradation of ingested DNA. In eukaryotes, phagocytic cells utilize this enzyme to degrade the DNA of engulfed apoptotic cells or invading organisms. Since phagocytosis is an essential component of innate immunity, we hypothesized that the loss in this enzyme would result in a phagocyte-deficiency and possibly other defects. Using RNA interference and available DNase II-deficient lines, we have recently demonstrated that DNase II-deficiency results in severe immunodeficiency against bacterial infection due to the disruption of hemocyte (plasmatocyte) function. Microarray and real-time PCR analyses also indicate that DNase II-deficient flies exhibit an abnormal regulation of various genes including anti-microbial peptide genes. Expression of the ahse II-RNAi construct in other tissues did not lead to detectable defects with the exception of defects in eye development. Similar eye defects were also detected upon the specific expression of the ahse II-RNAi construct in the eye. However, no defects were detected in control animals or when expression was restricted to other tissues. Although no human patients have been linked to a deficiency in this enzyme, DNase II polymorphisms have been associated with increased risk of renal disorder among Systemic Lupus Erythematosus (SLE) patients. Our ongoing studies should greatly enhance our understanding of the molecular and biochemical roles of an enzyme that is essential for engulfment-mediated DNA degradation, normal immune function and eye development.

Xanthine Oxidase in Conjunctival Epithelial Cells of Humans Suffering from Dry Eye

J. Čejková, T. Ardan, C. Čejka, G. Sechova, K. Jirsova; Eye Histochemistry and Pharmacology, Institute of Experimental Medicine, Academy of Sciences of the Czech Republic, Prague, Czech Republic

Conjunctival cells from patients with dry eye produce excessive xanthine oxidase and express xanthine dehydrogenase, enzymes which catalyze the conversion of hypoxanthine and xanthine to uric acid. Since these reactions generate superoxide anion and hydrogen peroxide, xanthine oxidase may be involved in oxidative damage of the ocular surface.

Inhibitory Effects of Stewartia Koreana Extract on Osteoclast Differentiation and Bone Resorption

C. Park, H. Kim, D. Yang, D. Jung, N. Baek, J. Kim, Z. Lee, H. Kim; Seoul National University, Seoul, Republic of Korea, Kyung Hee University, Seoul, Republic of Korea

Several plants and herbs have long been used to treat osteoporosis as folk medicine in oriental countries. In this study, we aimed to screen extracts and natural products from edible plants for potential application to osteoporosis prevention and therapeutic effects. The in vitro screening was performed with culture of osteoclasts, differentiated with receptor activator of nuclear kappa B ligand (RANKL), macrophage colony stimulating factor (M-CSF), and in the presence or absence of extracts and natural products for 6 days. Osteoclast formation was tested by tartrate-resistant acid phosphatase staining. TRAP-positive multinucleated cells containing more than three nuclei were counted. Of the several plants-derived materials, Stewartia koreana extract (SKE) showed inhibitory effects on osteoclast differentiation and bone resorption. We examined the expression of SKE on osteoclast signaling pathways, SKE reduced levels of NFATc1 and c-Fos, crucial transcriptional regulators for osteoclastogenesis. SKE also downregulated mRNA levels of c-Fos and NFATc1 in RANKL-stimulated BMMs. Finally, SKE showed a great inhibitory effect on LPS-induced bone resorption in mouse model. Taken together, we demonstrated that SKE strongly inhibited bone resorption in vitro and in vivo by blocking osteoclast differentiation signal.

Plekhi1 Is Involved in Vesicular Transport in Osteoclasts and Causes Osteopetrosis in the Incisors Absent Rat and Human

L. Van Wesenbeek, P. R. Ogden, F. P. Coxon, A. Frattini, P. Moens, B. Van Hul, J. Timmermans; Laboratory of Cell Biology and Histology, University of Antwerp, Antwerp, Belgium, Dept of Experimental Medicine, University of L'Aquila, L'Aquila, Italy

The osteopetroses are a heterogeneous group of bone disorders characterized by a reduction in bone resorption and a generalized net accumulation of skeletal mass. We have now identified the plekhi1 gene as the gene responsible for the osteopetrotic phenotype of the incisors absent rat and have identified a splice site mutation in the human PLEKHI1 gene in a family diagnosed with an intermediate form of osteopetrosis. Electron and confocal microscopy analysis demonstrated that osteoclasts (derived from M-CSF-dependent peripheral blood monocytes) from the patient differentiated normally. However, unlike osteoclasts from sib-brother lacking the mutation, osteoclasts from the patient showed hardly any evidence of resorptive activity when cultured on dentine discs, and had a more flattened morphology. This is the first evidence for a role of the plekhi1 protein in bone metabolism. The presence of RUN and PH domains suggests that the plekhi1 protein may be involved in small GTPase signaling. Overexpression studies in HEK293 cells demonstrated that the plekhi1 protein is partially associated with intracellular vesicles and colocalizes with Rab7 and Rab9, but not with Rab5 or Rab6, suggesting that these vesicles are late endosomes/lysosomes. Moreover, in cells overexpressing Rab7, plekhi1 becomes completely localized to Rab7-positive vesicles, an effect that is not seen with overexpression of Rab9. Inhibiting the prenylation of Rab proteins with the specific Rab-GTPase inhibitor 3-PiHPC disrupted the endosomal localization of both Rab7 and plekhi1, while coexpression of a dominant negative Rab7 mutant and plekhi1 also resulted in a mainly cytosolic distribution of both proteins, suggesting that plekhi1 interacts with Rab7. In conclusion, the identification of PLEKHI1 as a new osteoporosis gene indicates its crucial role in bone resorption. Moreover, our findings strongly implicate plekhi1 as a component of Rab7 signaling pathways and late endosomal trafficking in osteoclasts.

Inhibition of RANKL-induced Osteoclastogenesis, by DMS, a Sphingosine Kinase Inhibitor through Down Regulation of NFATc1

H. Kim, E. Chang, C. Park, H. Kim; College of Dentistry, Seoul National University, Seoul, Republic of Korea

2006 ASCB Annual Meeting Abstracts
Therefore, CpG-ODNs may inhibit osteoclast differentiation through by down-regulating TREM-2 expression in osteoclast precursor s. This fact suggests a novel mechanism of TLR9 derived macrophages and pre-osteoclasts in response to RANKL but not in osteoclasts. In line, CpG-ODNs inhibited RANKL-induced NFAT activity but not NF-κB. In osteoclasts included filamin A and gelsolin, suggesting a role of actin remodeling during early stage of differentiation. To identify differentially expressed proteins, lysates from surface-biotinylated cells were subjected to avidin column and those biotinylated proteins were separated on SDS PAGE. After gel staining, proteins in 12 bands showing significant increase or decrease during differentiation were in-gel trypsin digested and eluted. Finally, peptides were subjected to reverse-phase liquid chromatography connected to tandem mass spectrometer and identified by SEQUEST search. As a result, we have identified 160 proteins differentially expressed between macrophages and pre-osteoclasts. Proteins increased in pre-osteoclasts included filamin A and gelsolin, suggesting a role of actin remodeling during early stage of differentiation. Expression of proteases specific for macrophages such as c-fms, CD14, and F4/80 decreased, confirming that pre-osteoclast lost phenotype of macrophages. Interestingly, expressions of integrin subtypes either increased or decreased in pre-osteoclasts compared with those in macrophages. Collectively, these results suggest that actin remodeling and regulation of signaling upon cell-cell/cell-extracellular matrix contact may be controlled at a protein level during early osteoclast differentiation.

Matrix Metalloproteases (MMPs) which are a family of zinc-dependent endoproteases cleave extracellular matrix components and other physiologically functional proteins. Using our degradomic approach using proteomic techniques, we have identified apolipoprotein E (apoE) as a putative MMP-14 substrate from human plasma. ApoE which is synthesized in the liver and several extracellular tissues is involved in lipid metabolism and protection of atherosclerosis. Digestion of the purified ApoE with various MMPs demonstrated that apoE is the most susceptible for MMP-14 among the tested MMPs. The 34-kDa apoE was initially cleaved into 28-kDa, 23-kDa, 21-kDa, 20-kDa, and 11-kDa fragments by MMP-14. By N-terminal sequencing and MALDI-TOF mass determination of the MMP fragments, cleavage sites of apoE by MMP-14 were determined to be between A176-I177, P183-L184, P202-L203, and Q249-I250. The cleavage sites were confirmed by identification of the C-terminus of each MMP fragment using isotope labeling (O18/D18) of the C-termini of MMP fragments, protease digestion, and MALDI-TOF mass spectrometry of the peptides. The cleavage pattern of the lipid-bound apoE by MMP-14 was the same as that of the lipid-free apoE. The vesicle size of the lipid-bound apoE was decreased upon digestion with MMP-14. Considering the important role of apoE for lipid metabolism and atherosclerosis protection, our findings suggest that MMP-14 may play an important role for development of hyperlipidemia and atherosclerosis by degradation of apoE.

CpG oligodeoxynucleotides (Cpg-ODNs) mimicking bacterial DNA, stimulate osteoclastogenesis via Toll-like receptor 9 (TLR9) in receptor activator of NF-kappa B ligand (RANKL)-primed osteoclast precursors. In contrast, activation of TLR9 in early osteoclast precursors results in inhibition of RANKL-induced osteoclast differentiation. However, it is not yet defined well how TLR9 activation differently modulates it. In this study, we demonstrated that TLR9 activation modulates the expression of triggering receptors expressed by myeloid cells (TREM-2), known to co-stimulatory signals required for RANKL. During osteoclastogenesis, the surface expression of TREM-2 was increased in response to RANKL and which was inhibited by CpG-ODNs treatment through the flow cytometry analysis. However, mRNA level of TREM-2 did not regulated by TLR9 co-stimulation. Interestingly, TREM-2 level was up-regulated in bone marrow-derived macrophages and pre-osteoclasts in response to RANKL but not in osteoclasts. In line, CpG-ODNs inhibited RANKL-induced NFAT activity but not NF-kB and AP-1 activity. These data indicated the role of PKH2 in osteoclastogenesis. Furthermore, CpG-ODNs differentially modulate the expression of co-stimulatory molecules for RANKL-induced osteoclast differentiation.
Disease Research CBHR, Brain Research Institute, University of Niigata, Niigata, Japan, 2Mental Retardation and Birth Defect Research, National Institute of Neuroscience, NCNP, Tokyo, Japan, 3Department of Physiology and Biophysics and Department of Neurology, Howard Hughes Medical Institute, University of Iowa, Iowa City, IA

Reduced level in glycosylation of α-dystroglycan causes a group of muscular dystrophies, which have been called α-dystroglycanopathies. Six causative genes have been implicated: three responsible proteins, namely protein O-mannosyltransferase 1 (POMGnT1), and protein O-mannosyltransferases 1 and 2 have been characterized as glycosyltransferases; the functional roles of the other three which include fukutin, LARGE, and fukutin-related protein remain largely unknown. Here we demonstrate a novel function of fukutin and LARGE. The cytochemical staining of the proteins, immunoprecipitation analysis, in vitro measurement of POMGnT1 activity, mutagenesis of fukutin and metabolic labeling of α-dystroglycan were used in this study. These two proteins co-localized to cis-Golgi compartment with POMGnT1 by forming a complex in cultured myoblasts. Enzymatic assay revealed that only POMGnT1 has N-acetylglucosaminyltransferase activity, whereas fukutin and LARGE have no activity by themselves, but strongly activate POMGnT1. Mutated fukutins were not expressed in cis-Golgi and were unable to activate POMGnT1.Brains from patients with Fukuyama-type muscular dystrophy and N2 mouse also showed decreased levels in protein O-mannosyl N-acetylglucosaminyltransferase activities. These findings suggest that the three α-dystroglycanopathies whose responsible proteins are fukutin, LARGE and POMGnT1, are most likely to be caused by a common pathomechanism, that is a defect in the second step in O-mannosylglycan synthesis of α-dystroglycan.

1352 Ankyrins-B and -G Cooperate in a Stepwise Pathway for Sarcomere Targeting and Costamer Localization of the Dystrophin Glycoprotein Complex

G. Ayala, J. Q. Davis, V. G. Bennett; Cell Biology and IHMI, Duke University Medical Center, Durham, NC

Costameres are specialized sarcomere domains, connecting striated muscle contractile machinery to the extracellular matrix (ECM). Costameres contain the Dystrophin Glycoprotein Complex (DGC), which forms physical bridges connecting the actin cytoskeleton and the ECM. The DGC preserves sarcomere integrity during contraction-relaxation cycles. Mutated genes encoding DGC proteins cause muscular dystrophy due to weakening of the sarcolemma and its disruption when subjected to physical stress. Cellular pathways governing DGC sarcomeral targeting and costamer localization are poorly understood. Ankyrins are cytoplasmic adaptor proteins known to localize integral membrane proteins to specialized membrane domains. We show for the first time that ankyrin-B is required for targeting the DGC to the sarcolemma, while ankyrin-G is required for localization of sarcomeral DGC to costameres. In neonatal ankyrin-B null mice, multiple DGC proteins are missing from the sarcolemma. siRNA knockdown of muscle ankyrin-B in adult mice in vivo recapitulates this phenotype. Ankyrin-B-depleted cells exhibit Evans Blue dye uptake following exercise. Following ankyrin-G knockdown in vivo, the DGC is sarcolemmal but mislocalized. Strikingly, these fibers also are penetrated by the dye showing sarcolemmal fragility. This implies that sarcolemmal presence of the DGC is not sufficient. Specific localization of the DGC to costameres is physiologically critical and is ankyrin-G dependent. Ankyrin-B binds directly the DGC proteins dystrophin (Dp71) and γ-sarcoglycan but not β-dystroglycan. Ankyrin-G binds dystrophin and γ-sarcoglycan, and with high affinity to β-dystroglycan, the main DGC transmembrane axis. We propose a model of DGC transient targeting interaction with ankyrin-B and a stable anchoring to costameres by ankyrin-G. We describe here a new principle: a two-step cellular pathway where ankyrin-B mediates targeting of proteins to the plasma membrane and ankyrin-G subsequently restricts them to specialized membrane domains that are critical for their physiological roles.

1353 Paxillin Upregulation in Dystrophin Deficiency Increases Contractility and Mapk Signaling but is Pro-survival

S. Sen, 1 Michael DeBakey Institute for Comparative Cardiovascular Science, Small Animal Clinic, College of Veterinary Medicine, College Station, TX, 2Dept. of Biomedical Engineering, Texas A&M University, College Station, TX, 3Dept. of Systems Biology and Translational Medicine, Texas A&M Health Science Center, College Station, TX, 4Michael DeBakey Institute for Comparative Cardiovascular Science, Small Animal Clinic, College of Veterinary Medicine, College Station, TX, 5Dept. of Biomedical Engineering, Texas A&M University, College Station, TX

Development and normal functioning of myotubes depend on an optimal balance between adhesion and cellular protrast. Normal muscle cells posses both integrin-based adhesions and dystroglycan-complex based adhesions. However, the latter are mostly missing in dystrophin deficiency and is known to cause integrin upregulation. Here we show that adhesion signaling protein paxillin is also upregulated, allowing study of its functional effects in muscle cells. We demonstrate that paxillin, a multifunctional protein found to localize both in focal adhesions and cytoskeletal structures, is also an essential signaling molecule of the contractile loop. Extended studies in cell cultures show that overexpression of GFP-paxillin in C2C12 myotubes promotes contractility and contributes to enhanced sarcomeric organization with no significant changes in adhesion. Finally, we confirm that the activation MAPK signaling is a common pathway of dystrophin deficiency, and paxillin promotes the de-differentiation associated phenotypic changes by modulating pro-survival signals.

1354 TGF-beta and BMP Signaling in Hypertensive Vascular Remodeling

N. Poppovic, 1 J. D. Neiger, 2 M. Miller, 3 T. Fossain, 2 J. D. Humphrey, 1 E. Wilson, 1 Dept. of Systems Biology and Translational Medicine, Texas A&M Health Science Center, College Station, TX, 2Michael DeBakey Institute for Comparative Cardiovascular Science, Small Animal Clinic, College of Veterinary Medicine, College Station, TX, 3Dept. of Biomedical Engineering, Texas A&M University, College Station, TX

Hypertensive vascular remodeling is characterized by phenotypic switching of muscle cells (SMC) to less differentiated phenotype. Bone morphogenetic proteins (BMP) and transforming growth factor beta (TGFβ) proteins in SMC act through the same TGFβ control element (TCE) and have opposing effects on SMC differentiation. The goal of our study was to determine the role of BMP and TGFβ signaling in hypertensive vascular remodeling. Aortic coarctation in miniswine was used to cause 2 weeks of sustained hypertension (mean arterial pressure>150 mmHg). Ponce 10k oligoarray chips were used to compare gene expression in aortic tissue from 3 animals proximal (high pressure) and distal (low pressure) to coarctation.

1355 Hypoxia-inducible Factor-1α Is Stabilized by Angiotensin II in Vascular Smooth Muscle Cells

E. L. Page, 1 M. Levine, 2 D. E. Richard; 1Centre de Recherche de l'Hôtel-Dieu de Québec, Québec, PQ, Canada, 2Molecular and Clinical Nutrition Section, Digestive Diseases Branch, National Institute of Diabetes and Digestive and Kidney Diseases, Bethesda, MD

Hypoxia-inducible factor-1α (HIF-1α) is a decisive element in the transcriptional regulation of many genes induced under low oxygen conditions. Under normoxia, HIF-1α, the active subunit of HIF-1, is hydroxylated on proline residues by specific iron and 2-oxoglutarate dependant oxygenases named prolyl-hydroxylases (PHDs), enzymes using also ascorbate and oxygen as cofactors. This hydroxylation permits the binding of pVHL, the recognition component of an E3 ligase complex, leading to the ubiquitination-degradation of HIF-1α by the proteasome. In hypoxic conditions, hydroxylation and ubiquitination are blocked and HIF-1α accumulates in cells. Our studies have shown that non-hypoxic stimuli like vasoactive hormones may induce HIF-1α in vascular smooth muscle cells (VSMC). We have determined that angiotensin II (Ang II) increases HIF-1α levels through transcriptional and translational mechanisms. Our current studies suggest that Ang II may also modulate HIF-1α induction through its stabilization. Utilization of cycloheximide, a protein synthesis inhibitor, shows that the half-life of HIF-1α under Ang II stimulation is comparable to the half-life in hypoxic conditions. The use of a fusion protein between HIF-1α and luciferase shows that the stabilization of this protein is increased in VSMC treated with Ang II. Our data also show that the ubiquitination level of HIF-1α is decreased in Ang II-treated VSMC as compared to non-stimulated cells. Our studies demonstrate that the proteasome binding of HIF-1α protein is diminished in VSMC treated with Ang II. Ang II also decreases HIF-1α hydroxylation since pVHL binding is diminished in Ang II-treated cells. Additionally, an ascorbate supplementation of cells, a PHD cofactor, completely inhibits HIF-1α induction by Ang II. These results identify protein stabilization as a third mechanism responsible for HIF-1 induction by Ang II in VSMC. These mechanisms could modulate the expression of a number of genes controlled by the HIF-1 transcription factor under Ang II stimulation of VSMC.

1356 Apium graveolens Modulates Sodium Valproate-induced Reproductive Toxicity in Rats

A. Amin, A. Hamza; Biology, UAE University, Al-Ain, United Arab Emirates
Sodium valproate, a common treatment of epilepsy and other psychiatric disorders, is known to have severe toxic effects on tests both in experimental animals and in humans. The present study was designed to investigate the protective effect of Apium graveolens against the sodium valproate-induced tests injury. Testicular toxicity was induced by the administration of sodium valproate (500 mg/kg/day) once for 7 consecutive days. Protective group received daily doses (200 mg/kg/day) of AG crude extract for 23 days prior to sodium valproate administration. Sodium valproate-induced reproductive toxicity was assessed based on the weight of testes, sperm analysis and serum concentration of sexual hormones. The relative weights of testes and epididymes and the sperm numbers viability were all decreased following the valproate administration. Testosterone levels dropped while FSH level increased following the drug administration. Severe histopathological changes in tests were observed such as degeneration of seminiferous tubules and degeneration of germ cells. These biochemical and histological changes were also associated with alterations of oxidative stress markers. Levels of malondialdehyde have increased, while superoxide dismutase activity has decreased. Pretreatment with Apium graveolens extract has effectively attenuated all the sodium valproate-induced effects suggesting a protective role of Apium graveolens extract against experimental sodium valproate-induced toxicity. Apigenin content was estimated and was shown as a major fraction of the Apium graveolens extract.

1361 Inhibitor of CRM1-Dependent Nuclear Export Inhibits TNFα Release from Stimulated Human Monocellular U-937 Cells  
C. C. Ghosh, H. Vu, S. Robinson, I. Vancurova; Biology, St. John’s University, Queens, NY
cells. In contrast, release of another pro-inflammatory cytokine, interleukin-8 (IL-8), is not inhibited by LMB. In addition, we show that the mechanism of LMB inhibition of TNFα release consists of a specific inhibition of mRNA TNFα levels. Our data indicate that when there is excessive, persistent inflammation that results in tissue injury, as observed in sepsis, acute respiratory distress syndrome, or arthritis, the inhibition of TNFα release from activated mononuclear cells by the CR1M-dependent nuclear export mechanism could be used as a new therapeutic anti-inflammatory target.

1362 Hepatitis Delta Virus Biogenesis Requires Eososomal Tumor Susceptibility Gene 101

M. Mato, 1 J. S. Glenn, 2 B. Aroeti 1; 1Department of Cell and Animal Biology, Hebrew University of Jerusalem, Jerusalem, Israel, 2Division of Gastroenterology and Hepatology, Stanford University School of Medicine, Stanford, CA

Hepatitis delta virus (HDV) is an important cause of acute and chronic liver disease for which there is no current effective medical therapy. HDV is only found in patients that are also infected with hepatitis B virus (HBV). The HDV virion is composed of a RNA genome, small and large hepatitis delta antigens (HDAg-S and HDAg-L, respectively) and the surface protein of the HBV (HBsAg) embedded within a lipid envelope. The HDAg-S is expressed early during infection and is required for HDV RNA replication. The HDAg-L is produced in a later stage by editing processes, which add nineteen amino acids to the C-terminus of the small protein. Prenylation of the cysteine in the CXXX box positioned at the C-terminus of the HDAg-L is required for protein association with the endoplasmic reticulum and viral particle assembly. The overall goal of this project is to better understand the mechanisms of HDV assembly and budding. We hypothesize that a proline-rich region preceding the CXX box, functions as a late domain that is essential for viral particle budding. We reasoned that the late domain is required for interactions with Tsg101 (tumor susceptibility gene 101), a protein associated with the ESCRT complex and the biogenesis of exosomes budding in the lumen of multivesicular bodies. We hypothesized that a similar machinery is recruited by HDAg-L to mediate HDV budding into the lumen of the ER, or other organelles. We found that both, over-expression of wt Tsg101, or a dominant negative mutant form of Tsg101, diminished HDV budding in COS7 cells. Furthermore, depletion of Tsg101 by siRNA also decreased viral particle release. Tsg101 co-immunoprecipitates with anti-HDV antibodies. Our data signif for the first time the importance of eososomal sorting mechanisms in the biogenesis of hepatocellular viruses, whose budding is thought to take place in the endoplasmic reticulum.

1363 Prevotella intermedia LPS Stimulates Release of TNF-α through MAPK Signaling Pathways in Monocyte-derived Macrophages

S. Kim, 1 E. Choi, 1 J. Jin, 1 C. Kim, 1 I. Choi 1; 1Department of Periodontology, College of Dentistry, Pusan National University, Busan, Republic of Korea, 2Department of Life Science, College of Medical and Life Science, Busan, Republic of Korea

The purpose of this study was to investigate the effects of lipopolysaccharide from Prevotella intermedia, a major cause of inflammatory periodontal disease, on the production of TNF-α and the expression of TNF-α mRNA in differentiated THP-1 cells, a human monocytic cell line. We also investigated the potential involvement of the three main MAPKs signaling pathways in the induction of TNF-α production. LPS from P. intermedia ATCC 25611 was prepared by the standard hot phenol-water method. THP-1 cells were incubated in the medium supplemented with phorbol myristate acetate (PMA) to induce differentiation into macrophage-like cells. The amount of TNF-α was determined by ELISA using a commercially available kit. The effect of P. intermedia LPS on TNF-α transcription and accumulation of TNF-α mRNA was confirmed by real-time PCR. The levels of total and phosphorylated MAPKs (ERK1/2, p38 MAPK and JNK1/2) in differentiated THP-1 cells were determined by immunoblotting. We found that P. intermedia LPS can induce TNF-α mRNA expression and stimulate the release of TNF-α in differentiated THP-1 cells in the absence of other stimuli. Treatment of the cells with P. intermedia LPS resulted in a time-dependent increase in phosphorylated forms of MAPKs. Furthermore, all three MAPK inhibitors reduced the phosphorylation of their specific MAPKs by P. intermedia LPS. The MAPKs signaling pathways appeared to play a dominant role in the induction of TNF-α production by P. intermedia LPS as documented by a very significant inhibition of TNF-α mRNA and protein production after blocking with three MAPK inhibitors.

1364 Increased Oxidative Stress in Myoblasts from Inclusion Body Myopathy Patients

S. Sabedi, 1 S. Zanotti, 1 C. Di Blasi, 1 A. Ruggeri 2, S. Romaggi 3, F. Colleoni 3, H. Lochmuller 4, P. Bernasconi 5, M. Mora 5; 1Neuromuscular Diseases and Neuroimmunology, National Neurological Institute C. Besta, Milano, Italy, 2Neurologische Klinik und Poliklinik, Ludwig-Maximilians-Universitat, Muenchen, Germany

Sporadic inclusion body myositis (sIBM) is the most common disorder of skeletal muscle in aged humans, is of unknown etiology and pathogenesis and lacks definitive treatment. It shares biochemical features with Alzheimer's disease (AD), including coprophilic deposits, which are immunoreactive for beta-amyloid peptide (Abeta) and AbetaPP. Traditionally considered as an inflammatory myopathy, inclusion body myositis is now rather thought to be a disease of muscle aging, just like AD is considered a disease of brain aging. It is characterized by progressive vacuolar degeneration with accumulation of insoluble misfolded proteins such as AbetaPP; beta-amyloid, phosphorylated tau protein, prion protein (PrP), presenilin-1, alpha-synuclein, and others. There are numerous other familial forms of inclusion body myopathy, either autosomal dominant or recessive, similar to SIBM for the presence of vacuolar degeneration and toxic proteins in muscle fibers, but without inflammation, and therefore called hereditary inclusion body myopathies (hIBM). There is increasing evidence that oxidative stress, is involved in neurodegenerative disorders as well as in IBM. In order to investigate whether oxidative stress is increased in primary muscle cultures, we evaluated nitric oxide basal content in myoblasts from s-IBM and h-IBM patients and in control myoblasts. We found a 20-30 % increase in nitric oxide content in IBM myoblasts compared to control cells, and a 30-80% increase with greater variability in sIBM cells probably in relation with the inflammatory changes observed in this patient group. Toxic protein deposition in muscle fibers is likely to have a multifactorial origin in sIBM and has genetic causes in IBM forms. The most important factors contributing to accumulation of toxic proteins are those of aging; among these, increased oxidative stress and, possibly, inadequate denaturation systems, are likely to play a role.

1365 Induction of Inflammatory Cytokines and Their Repression by Small Molecules in a Mouse for EBS

S. Löffèl, 1 H. Lu, 2 P. Zigrino, 2 T. Magini 2; 1University of Bonn, Institute of Physiological Chemistry, Bonn, Germany, 2University of Cologne, Department of Dermatology and Center of Molecular Medicin, Cologne, Germany

Keratins K5 and K14 form the major intermediate filaments of basal epidermis. Their primary function is to impart mechanical strength to cells, as highlighted by dominant mutations causing inherited skin disorders including epidermolysis bullosa simplex (EBS). Moreover, keratins mediate the response to apoptosis and cause pigmented changes in keratinocytes. Until recently, EBS was widely regarded as a mecanobullous disease, resulting from a weakened cytoskeleton, followed by extensive cytolysis. It was postulated by others that certain K14 mutations induce TAF-α, increase apoptosis and mediate an unfolded protein response, thereby adding to EBS pathomechanisms. Here, we compared K5- mice to controls by Affymetrix analysis to examine a potential induction of inflammatory pathways which might contribute to EBS. We found an increase in interleukin (IL)-6, CXCL1 and IL-1β in K5- mice versus controls. These results were confirmed by real-time PCR. In contrast, we found no alteration in TAF-α, neither in K5- nor in a mutant K14 cell culture model, employing Affymetrix and ELISA assays. We conclude that keratin mutations induce certain inflammatory cytokines but not TAF-α. Following a clinical report using tetracyclines to treat EBS patients, we extended our studies on K5- mice to investigate whether systemic tetracycline application leads to a reduction of skin blistering and less fragile epidermis. Here, we demonstrate that systemic treatment of pregnant K5- females with doxycycline prolonged the survival of K5- pups from 1 to 8 hours. Microwave and TaqMan real-time PCR showed a down-regulation of MMP-13, serine protease and IL-1 beta, indicating an affect of doxycycline on transcription. Our findings lead to the hypothesis that mutations in keratins induce a stress response which can lead to inflammation, changes in gene expression and translational arrest. Collectively, our data offer novel small molecule-based therapy approaches for EBS.

1366 Structure and Molecular Basis of the Interactions of Dipeptidyl Peptidase IV with Adenosine Deaminase and HIV-1 Transactivator

H. Fan, 1 W. Weihofen, 1 K. Ludwig, 2 C. Boettcher, 1 J. Lin, 1 F. Tani, 1 M. Ledermann, 3 S. Stehling, 1 W. Reutter, 1 W. Sanger, 2 Institut fuer Molekularbiologie und Biochemie, Charite-Universitaetsmedizin, Berlin, Germany, 3Institut fuer Kristallographie, Freie Universitaet, Berlin, Germany

INTRODUCTION: Dipeptidyl peptidase IV (DPPIV, CD26; EC. 3.4.14.5) is a widely distributed multifunctional membrane glycoprotein. This protein is engaged in immune functions by co-stimulatory effects on activation and proliferation of T-lymphocytes, binding to adenosine deaminase (ADA) and regulation of various chemokines and cytokines. It's peptidase activity is inhibited by HIV-1 Transactivator (Tat) suggesting that DPPIV mediates immunosuppressive effects of Tat protein (1). METHODS: The activity of DPPIV was measured by cleavage of the substrate Gly-Pro-pNA. The ADA activity was assayed by spectrophotometric monitoring the conversion of adenosine to inosine. The 3D structure was obtained by cryo-TEM and single particle analysis. X-ray data were collected at BESSY II, Berlin, Germany and at beamline ID14-2, ESRF, Grenoble. These data were processed with DENZO and SCALEPACK. RESULTS: |
The page contains scientific text discussing mitochondrial disorders, including the molecular diagnosis of mitochondrial disorders, molecular diagnosis of 22 tRNA genes, and the mutations observed in Korean patients with mitochondrial cytopathies. The text also mentions the molecular design of mitochondria and the resolution video-microscopy techniques used to study endosomes. The page further discusses the role of Rab GTPases in vesicle formation, tethering, and fusion, and the cellular roles of mitochondrial fission and fusion in inherited human diseases.
Student Mobility Profile: An Instrument for Measuring the Effectiveness of Efforts to Improve Teaching and Learning
W. S. Bradshaw,1 J. Nelson,2 J. D. Bell;3 Microbiology and Molecular Biology, Brigham Young University, Provo, UT, 1Physiology and Developmental Biology, Brigham Young University, Provo, UT

The process of educational renewal, including efforts to improve the learning of cell biology, should incorporate assessment - a rigorous evaluation of whether or not changes made to a course actually achieved their intended goals. The Student Mobility Profile (SMP) is a novel statistical instrument designed to facilitate such an assessment. The SMP will process data obtained from the beginning and end of a scholastic interval, scores from a first and final exam, or from a pre and post semester problem-solving exercise, for example. An important advantage is that it can be applied post hoc allowing one to utilize existing data from past versions of a course for comparison to recent offerings in which innovations have been attempted. The results of the analysis indicate the presence or absence of systematic factors leading to either improvement or decline in performance of the student population over the time period being assessed. Consequently, instead of indicating whether students have simply acquired the factual information from the course, the analysis reveals the extent to which they have improved in their ability to learn. For example, the teacher might discover whether students have developed additional expertise in practicing an important scientific skill, such as drawing valid conclusions from experimental data. The theory upon which the SMP is based will be provided, along with examples of its application in university science courses. The results of computer simulations to determine the range and limitations of this instrument will also be reported.

Yeast as a Model System for Complex Neurological Problems and Drug Discovery
S. Lindquist,1 A. A. Cooper,2 A. D. Gritle,3 A. Cashikar,4 M. L. Daenwally,1 L. J. Sui,1 T. F. Oteirola,1 C. M. Haynes,2 J. K. Hill,1 B. Bhullar,1 K. Liu,1 K. Xu,1 K. E. Straathorn,4 F. Liu,1 S. Cao,1 K. A. Caldwell,1 G. A. Caldwell,1 G. Marischky,2 R. D. Kolodner,3 J. LaBaer,4 J. Roche,1 N. M. Bonini;2 Whitehead Institute for Biomedical Research, Cambridge, MA, 1School of Biological Sciences, University of Missouri-Kansas City, Kansas City, MO, 2Department of Biology, University of Pennsylvania, Philadelphia, PA, 3Department of Medicinal Chemistry and Molecular Pharmacology, Purdue University, West Lafayette, IN, 4Department of Biological Sciences, University of Alabama, Tuscaloosa, AL, 1Institute of Proteomics, Harvard, Cambridge, MA, 5Institute for Cancer Research, UCSF, La Jolla, CA

Protein conformational changes govern most processes in cell biology. We have developed yeast models of protein folding diseases and used them to investigate mechanisms of cytotoxicity and to screen for novel therapeutic targets. Strong evidence links the misfolding of alpha-synuclein (αSyn) to Parkinson’s Disease (PD). Cellular toxicity depends on the level of αSyn expression and is associated with cytoplasmic inclusions. Our yeast αSyn overexpression model recapitulates many features of αSyn-related pathology, including the inhibition of phosphatase D, the production of reactive oxygen species, and problems in vesicle trafficking. The earliest defect following αSyn induction in yeast was a block in vesicle trafficking from the endoplasmic reticulum (ER) to the Golgi. To identify relevant biochemical pathways and targets we screened an expression library for genetic enhancers and suppressors of αSyn toxicity. The largest class of toxicity modifiers includes proteins functioning at this same trafficking step, including the Rab GTPase Ypt1p, which is also associated with cytoplasmic αSyn inclusions. Elevated expression of Rab1, the mammalian YPT1 homolog, protects against αSyn-induced dopaminergic neuron loss in whole-animal models of PD, and in cultures of rat midbrain, demonstrating the relevance of these results obtained in yeast to mammalian neurons. We also screened >150,000 small molecules for toxicity suppressors. Strikingly, the two most effective compounds in our screen also selectively rescued cultured rat dopaminergic neurons from rotenone and from A35T αSyn expression. We have expanded our efforts to screen for toxicity enhancers and suppressors in a yeast Huntington’s Disease model expressing human huntingtin exon. Our work presents a paradigm for how toxicity is the result of the interaction of particular disease-associated proteins with eukaryotic cell biology and not merely a non-specific response to protein misfolding. The specific pathways elucidated by our yeast models provide new targets for therapeutic intervention.

Genetic Mutations in Cardiac Hypertrophy: Rare Events or Common Etiologies
C. Seidman, Department of Genetics, Harvard Medical School, Boston, MA
Unexplained cardiac hypertrophy, which affects 4% of the population, is a recognized risk factor for adverse cardiovascular events. Human molecular genetic studies have been productive for delineating triggers of hypertrophic remodeling. Studies of hypertrophic cardiac myopathy (HCM) revealed sarcomere protein gene mutations and to date over 400 different mutations in 11 genes have been identified. In part, genetic diversity explains the variable clinical manifestations of HCM. Genetic analyses of unexplained cardiac hypertrophy genetic in subjects from the Framingham Heart Study revealed sarcomere gene mutations in approximately 14%, indicating that allelic variation in sarcomere genes cause both monogenic disorders and common forms of hypertrophy. Some patients clinically diagnosed with HCM do not have sarcomere protein mutations, but defects that alter glycogen storage and metabolism to cause LVH. Gene mutations in the AMP-dependent kinase g2 subunit (PRKAG2) mutations produce a cardiomyopathy characterized by glycogen accumulation in myocyte vacuoles, ventricular hypertrophy and electrophysiological abnormalities (Wolf-Parkinson-White Syndrome and progressive degenerative conduction system disease). Human mutations in the lysosome-associated membrane protein-2 (LAMP2) cause X-linked lysosomal glycogen storage disease that presents with cardiac hypertrophy and pre-excitation, with variable degrees of skeletal myopathy and cognitive impairment, and evolves to heart failure. To delineate cell and molecular responses triggered by these different genetic causes of LVH, we engineered human mutations into mice. Using these models we determined the relationship between histopathology and clinically important events such as arrhythmia vulnerability. Biochemical analyses and transcriptional profiling reveal the cell and molecular signals triggered by gene mutations that result in hypertrophic growth. This discovery system defines potential therapeutic targets to abrogate remodeling and improve prognosis in cardiac hypertrophy.

Development of Novel Cancer Therapeutic Agents Based on Human Apoptotic Pathways
W. Xiang, H19), Department of Biochemistry, UT Southwestern Medical Center at Dallas, Dallas, TX
Apoptosis is a form of cell death that is executed by chains of controlled biochemical reactions. Apoptosis plays important roles during animal development, immune response, elimination of damaged cells, and maintenance of tissue homeostasis. However, apoptosis defects are also associated with tumorigenesis, tumor metastasis, and resistant to therapy. We have been working to understand specific and general biochemical mechanism of apoptosis defects in human cancer cells and trying to design chemical strategies to counter these defects so that we can induce apoptosis specifically and efficiently in a cancer cell specific manner. Progress toward this goal has been made when we designed a small molecule that takes on the function of an apoptosis promoting protein Smac. Smac promotes apoptosis by binding and neutralizing a group of inhibitor of apoptosis protein (IAP) in human cells. Smac normally localizes in mitochondria. During apoptosis, Smac is released from mitochondria to cytosol where IAPs are located. However, in many cancer cells, this release is blocked by the elevation of Bcl-2 and related proteins. Moreover, IAP proteins are also often elevated in many human cancer cells as well. Our Smac-mimicking small molecule can pass through cell membrane and neutralize cytosolic IAP proteins directly, thereby circumventing both Bcl-2 and IAP-mediated apoptosis block that often used by cancer cells. This molecule sensitizes over 80% cancer cell lines from a variety of tissue origins to apoptosis while does no harm for normal fibroblasts and endothelial cells. In animal tumor xerographic studies, the molecules demonstrated excellent efficacy as well. Interestingly, there are about 20% human cancer cell lines shown sensitivity to Smac mimetic treatment alone, indicating that an apoptotic pathway was already turned on in these cells that was blocked by IAPs. Using combination of Smac mimetic treat this might, we will use the development of Smac mimic molecules for cancer therapy as an example to discuss ways to develop novel anti-cancer agents based on our studies on the biochemical pathway of apoptosis in human cancer cells.
Our studies show that caspase-11 interacts physically and functionally with Apal. Inhibition of Apal or caspase-11 expression reduces cell motility. Actin dynamics is altered in caspase-11 knockout cells. These results reveal a novel function of caspase-11 in regulating actin dynamics and cell migration and suggest caspase-11 might be able to regulate inflammatory response at multiple levels.

Structural Knockout of an ASC Speck Rescues Cells from Apoptosis; the Speck Is a Platform for Apoptosis

K. Ke, A. L. Waite, N. Richards, A. J. Hunt, D. L. Garmy; University of Michigan, Ann Arbor, MI

ASC is a 22-kDa adapter protein composed of a PYD and a CARD domain that is capable of interacting with proteins upstream of IL-1β and NF-κB. Through its interacting partners, ASC affects a wide spectrum of pathways critical to apoptotic and inflammatory events. The activation of the apoptotic pathway in ASC expressing cells often coincides with the formation of an ASC aggregate widely known as a "speck". Although cells with specks progress to apoptosis, it is not clear if the speck is a byproduct or is required for the mediation of the apoptotic process. We studied the functional role of the speck through a technique called structural knockout. An ultrafast laser was used to physically remove the speck from transfected HeLa cells in a surgical procedure we call speckectomy. In contrast to gene knockout, RNAi, and antibody inhibition, this procedure allows spatial and temporal control over the removal of particular sub-cellular structures in cells. Ablation using tightly focused ultrafast laser pulses virtually eliminates the collateral damage that typically associated with laser microsurgery. Our real time tracking of the life cycle of cells expressing ASC and forming a speck revealed that over 48 hours, 60 percent of such cells die, 30 percent undergo mitosis, and 10 percent undergo unsuccessful mitosis. In contrast, cells in which the speck is removed by speckectomy, 75 percent undergo apoptosis; 25 percent undergo unsuccessful mitosis. In the speckectomized cells that undergo mitosis, mitotic duration and morphology is normal. The survival of cells that undergo speckectomy is nearly identical to control cells that express ASC but do not form specks: 75 percent mitosis and 25 percent cell death. Our results strongly support the notion that the physical aggregate known as the speck participates actively in the apoptotic process, perhaps as an agglutinating platform for the apoptotic machinery.

A Morphologically Conserved Non-Apoptotic Program Promotes Linker Cell Death in C. elegans

M. C. Abraham, Y. Lu, S. Shaham; Developmental Genetics, The Rockefeller University, New York, NY

Apoptosis, a form of programmed cell death characterized by stereotypical morphological features including chromatin compaction and cytoplasmic shrinkage, requires the activity of caspase proteases. Conserved gene pathways controlling caspase activity have been described. Although non-apoptotic, caspase-independent programmed cell death pathways have been postulated, little is known about their molecular constituents or their possible in vivo functions. We have shown that the death of the Caenorhabditis elegans linker cell during development is independent of the casp-3 caspase and all other known C. elegans cell death genes. Linker cell death proceeds efficiently even in animals carrying multiple mutations that block the death of other C. elegans cells destined to die. We demonstrated that the linker cell still dies when we ablate neighboring cells or when the linker cell is abnormally positioned, suggesting the linker cell employs a cell-autonomous program to promote its demise. Furthermore, although the linker cell can be engulfed by the canonical apoptotic cell engulfment program when the cell is at an abnormal position, a previously unidentified engulfment program is required for its clearance at its normal location. Electron microscopy of dying linker cells reveals non-apoptotic features including nuclear crenellation in the absence of chromatin condensation, swelling of mitochondria and endoplasmic reticulum, and accumulation of single- and multi-layered cytoplasmic membrane-bound structures. Remarkably, similar morphological changes occur during the normal developmental death of neurons in the vertebrate spinal cord and ciliary ganglia. Linker cell death is controlled by the microRNA let-7 and by the Zn-finger transcription factor LIN-29, both components of the main developmental timing pathway in the animal. LIN-29 functions within the linker cell to promote its demise, consistent with the idea that the linker cell employs a cell-autonomous death program. We propose that the program executing linker cell death is conserved and may play important roles during vertebrate development.

Autophagy Functions as a Tumor Suppression Mechanism by Limiting Metabolic Stress

E. White; Rutgers University, Piscataway, NJ

Defective autophagy renders immortalized epithelial cells highly tumorigenic, but how tumor cells survive metabolic stress in vivo during tumorigenesis is not known. In apoptosis-deficient cells, inhibition of autophagy by Akt activation or by anisomycin (which is a specific inhibitor of the mammalian target of rapamycin (mTOR)) results from its ability to mitigate these bioenergetic stresses during ECM detachment.

1380

Autophagy Restricts Apoptosis during ECM Detachment

J. Debnath, C. Fung; Department of Pathology, University of California San Francisico, San Francisco, CA

The individual units (acini) comprising glandular epithelium possess a hollow lumen that is filled during early oncogenesis. While investigating the generation of luminal space using an in vitro 3D cell culture model, we found that lumen formation involves the selective apoptosis of centrally-located cells within developing acini. However, a hollow lumen still forms when apoptosis is blocked, indicating additional processes regulate luminal clearance. During lumen formation, the central cells of acini contain numerous autophagic vacuoles, suggesting autophagy, a lysosomal process through which a cell digests its own contents, may influence cell fate in the lumen. To clarify the role of autophagy in epithelial cells, we have examined how autophagy regulators (called ATGs) influence 3D morphogenesis. Remarkably, RNAi-mediated downregulation of Beclin1/ATG6 enhances proliferation in developing acini. Although the resulting acini grow larger in size, they exhibit enhanced luminal apoptosis and remain hollow. Remarkably, Beclin1/ATG6 knockdown does not cooperate with Bcl-2-mediated apoptotic inhibition to fill the lumen, despite the decreased autophagy and increased proliferation in these structures. Because epithelial cells die in the lumen due to extracellular matrix (ECM) deprivation, we have further investigated how ECM detachment (anoikis) regulates autophagy. ECM detachment strongly induces autophagy in epithelial cells, confirmed by electron microscopy and LC3/ATG8 relocation to autophagosomes. Importantly, matrix-detached cells still exhibit autophagy when apoptosis is blocked by Bcl-2 expression. In contrast, siRNA-mediated knockdown of ATG5, ATG6/Beclin and ATG7, inhibits autophagy in ECM-detached cells and enhances apoptosis during anoikis. Hence, autophagy protects ECM-detached cells from apoptosis. Recently, we have found that AMP-activated protein kinase (AMPK), is activated during anoikis, indicating that ECM-detached cells exhibit evidence of energy (ATP) depletion. We are currently investigating if the pro-survival effects of autophagy during anoikis result from its ability to mitigate these bioenergetic stresses during ECM detachment.

1381

Regulation of Mammary Epithelial Anoikis and Morphogenesis by the BH3-Only Protein Bmf

T. Schmelzle,1 A. A. Maileux,1 M. Overholtzer,1 J. S. Carroll,2 N. L. Solimini,1 E. S. Lightcap,3 O. P. Veiby,3 J. S. Brugge,11 Cell Biology, Harvard Medical School, Boston, MA; 2Medical Oncology, Dana-Farber Cancer Institute, Boston, MA; 3Millennium Pharmaceuticals, Inc., Cambridge, MA

Mammary epithelial cells cultured in a three-dimensional basal membrane substrate model system assemble into polarized, proliferation-arrested structures with a hollow lumen that resemble acini found in the mammary gland. Using such a 3D model with human MCF-10A cells our objective is to identify and characterize the signaling pathways and mechanisms that are required to form and maintain the normal acinar architecture in vitro. Microarray experiments revealed a pronounced proliferation arrest signature starting around culture day 5 as the principal transcriptional program during morphogenesis whose hallmark was the analysis of several different proliferation markers. We have also exploited potential similarities between anoikis (epithelial cell death in response to loss of adhesion) and the selective death of inner cells of 3D structures during lumen formation. Our comparative microarray studies have identified the proapoptotic BH3-only protein Bmf as a candidate regulator involved in MCF-10A anoikis and 3D lummn formation. Bmf RNA levels are upregulated in suspension and morphogenesis samples, and knockdown of Bmf by RNAi results in significant protection from cell death in both culture conditions. Knockdown of BH3-only proteins other than Bmf or Bid, however does not affect apoptosis in MCF-10A anoikis or morphogenesis, suggesting specific processing of death signals rather than a BH3-level ‘threshold’. Transcriptional regulation of Bmf is specifically observed in response to detachment from matrix and significantly suppressed upon oncogenic activation of the MEK/Erk and PI3K pathways. Moreover, downregulation of Bmf, when combined with a proliferative oncogene, confers anchorage-independent growth. Taken together, our findings contribute new insights into the mechanisms whereby oncogenes and signaling aberrations disrupt the regulation of normal mammary epithelial morphogenesis and serve as a model for events associated with the initiation and progression of epithelial tumors.
Innovations in Fluorescence Imaging of Cellular Functions Using Fluorescent Proteins
A. Miyawaki; Lab for Cell Function Dynamics, RIKEN Brain Science Institute, Wako City, Japan

Fluorescence imaging has enabled us to decipher spatio-temporal information coded in complex tissues. Genetically encoded probes that enable fluorescence imaging of enzymatic activity have been constructed by fusing fluorescent proteins to functional proteins that are involved in physiological signaling. The probes are introduced into an intact organism and targeted to specific tissues, cell types, or subcellular compartments, thereby allowing specific signals to be extracted more efficiently than was previously possible. I will describe how this approach has met cell-biologists' demands and desires.

Site-specific Protein Labeling with Biophysical Probes in Living Cells Using Enzyme Ligases
A. Ting; Department of Chemistry, Massachusetts Institute of Technology, Cambridge, MA

Our lab develops new methodology for imaging protein trafficking and function in living cells. We will describe site-specific protein labeling techniques based on enzyme ligases, quantum dot targeting strategies, protein-protein interaction detection methods, and single molecule imaging of neuronal receptors.

Demonstration of p130Cas as a Direct Mechano-sensor by In Vitro Stretching of Single Molecules
Y. Sawada,1 M. Tamada,2 B. J. Dubin-Thaler,2 R. Sakai,3 S. Tanaka1 M. P. Sheetz2,1 Department of Biological Sciences, Columbia University, New York, NY, 2Graduate School of Medicine, Kobe University, Kobe, Japan, 3Growth Factor Division, National Cancer Center Research Institute, Tokyo, Japan, 4Department of Orthopaedic Surgery, Graduate School of Medicine, The University of Tokyo, Tokyo, Japan

Cellular responses to mechanical force underlie many critical functions from normal morphogenesis to carcinogenesis, cardiac hypertrophy, wound healing and bone homeostasis. Recent studies indicate that various signaling pathways are involved in force transduction, including tyrosine phosphorylation. However, because suitable in vitro experimental systems have not been available, direct sensors of forces, i.e. force receptors, have not been identified with the exception of ion channels. We previously showed that cytoskeletal complexes (Triton cytoskeletons) can transduce stretching forces into focal contact protein binding and Rap1 activation. Because we found that tyrosine phosphorylation of p130Cas (By Src family kinases (SFKs)) was involved in stretch-dependent Rap1 activation in intact cells, we explored whether activation of the kinase was primarily responsible for stretch-increased phosphorylation of Cas and found that cell stretching caused no apparent change in c-Src activity while Cas phosphorylation increased. To test if modification of Cas could enhance its phosphorylation, we developed an experimental system for in vitro stretching of single molecules (ISS). Using the ISS system, we mechanically stretched bacterially expressed Cas substrate domain (CasSD) and found stretching of CasSD remarkably enhanced its phosphorylation by c-Src, FynT, or Abi1 but not Nck or Zap-70 kinases, independent of kinase activation. By YFP amino-terminal swapping assay based on the interaction between amino- and carboxy-terminal domains of YFP, which was expected in bimolecular fluorescence complementation, we confirmed that CasSD molecules are stretched in the ISS system. In intact cells, an antibody that bound to unfolded CasSD preferentially recognized Cas molecules in the peripheral regions of spreading cells where higher forces were expected and phosphorylated Cas was found. Thus, Cas converts force into a biochemical signal through mechanical unfolding of its substrate domain, causing priming to phosphorylation. We suggest that Cas substrate priming is the first example of a more general mechanism for signal transduction.

Computationally Multiplexed Imaging of Rho GT-Pase Activities
M. Machacek,1 L. Hodgson,2 P. Nabant,3 O. Pertz,4 F. Shen,5 K. M. Hahn,6 G. Danuser5; 1Department of Cell Biology, TSRI, La Jolla, CA, 2Department of Pharmacology, University of North Carolina at Chapel Hill, Chapel Hill, NC, 3Department of Immunology, TSRI, La Jolla, CA, 4Department of Pathology and Moores Cancer Center, University of California at San Diego, La Jolla, CA

We present a computational approach to reconstruct the coordinated dynamics of a theoretically unlimited number of protein activities visualized by biosensors. Biosensors are emerging as a powerful tool for measuring the activities of functionally related proteins and by doing so systematically uncovering the spatio-temporal characteristics of entire signaling networks. In practice, this approach is limited by the number of spectrally separable biosensors and by the formidable technical complexity of multiplex biosensor measurements. Here, we demonstrate that by statistical analysis of the random temporal fluctuations of signaling network activity, functional relationships between network components can be established. The hierarchy of signaling events in the entire network can be inferred indirectly, by compiling activity fluctuations from a series of separate experiments, each using a distinct set of biosensor probes. Registration of activity fluctuations on a common time scale across the experiments is achieved either by measuring two activity probes per experiment, with one serving as the time fiduciary linking different experiments, or by observing a morphological event sequence that can serve as a fiduciary. We use this approach to reconstruct the timing of the small GTPase family members Rac1, RhoA and Cdc42 during cell protrusion. We found that the GT-Pases were activated in a strictly conserved sequence relative to protrusion. Activation of RhoA was synchronous with protrusion, Cdc42 was delayed by 20 sec, and Rac1 by 70 sec, respectively. As a proof of principle we confirmed this relative timing by monitoring Cdc42 and RhoA activities simultaneously in the same cell. We found an exact quantitative match between the indirectly and the directly reconstructed event sequence.

High-Resolution, Doxycycline-dependent Phototoxic Gene Expression in Eukaryotic Systems
S. B. Cambride,1 F. Calegari,2 K. Anastassidou,3 D. Geisser,1 T. Bonhoeffer1; 1Max-Planck-Institute of Neurobiology, Munich-Marienried, Germany, 2Max-Planck-Institute of Cell Biology and Genetics, Dresden, Germany, 3Biotec Centre, Dresden, Germany

To improve our understanding of gene function, tools are needed which allow the manipulation of gene function in a specific cell at a specific time. Unfortunately, none of the current conditional gene expression paradigms provides the required spatial and temporal resolution. To overcome this, we synthesized a reversibly inhibited, photosensitive (‘caged’) doxycycline analogue for precise light-controlled activation of transgenes based on the Tet-on system. With this method, gene expression can simply be induced with DAPI excitation light after adding the membrane-permeant caged doxycycline directly to the medium. Phototoxic gene expression was achieved in diverse biological systems including mice, plants, and Xenopus. We demonstrate that this method allows induction of transgenes with very high spatial resolution, including single cells. Moreover, levels of UV light needed for induction were harmless as no signs of toxicity could be detected. Thus, phototoxicated gene expression will be a very powerful tool for biomedical research.

Optical Tweezers as a Sensor for Intracellular Mechanical Properties of Endothelial Cells
M. Mengistu,1 D. H. Ou-Yang,2 L. J. Lowe-Krentz2; 1Biological Sciences, Lehigh University, Bethlehem, PA, 2Physics, Lehigh University, Bethlehem, PA

Characterizing the mechanical properties of cells is becoming increasingly important for understanding processes such as cell movement, shape, growth, and even the development of disease. In this study, we explore the mechanical properties of endothelial cells, whose dysfunction leads to the development of atherosclerosis. We employ the optical tweezers technique as a sensor, a technique that allows us to probe very local mechanical properties to account for cytoskeletal inhomogeneity, as well as measure cell dynamics. We extracted the viscoelastic moduli, G’ and G”, which are measures of elasticity and viscosity respectively, in endothelial cells using endocytosed polystyrene beads and intrinsic granular structures as probes. Our results show that endothelial cells have a dominant elastic modulus, with an average G’ value varying between 3.44±102 - 7.13±102 dyn/cm2. These results were consistent with intracellular cytoskeletal distributions, where the higher G’ values correspond to probed regions of the cell that are nearest to the nucleus, suggesting that cell elasticity increases in cytoskeleton-rich regions near the nucleus relative to cell peripheries. We also treated the cells with cytochalasin B and nocodazole, to depolymerize actin filaments and microtubules respectively, then measured the viscoelastic moduli to obtain their contribution in the mechanical properties of endothelial cells. The disruption of actin filaments affected cell dynamics drastically, but did not significantly change cell elasticity, with average G’ values around 300 dyn/cm2. Microtubule depolymerization, on the other hand, lead to an increase in cell elasticity, G’=103 dyn/cm2, possibly due to compensating stress fibers made by endothelial cells. Our results establish optical tweezers as effective and non-invasive probes of viscoelastic moduli in endothelial cells, where they can be applied to study the effect of flow on their mechanical properties, as well as mechanosensing and mechanotransduction events carried out by these cells.
Polarized Targeting of E-cadherin to Sites of Cell-Cell Contact in Early Embryos and Epithelial Cells Requires Ankyrin-G and Beta-2-spectrin

K. Kizhatil,1 J. Q. Davis,1 W. Yoon,1 B. L. M. Hogan,1 V. Bennett1; 1Cell Biology and HHMI, Duke University, Durham, NC, 2Cell Biology, Duke University, Durham, NC

Cadherins define specialized membrane domains at sites of cell-cell contact. In epithelial cells, E-Cadherin function requires an interaction with the membrane skeleton. However, the mechanism of E-cadherin-membrane skeleton interaction is unknown. We report here that E-cadherin targeting to sites of cell-cell contact requires the membrane skeleton proteins ankyrin-G and beta-2-spectrin. Moreover, we also present the first evidence that ankyrin-G binds the cytoplasmic domain of E-cadherin directly with high affinity. Ankyrin-G and beta-2-spectrin colocalize with E-cadherin at the plasma membrane of mouse early embryo blastomerses and relocate to sites of cell-cell contact during compaction. Depletion of ankyrin-G or beta-2-spectrin in one cell of a 2-cell embryo by siRNA injection reduces E-cadherin at sites of cell contact between the daughter cells of the injected cell. These daughter cells fail to compact and fail to undergo cytokinesis. In polarized human bronchial epithelial (HBE) cells the levels of ankyrin-G and beta-2-spectrin increase in parallel with the height of the newly formed lateral membrane. Depletion of ankyrin-G or beta-2-spectrin by siRNA results in inability to form the HBE lateral membrane and also disrupts the de novo biogenesis of the lateral membrane during cytokinesis. Several experiments in HBE cells demonstrate that ankyrin-G and beta-2-spectrin collaborate in a lateral membrane assembly pathway. Depletion of ankyrin-G or beta-2-spectrin in HBE cells results in the accumulation of E-cadherin in the trans-Golgi network (TGN) but not the cis/Golgi, ER or endosomes. Accumulation of E-cadherin in the TGN also resulted from microtubule disruption using nocodazole in HBE cells. Nocodazole washout allowed visualization of trafficking intermediates of E-cadherin which contained ankyrin-G and beta-2-spectrin. These results suggest a model where E-cadherin binds ankyrin-G which is then coupled to microtubule motors proteins by beta-2-spectrin for post-TGN transport along microtubules to sites of cell-cell contact in epithelial cells and early embryos.

Tyrosine-phosphorylated Cortactin Regulates Rosettes II and MLCK to Maintain the Integrity of Cell-Cell Contacts

F. M. Helwani,1 S. Verna,1 S. A. Weed,4 A. S. Yap3; 1Institute of Molecular Biosciences, University of Queensland, Brisbane, Australia, 4Mary Babb Randolph Cancer Center, West Virginia University, Morgantown, WV

Epithelial architecture is critically influenced by the ability of E-cadherin adhesion receptors to support the integrity and cohesion of cell-cell interactions. It has long been recognised that E-cadherin functions in close cooperation with the actin cytoskeleton; indeed, E-cadherin can actively regulate actin during cell-cell contact formation and reorganisation. More recently, we demonstrated that E-cadherin could influence at least two modes of actin regulation: 1) Arp2/3 mediated actin assembly; and 2) Myosin II-dependent contractility. The molecular intermediates involved in linking E-cadherin adhesion to these different actin regulatory processes are a current area of focus in our laboratory. One such intermediate is cortacin, a multifunctional actin binding protein implicated in a wide variety of cellular processes and signalling pathways within the cell. Cortacin function is tightly regulated by tyrosine phosphorylation in a number of cellular contexts. Previously we and other groups identified a role for cortacin in regulating Arp2/3-based actin assembly at cadherin contacts. Here we report an additional role for cortacin at cadherin contacts that is distinct from its role in Arp2/3 regulation. We found that cortacin controls Myosin II activity at cadherin contacts in a Src-dependent manner. Cortacin was necessary for the recruitment and activation of Myosin II at cadherin contacts, a process that may reflect the ability of cortacin to bind and recruit MLCK to contacts. Importantly, tyrosine phosphorylated cortacin was essential for its role in regulating Myosin II. Therefore we propose that cortacin might provide a link between these two functionally distinct modes of cadherin-regulated actin organization, by integrating signalling pathways that are activated downstream of E-cadherin adhesion.
Microtubule Plus-end Tracking Proteins Target Gap Junction Proteins Directly from the Cell Interior to Adhesions Junctions
Gap junctions are intercellular channels that connect the cytoplasms of adjacent cells. For gap junctions to properly control organ function and electrical synchronization in the heart and brain, connexin 43-based hemichannels must be correctly targeted to cell-cell borders in enriched regions called plaques. Mislocalization of plaques in cardiomyocytes is a major cause of ischemia related sudden cardiac death. While it is generally accepted that plaques form via lateral diffusion of hemichannels following microtubule-mediated delivery to the plasma membrane, we provide evidence for direct targeting of hemichannels to plaques at cell-cell junctions through a pathway dependent on microtubule dynamics, the adherens junction proteins N-cadherin and beta-catenin, the microtubule plus-end tracking protein (+TIP) EB1, and its interacting protein p150(Glucl). Live cell microscopy reveals cortical capture of microtubules at cell-cell borders as well as an intimate association between microtubules and gap junction plaques. Dynamic studies using both fluorescence recovery after photobleaching (FRAP) and total internal reflection fluorescence (TIRF) demonstrate rapid, preferential delivery of cytoplasmic hemichannels to adherens junctions in a microtubule dependent fashion. siRNA knockdown and cadherin blocking peptides confirm involvement of EB1, p150(Glucl), beta-catenin, and cadherin on gap junction plaque formation. In conclusion, we have found that preferential tethering of microtubule plus-ends at the adherens junction promotes delivery of connexin hemichannels directly into plaques at the cell-cell border. Moreover, hemichannel delivery to the cortical membrane is facilitated by interaction between +TIP proteins and the adherens junction. Together, these data support a novel mechanism for gap junction delivery to points of cell-cell contact.

Cellular Responses to Pore-forming Toxins
G. van der Goot, L. Garidel; Global Health Institute, Ecole Polytechnique Federale de Lausanne, Lausanne, Switzerland
Many pathogenic organisms produce pore-forming toxins as virulence factors. Target cells however mount a response to such membrane damage. We have found that upon infection with pore-forming toxin producing bacteria, cells respond by switching on lipid metabolic pathways that promote survival. More specifically, toxin induced membrane permeabilization leads to a decrease in cytoplasmic potassium, which triggers activation of the NALP3 and IPAF inflammasomes, which in turn activate caspase-1. We demonstrate a novel role for caspase-1, which is to trigger the activation of the central regulators of membrane biogenesis, the Sterol Regulatory Element Binding Proteins (SREBPs). Upregulation of lipid metabolic pathways in turn promotes cell survival.

Coxsackievirus Entry through Epithelial Tight Junctions Requires Occludin and the Small GT-Pases Rab34 and Rab5
C. B. Coyle, J. M. Bergelson; Infectious Diseases, The Children’s Hospital of Philadelphia, Philadelphia, PA
Group B coxsackieviruses (CVB) infect by crossing the intestinal mucosa, which is lined by polarized epithelium. We previously found that CVB infection of polarized epithelial cells in vitro requires virus movement to the tight junction (TJ), and that interaction with the coxsackievirus and adenovirus receptor (CAR), a TJ component, is essential for subsequent internalization and infection. Virus entry from the TJ depends on functional cavelin 1, as well as on phosphorylation of cavelin, unlike many endocytic processes it is independent of dynamin 1. Because virus entry is accompanied by a transient loss of junctional integrity, we have used fluorescence microscopy to examine the localization of TJ proteins during the early stages of infection. In cells exposed to virus, a single TJ protein, occludin, moved from the junction and was observed both with virus in cavelin-containing vesicles, and in typical macroinosomes. Depletion of occludin with siRNA prevented virus entry and infection, trapping virus at the TJ, as did inhibitors of macropinocytosis (amiloride and rottlerin). Rab34, a GTPase that functions in macropinocytosis, was concentrated at the TJ even in infected cells, and both dominant-negative Rab34 and Rab34 siRNA prevented internalization of virus and occludin. Furthermore, dominant-negative Rab5 prevented infection and entry, as did siRNA depletion of Rabankyrin-5, a Rab5 effector also implicated in macropinocytosis. These results indicate that virus entry is coupled to the internalization of occludin by a macropinocytic process, and that in addition to functional cavelin) Rab34, Rab5, and Rabankyrin-5 are needed for virus entry from the TJ. The results suggest that, in polarized epithelial cells, traffic from the TJ may involve cellular machinery associated both with cavelar endocytosis and macropinocytosis.

Differential Activation and Function of Rho GT-Pases during Salmonella-Host Cell Interactions
J. C. Patel, J. E. Galan; Section of Microbial Pathogenesis, Yale University New Haven, CT
Salmonella enterica, the cause of food-poisoning and typhoid fever, has evolved sophisticated mechanisms to modulate Rho-family GT-Pases to mediate specific cellular responses such as actin remodeling, macropinocytosis, and nuclear responses. These responses are largely the result of the activity of a set of bacterial proteins, SopE, SopE2 and SopB, which upon delivery into host cells via a type III secretion system, activate specific Rho-family GT-Pases either directly (SopE and SopE2) or indirectly (SopB). We show here that different Rho-family GT-Pases play a distinct role in Salmonella induced cellular responses. In particular, we find that upon infection Salmonella elicits GTP loading on Rac and Cdc42 independently. Activation of Rac leads to actin cytoskeleton rearrangements whilst Cdc42 activation mediates nuclear responses, such as IL8 induction. Moreover, we report that SopB stimulates cellular responses by activating SGEF, a host cell encoded guanine nucleotide exchange factor (GEF) for RhoG, which we found also plays a central role in the actin cytoskeleton remodeling stimulated by Cdc42 activation mediates nuclear responses, such as IL8 induction. We demonstrate a novel role for caspase-1, which is to induce the activation of the central regulators of membrane biogenesis, the Sterol Regulatory Element Binding Proteins (SREBPs). Upregulation of lipid metabolic pathways in turn promotes cell survival.

Membrane Nanotubes Connect Human T-cells and Could Facilitate Intercellular Transmission of HIV-1
S. Sowinski,1 C. Jolly,2 Q. Sattentau,2 D. Davis1; 1Cell and Molecular Biology, Imperial College London, London, United Kingdom, 2Pathology, William Dunn School of Pathology, Oxford, United Kingdom
We report that T-cells could be connected by long intercellular membrane tethers, a third of such connections having derived from cytokinesis. Connections derived from cytokinesis contained both filamentous actin and microtubules, and were accessible to the small cytoplasmic dye calcein. In contrast, T-cell membrane nanotubes formed independently of cell division contained filamentous actin but not microtubules, and excluded the cytoplasmic dye calcein. Membrane tethers from differentially labeled cells did not freely mix within membrane nanotubes, and instead met at junctions, revealing synaptic connections within T-cell membrane nanotubes. Furthermore, we observed that the HIV-1 Gag and Env proteins were present in membrane nanotubes connecting HIV-1-infected CD4+ T-cells to uninfected CD4+ T-cells. HIV-1 Gag and Env proteins were detected within uninfected T-cells linked via membrane nanotubes to chronically infected T-cells suggesting that membrane nanotubes may provide a novel mechanism for direct cell-to-cell dissemination of HIV-1.

Differential Mechanisms of Chlamydia Egress from Non-phagocytic Cells
K. Hybiske, R. S. Stephens; Department of Infectious Diseases, School of Public Health, University of California Berkeley, Berkeley, CA
The egress of infectious Chlamydia from its host cell is a critical stage in its pathogenic cycle. Although it has been proposed that release may occur by a cytokidal or exocytic mechanism, this process remains poorly understood at the cellular and molecular level. To this end, we employed time-lapse confocal fluorescence videomicroscopy to determine what processes mediate Chlamydia egress. HeLa cells with stable expression of cytosolic GFP were generated by retroviral transduction. Upon infection with Chlamydia, the bacteria were readily internalized and sequestered into a parastropliphic vacuole, or inclusion, that increased in size within the cytoplasm of the host cell. Due to the inherent ability of the Chlamydia inclusion to exclude cytosolic GFP, our technique enabled unambiguous visualization of inclusions and their dynamic processes in live cells. Analysis of infected cells in the throes of Chlamydia egress revealed two distinct mechanisms of lysis: a lytic mechanism involving rapid rupture of the inclusion and host cell; (i) a novel process we have named “extrusion”, in which the inclusion is pushed outward from the cell body into a tethered, membrane- and cytoplasm-bound compartment. Extrusion-based egress had a 53% occurrence rate, while lysis occurred for 47% of the cells that underwent egress. Additionally, we characterized essential cellular mediators of each egress pathway. Lysis was comprised of a stepwise sequence of intracellular permeabilizations - first the Chlamydia inclusion, subsequently followed by nuclear permeabilization and finally plasma membrane rupture. Treatment with cycloheximide, yielded no effects on either egress mechanism. Thus, we have identified and characterized two pathways for Chlamydia release from infected cells; extrusion represents a novel release mechanism for obligate intracellular bacteria.
Mechanism of Monomeric Actin sequestration by Toxofilin from Toxoplasma gondii: A Structural-Functional Study

S. Lee, Y. Li, G. Rebowsky, I. Tardieux, R. Dominguez; 1Physiology, University of Pennsylvania, Philadelphia, PA, 2Département des Maladies Infectieuses, Institut Cochin, Paris, France

Toxoplasma gondii is a parasite belonging to the phylum Apicomplexa, which includes human pathogens of major medical importance, such as Plasmodium the agent of malaria. In contrast to other pathogens such as Listeria, which utilize the host-cell actin cytoskeleton to move within and between cells, T. gondii has developed its own actin cytoskeletal system, necessary for host invasion. T. gondii is unique in that it presents a strikingly low amount of F-actin, suggesting that G-actin-binding proteins play a key role in the regulation of actin dynamics and pathogenicity. Toxofilin is an abundantly expressed G-actin-binding protein of T. gondii. The mechanism of G-actin sequestration by toxofilin is unknown. We determined the crystal structure of toxofilin complexed with actin. Toxofilin interacts extensively with actin, displaying multiple, apparently independent, actin-binding sites. The central region of toxofilin binds in the cleft between actin subdomain 1 and 3, a common binding site for many actin-binding proteins. Despite the lack of sequence identity with known eukaryotic actin-binding proteins, this interaction is strikingly similar to that of the WASP-homology domain 2 with actin. However, toxofilin presents two additional, and so far unique, actin-binding sites. This result suggested that a single molecule of toxofilin could interact with multiple actin molecules simultaneously. Analytical ultracentrifugation studies of complexes of toxofilin fragments with actin confirmed this observation, and indicated that toxofilin could bind up to three actin monomers. Toxofilin is also the only actin-binding protein shown so far to interact directly with the nucleotide in actin, resulting in a dramatic increase in G-actin polymerization. This ability to bind multiple actin monomers and bind G-actin could be used as a tool to delve into toxofilin's role in T. gondii, emphasizing its importance for pathogen invasion. This structure provides a molecular target for the development of drugs against this deadly group of parasites.

1400 Determinants of the Interaction between the CENP-A Nucleosome and Its Associated Complexes

D. R. Foltz,1 D. W. Black,1,2 L. E. T. Jansen,1,2 A. O. Bailey,3 J. R. Yates,4 D. W. Cleveland; 1Cell Biology, Ludwig Institute for Cancer Research, La Jolla, CA, 2Department of Cellular and Molecular Medicine, UCSD, La Jolla, CA, 3Department of Biochemistry and Biophysics, University of Pennsylvania, Philadelphia, PA, 4Department of Cell Biology, The Scripps Research Institute, La Jolla, CA

Proper chromosome segregation requires the establishment of a specialized chromatin domain known as the centromere that is characterized by its incorporation of a specialized nucleosome containing the histone H3 variant CENP-A. This centromeric histone is thought to be important for the epigenetic inheritance of the centromere. The CENP-A nucleosome is responsible for recruiting a set of six protein variant CENP-A proteins comprised of CENP-C, H, M, N, U(50) and T. The CENP-A complex is in turn responsible for recruiting a set of CENP-A distal (CAD) components (CENP’s K, L, P, Q, R and S). CENP-T and CENP-S contain a region of similarity to a subdomain of the histone fold present in all histone H3 variants. Here we show that knockdown of CENP-T results in the disruption of the CENP-A complex and dramatically alters mitotic progression. Deletion of histone-like domain of CENP-T eliminates it centromeric localization. Tandem affinity purification of CENP-T co-purifies components of the CENP-A complex. Use of deuterium exchange mass spectrometry demonstrates that the 22 amino acid CENP-A Targeting Domain (CADT) that is responsible for localizing it to the centromere confers a unique structural rigidity to both the pre-nucleosomal CENP-A/H4 heterotetramer and to nucleosomes assembled from it, independent of the DNA template. To assess whether this unique nucleosome structure is recognized by CENP-A nucleosome recruiting partners, histone H3-CADT containing nucleosomes have been purified by tandem affinity purification and their composition compared with that of histone H3.1 or CENP-A nucleosomes. The FACT complex, as well as CENP-D, -E, and -F, originally isolated with CENP-A nucleosomes, are also found associated with the centromere targeted histone H3 nucleosomes containing the FACT complex, demonstrating that at least a subset of the CENP-A nucleosome interaction partners are able to recognize the unique, CENP-A dependent CENP-A nucleosome structure.

1401 Xenopus Cenp-V Is Required to Anchor Microtubules to Kinetochores and Centrosomes in Mitosis

M. J. Emanuele, T. Stukenberg; Biochemistry and Molecular Genetics, University of Virginia, Charlottesville, VA

The anchorage of microtubules within the mitotic spindle apparatus is critical for generating the forces required for chromosome movement. We report here the characterization of the Xenopus Cenp-V (Centromere associated protein V) and demonstrate its role in microtubule attachment at centrosomes and kinetochores. Cenp-V was identified using sequence analysis searches for the a vertebrate homolog of yeast Dam1. We show that Cenp-V localizes to the kinetochore, centrosome and mitotic spindle in Xenopus extracts. Cenp-V depletion results in an elongated mitotic spindle with reduced tubulin incorporation and unaligned chromosomes. Cenp-V interacts by immunoprecipitation with the kinetochore proteins Zwint, Mis12 and CLIP-170. Inhibition of Cenp-V reduces chromosome-microtubule binding in vitro, and the effect is equivalent to that observed for inhibition of the outer plate protein Ndc80. Since stably attached spindle microtubules are resistant to depolymerization we challenged bipolar spindles assembled in cyclized extracts with a low dose of nocodazole. We found that Cenp-V inhibition generated spindles lacking stabilized microtubules. Cenp-V also interacted with the centromere protein gamma-tubulin. After Cenp-V depletion, centrosome mediated astras nucleated with normal kinetics but rapidly lost their ability to anchor microtubules. Real time imaging revealed microtubule bundles floating away from centrosomes in Cenp-V depleted extracts. We conclude that Cenp-V has a role in microtubule binding at both the centrosome and kinetochore in Xenopus extracts.

1402 Molecular Dissection of Kinetochore-based Regulation of Microtubule Dynamics in Drosophila

D. W. Basu, J. Tupper, J. Sharpe; 1Physiology and 2Pharmacology, College of Medicine, Bronx, NY, 3Biology, University of North Carolina, Chapel Hill, NC

The centrosome is a multiprotein complex that serves as the primary interface between chromosomes and microtubule spindle. As such, kinetochores perform a variety of regulatory and mechanical functions central to chromosome segregation during mitosis. A particularly interesting facet of kinetochore function is its ability to control the assembly state of associated microtubule plus-ends: Kinetochore-induced microtubule depolymerization stimulates poleward chromatid motility, while polymerization drives the movement of chromatids towards the spindle equator. To dissect the molecular machinery responsible for this, we have utilized RNAi to deplete all of the known effectors of microtubule assembly/dissassembly and severing in Drosophila S2 cells and assayed the effects on both chromosome motility and microtubule assembly state using live cell microscopy and photobleaching/FRAP analyses. The proteins examined in this study include I) the microtubule assembly promoters CLIP199, EB1, Minispinules and Mast II) the disassembly promoters KLP67A, KLP59C and KLP10A and III) the severing proteins Katamin, Spastin, and Fidgetin. Our findings reveal a remarkable integration of the activities of these three classes of proteins. We have observed functional antagonism between multiple assembly and disassembly factors throughout mitosis indicating that the net assembly state of kinetochore-associated microtubule plus-ends is determined by the cumulative activities of these proteins. Alternatively, severing proteins appear to enable kinetochore microtubule dynamics but do not directly influence the their assembly state. Prior to anaphase, severing proteins are required for normal microtubule polymerization while subsequently, after anaphase onset, severing is required for normal microtubule depolymerization. In light of these findings, a new model of kinetochore-driven chromosome motility will be presented.

1403 Defining Discrete Steps in Centriole Assembly Using an In Vivo Imaging Approach

A. Dammann, A. Desai, K. Oegema; Department of Cellular and Molecular Medicine, University of California–San Diego, Ludwig Institute for Cancer Research, La Jolla, CA

Centrioles are small cylindrical structures consisting of a 9-fold symmetric array of stable microtubules. Centrioles have two critical functions in cells: (1) they recruit pericentriolar material to form centrosomes that contribute to cell division, and (2) they template the formation of cilia, which perform a variety of motile and sensory functions. The first post-fertilization division of the C. elegans embryo has recently emerged as a powerful system to study centriole assembly. A set of 4 C. elegans proteins (SAS-4, SAS-5, SAS-6 and ZYG-1) have been identified that localize to centrioles and are specifically required for their duplication. Due to their small size, centriole duplication has typically been studied by electron microscopy, which has limited the repertoire of experiments that can be used to study them. To circumvent this problem, we are developing light microscopy-based methods to visualize centriole assembly in living embryos. We began by analyzing the kinetics of recruitment of two centriole components, SAS-4 and SAS-6, that are incorporated into daughter centrioles during assembly and do not subsequently exchange with the cytoplasm. Ultrastructural analysis has shown that centriole assembly proceeds in two discrete steps: 1) the formation of a structural intermediate called central tube, followed by 2) assembly of the microtubule containing outer centriole wall. Our analysis of the recruitment of SAS-6 and SAS-4 indicates that they are incorporated during the assembly of the central tube and outer centriole wall, respectively. As the first constituents of these centriolar substructures to be identified, this work represents an important step towards a molecular understanding of centriolar development. The methods described here have demonstrated should also serve as a useful tool for defining the relationship between the steps in pathway of centriole assembly, and in analyzing the role of other components implicated in duplication.
HsSAS-6 Is a Cell Cycle Regulated Centriolar Protein Required for Daughter Centriole Formation

We have characterized hPOC5, required for procentriole assembly but for that of the distal end of centrioles, revealing that centriole duplication and centriole differentiation correspond to structurally distinct assembly processes (1). Interestingly, hPOC5 family revealed an evolutionary divergence between Drosophila or C. elegans, which have lost hPOC5 homologues, and the other animals. The divergence of centriole structure in those species could result from the loss of the distal part of centrioles, concomitantly with the loss of genes from the POC5 family, or from centrin sub-families (2). Candidates for hPOC5-interacting proteins were identified by a two-hybrid approach. We selected a p83 protein whose interaction was confirmed biochemically. p83 defines a conserved family in eukaryotes, and the Chlamydomonas homologues is present in centriole fractions (3). In agreement, a GFP-tagged version of p83 labeled centrioles in human cells. When overexpressed, GFP-p83 labeled microtubules. Its binding stabilized microtubules and progressively induced the formation of long bundles along the plasma membrane or of a thick and continuous bundle apposed to the nucleus periphery, in which microtubules were closely linked by regularly spaced bridges. Endogenous p83, expressed at a low level, is likely restricted to centrioles. We speculate that p83 would interact with the intraluminal centrin- and hPOC5-containing structures and bind centriole blades to stabilize them or participate in their assembly. Interestingly, the p83 family is conserved in Drosophila and C. elegans. Characterizing the mechanisms in which p83 participates could help deciphering the evolution of centriole structure and function among divergent animal species. 1- Azimzadeh, et al., Submitted. 2- Azimzadeh J, Bornens, M (2004) In Centrosomes In Development and Disease Ed EA Nigg, Wiley-Vch 3- Keller et al., Curr Biol. 2005 Jun 21;15(12):1090-8.

Dissecting the Centriole/Basal Body Structure in Animal Cells

J. Azimzadeh,1 A. Delouve,1 U. Euteneuer,1 L. Daviet,1 M. Bornens1; 1Cnrs/umr144, Institute Curie, Paris, France, 2Zellebiologie, Adolf-Butenandt-Institut, University of Munich, Germany, 3Hybrigenics, Paris, France.

We have characterized hPOC5, a conserved centrin-binding protein containing SH3-like centrin-binding repeats, concentrated in the distal lumen of centrioles from human cells. hPOC5 is not required for procentriole assembly but for that of the distal end of centrioles, revealing that centriole duplication and centriole differentiation correspond to structurally distinct processes (1). Interestingly, hPOC5 family revealed an evolutionary divergence between Drosophila or C. elegans, which have lost hPOC5 homologues, and the other animals. The divergence of centriole structure in those species could result from the loss of the distal part of centrioles, concomitantly with the loss of genes from the POC5 family, or from centrin sub-families (2). Candidates for hPOC5-interacting proteins were identified by a two-hybrid approach. We selected a p83 protein whose interaction was confirmed biochemically. p83 defines a conserved family in eukaryotes, and the Chlamydomonas homologues is present in centriole fractions (3). In agreement, a GFP-tagged version of p83 labeled centrioles in human cells. When overexpressed, GFP-p83 labeled microtubules. Its binding stabilized microtubules and progressively induced the formation of long bundles along the plasma membrane or of a thick and continuous bundle apposed to the nucleus periphery, in which microtubules were closely linked by regularly spaced bridges. Characterizing the mechanisms in which p83 participates could help deciphering the evolution of centriole structure and function among divergent animal species. 1- Azimzadeh, et al., Submitted. 2- Azimzadeh J, Bornens, M (2004) In Centrosomes In Development and Disease Ed EA Nigg, Wiley-Vch 3- Keller et al., Curr Biol. 2005 Jun 21;15(12):1090-8.

Activities and Regulation of Full-length Formin Proteins

S. Maiti,1 J. B. Moseley,1 A. DuPage,1 O. Sokolova,2 N. Grigorieff,2 B. L. Goode1; 1Biology Department, Brandeis University, Waltham, MA, 2Biochemistry Department, Brandeis University, Waltham, MA.

Formins nucleate actin assembly and processively cap the fast-growing ends of actin filaments, but the molecular mechanisms regulating their activities remain poorly understood, in part because the activities of full-length formins have not been characterized. Here, we isolated five different full-length formin proteins (human Daam1, mouse mDia1 and mDia2, and budding yeast Bni1 and Bnr1), all of which have a conserved diaphanos auto-inhibitory domain (DAD). We find that Daam1, mDia1, mDia2, and Bnr1 are strongly auto-inhibited, whereas Bni1 is constitutively active. Thus, the presence of a DAD is not a reliable predictor of formin autoinhibition. Truncation of DAD from mDia1 disrupts autoinhibition and induces a significant increase in Stokes radius consistent with release from a compact form. Structural analysis by electron microscopy and single particle averaging supports this view. RhoA is sufficient to only partially activate N-terminally truncated mDia1 molecules or trans-inhibited mDia1 fragments, and minimally activates intact, full-length mDia1. This suggests that additional cellular factors besides RhoA are required to release mDia1 from an autoinhibited state. Finally, our analyses reveal an unexpected role for the DAD in promoting formin-mediated actin assembly that involves direct interactions between the DAD and actin. This function likely explains why DAD is conserved in both autoinhibited and constitutively active formins.

Dynamic Formation of Actin Bundles by Formins

A. Michelou,1 J. Berro,2 E. Derivery,1 R. Pateras-Boujelma,1 C. Guerin,1 H. N. Higgs,2 J. C. Stauger,1 J. L. Martel2,1 L. Blanchon1; 1DRDC, Laboratoire de Physiologie Cellulaire Végétale, CEA Grenoble, Grenoble, France, 2Laboratoire TIMC-TIMB, UMR CNRS 5525, Grenoble, France.

We characterize the dynamic formation of actin bundles by full-length formins. We show that AFH1 does not remain attached at the growing barbed end of elongating filaments, as would be expected for a processive assembly factor, but rather it moves from the end to the side of an actin filament following nucleation. This behavior is crucial for the mechanism of actin bundle initiation by AFH1. However, processive formin as mDia2 is able to generate also actin bundles with a different polarity compare to AFH1. We propose a model for bundle formation that requires tight coordination between the nucleation events, the rate of elongation of actin filaments, and the thermal fluctuation of flexible polymers induced by Brownian motion.

Assembly of the Contractile Ring in S. pombe

D. Vasyukonis,1 J. Q. Wu,2 S. Hao,2 T. Kamine,2 B. O'Slaughnessy,1 T. D. Pollard2; 1Chemical Engineering, Columbia University, New York, NY, 2Cellular, Molecular and Developmental Biology, Yale University, New Haven, CT.

We used high resolution quantitative confocal microscopy and mathematical modeling to study the assembly of the actomyosin contractile ring during cytokinesis of S. pombe. The contractile ring in fission yeast is formed from the condensation of a broad band of ~70 membrane-bound “nodes” containing myosin-II (Myo2p), formin (Cdc12p), and other proteins (Wu et al. J. Cell Biol. 2006). We observed nodes in cells expressing myosin regulatory chain Rlc1p triply labeled with GFP. Nodes condense into rings through movements and coalescence events. A typical movement episode lasts ~ 20 s during which a node moves with a speed ~ 40 nm/s. A large fraction of node motions can be attributed to pair-wise node motions. Before the onset of condensation the nodes appear to execute Brownian motion with a diffusion coefficient ~dT = 4n m2/s. We thus estimate that the force exerted on a moving node is F = v kT / D > 4 pN, in the same range as the force exerted by a few molecular motors. These observations support a picture where myosin pulls nodes together by pulling on an actin filament, which is nucleated in a node by Cdc12p and grows to establish a transient connection with a neighboring node. To test if such a mechanism is robust enough to account for the uniform contraction of the broad band of nodes into a ring, we performed numerical simulations of simple models, which involve establishment of node connections, node movement, connection breakage, and our measured experimental parameter values. If we assume that the connection probability decreases with increasing distance between nodes, we observe a high probability of formation of disconnected aggregates, instead of a continuous ring. We speculate on possible mechanisms that may have evolved to bypass such instabilities.
Dynamic actin networks drive cell locomotion, phagocytosis, and intracellular motility of lipid vesicles, organelles, and invasive pathogens. Arp2/3 complex is the key component of these networks by virtue of its ability to form actin filament branches. Here, I will describe how we applied a hybrid approach that involves a combination of electron tomography, image analysis, computational docking, and modeling to obtain a detailed model of the branch junction at near-atomic resolution.

A Structural Look into the Mechanism of Actin Polymerization-based Motility
F. Ferron, D. Chereau, M. Boczkowska, G. Rebowski, R. Dominguez; Department of Physiology, University of Pennsylvania School of Medicine, Philadelphia, PA. Elan Pharmaceuticals, Inc, San Francisco, CA.

Actin-polymerization-based proteins drive multiple cellular processes, including cell locomotion, cell division, endocytosis, and the movement of various infectious pathogens. Despite dramatic progress during the last ten years in our understanding of the proteins and regulatory pathways that lead to such motile processes, the molecular bases of actin-polymerization-based movement remain a mystery. Actin, a 375 amino acid-long ATPase and the most abundant protein in eukaryotic cells, constitutes the "fuel" for such cellular motilities. This is in part due to actin’s ability to exist in two states, a monomer (G-actin) and a filamentous polymer (F-actin). However, actin polymerization is harnessed into directed movement by the interactions of actin with hundreds of proteins, generally known as actin-binding proteins (ABPs). These proteins determine the location, rate and timing for actin assembly into functional networks. Two families of ABPs, Ena/VASP and WASP, have emerged as key regulators of actin cytoskeleton remodeling. Ena/VASP is linked to actin filament elongation, whereas WASP plays a role in filament nucleation and branching mediated by Arp2/3 complex. Although Ena/VASP and WASP are considered two fundamentally different regulators of cytoskeleton dynamics, our structural studies suggest a striking resemblance in the way these two proteins function during nucleation and elongation. In particular, their roles in these processes are mediated by similar G- and F-actin-binding domains belonging to the WASP-homology (WH2) family, and by long poly-Pro regions, which mediate the binding of profilin-actin complexes. Based on various crystal structures (including those of the transitional state in elongation by VASP and WH2-assembled actin minifilaments) and a throughout biophysical characterization of some of the transitional complexes involved in nucleation and elongation, we will discuss emerging principles underlying the mechanism of actin-polymerization based motility.

PAK1-regulated Cofilin Activity Spatially Organizes Lamellipodium and Lamella Networks and Controls Leading Edge Protrusion
V. D. Delorme, M. Machack, T. Wittmann, C. Waterman-Storer, G. Danuser; Immunoology, The Scripps Research Institute, La Jolla, CA. Cell Biology, The Scripps Research Institute, La Jolla, CA, CA. UCSF, San Francisco, CA.

Actin filaments at the leading edge of migrating epithelial cells are organized in two distinct but overlapping modules: the lamellipodium and the lamella. Factors exist to regulate the intersection and dynamics of the two networks differentially and specifically to allow efficient cell edge protrusion. Cofilin constitutes an excellent candidate regulator: by virtue of its F-actin severing and depolymerizing activity, cofilin is known to promote actin remodeling. Paradoxically, cofilin severing activity may also decrease the mechanical stability of the lamellipodium and thus reduce cell protrusivity. To test this, we used quantitative Fluorescent Speckle Microscopy and measured F-actin dynamics in vivo in the two actin networks upon perturbation of the full signaling pathway of cofilin. We show that cofilin activity is regulated by PAK1, but not ROCK, at the cell leading edge. Increase of active cofilin downstream of active Rac, achieved using either PAK1 inhibitory domain, kinase-defective LIMK, or non-phosphorylatable active cofilin mutants, induces the formation of a unique region in which F-actin undergoes a fast retrograde flow. We provide evidence that this region displays kinetics and molecular characteristics of the lamellipodium. In addition, active cofilin increases the rate of F-actin treadmill in vivo and contributes to the formation of a wide region of F-actin polymerization at the cell edge. This effect is due to an enhancement of the density of polymerization-competent free barbed-ends but happens in an Arp2/3-independent fashion. Finally, classification of lamellipodium/lamella speciﬁcs in cells expressing active cofilin suggests a decoupling of the lamellipodium and the lamella at the leading edge. Tracking of the leading edge and measure of protrusion rates indicate that enhanced cofilin activity leads to a loss of spatio-temporal leading edge dynamics and to a decrease in net protrusion. We propose a model by which cofilin regulates lamellipodium/lamella spatial organization that is required for cell protrusion.

Defective ER-to-Golgi Transport Caused by a Mutation in the COPII Protein SEC23A Is Responsible for the Human Disease Cranio-Lenticulo-Sutural Displasia

Intra-Golgi Vesicular Transport and Glycosylation Disorders
D. Ungar, M. F. Hughson; Molecular Biology, Princeton University, Princeton, NJ.

Eukaryotic glycoproteins contain a variety of glycan structures ensuring their specific functionality. Diversification of the glycans occurs in the Golgi by a large number of glycosyltransferases and glycosidases. To ensure correct synthesis of the glycans, different sets of enzymes are stationed to different Golgi cisternae. Therefore the Golgi constantly needs to sort the enzymes from the moving secretory cargo. This is done by a combination of cisternal retention and vesicular transport, during which resident enzymes are packaged into retrograde vesicles for recycling within the Golgi. The conserved oligomeric Golgi (COG) complex is a hetero-oligomeric peripheral membrane protein functioning in intra-Golgi retrograde vesicle transport. Several mutations in COG subunits have been found to cause congenital glycosylation disorders, suggesting that COG is necessary for the correct sorting of glycosyltransferases, which create a variety of developmentally important glycans. To understand its molecular function, we investigated the structure of mammalian COG. The complex consists of two lobes, each containing a different heterotrimeric subunit assembly, that are connected by the remaining two subunits. We further find that three Golgi localized Rabs (Rab1, 2 and 6) in the TGN generate functional COG complexes.

Intra-Golgi Vesicular Transport and Glycosylation Disorders
D. Ungar, M. F. Hughson; Molecular Biology, Princeton University, Princeton, NJ.

Cranio-lenticulo-sutural dysplasia (CLSD) is an autosomal recessive syndrome featuring cranial and skeletal defects and cataracts that segregates with a missense mutation in the coding region of the SEC23A gene. SEC23A and its homolog SEC23B are two of the human genes encoding the SEC23 protein, an essential component of the COPII protein coat responsible for formation of vesicles budding from the endoplasmic reticulum (ER) destined for the Golgi complex. Electron microscopy and immunofluorescence studies of SEC23A-/- primary fibroblasts show obvious disorganization of the ER. Additionally, SEC31, another essential component of the COPII protein coat, is observed to be mis-localized to the cytoplasm in these cells by immunofluorescence. Purified mutant SEC23A is able to bind membranes and activate GTP hydrolysis by the COPII protein SAR1A at a level similar to wild-type. ER-derived vesicle budding assays performed in vitro with purified mutant SEC23A reveal that the mutation results in loss of functional budding activity. Surprisingly, the loss of budding activity is observed when SAR1B is used in the assay, but activity is restored if the highly homologous SAR1A is used instead. The loss of function can also be suppressed in vitro by addition of excess SEC13/SEC31A protein complex, suggesting that SEC13/SEC31A can interact with COG. This activity was confirmed through binding assays demonstrating the mutant SEC23A protein is impaired in its ability to recruit SEC13/SEC31A to both synthetic liposomes and microsomal membranes. Our observations suggest CLSD is caused by disrupted ER export of secretory proteins required for normal morphogenesis, and our in vitro data begin to explain the molecular basis for the disease.
The Dicytostele LvsB Is Localized on Post-Lysosomes and Controls the Fusion of Endocytic Vesicles

E. Kypri, A. De Lozanne; University of Texas at Austin, Austin, TX

The Chediak-Higashi Syndrome (CHS) is a rare autoso-mal recessive immunodeficiency disorder characterized by albinism and recurrent infections. At the cellular level, CHS is characterized by the presence of enlarged lysosomes and secretory defects. The gene affected in humans with CHS encodes a 430KDa protein named LYST (lysosomal trafficking regulator). To date, it is not clear how LYST contributes to lysosome biogenesis. Dicytostele discoidium contains a gene homologous to CHS termed lvsB that encodes the LvsB protein. LvsB mutants model the lysosomal defects associated with the Chediak-Higashi Syndrome. The aim of our studies is to determine the molecular function of LvsB and to provide insights into the regulation of lysosome biogenesis and the Chediak-Higashi syndrome. To better understand the role of LvsB, we used a knock-in approach to introduce the coding sequence of GFP at the 5’end of the lvsB gene. Imaging of cells expressing GFP-LvsB revealed that it is localized in the cytosol and on vesicular compartments of various sizes. Staining with antibodies against different endolysosomal markers revealed that GFP-LvsB colocalized with vacuolin on post-lysosomes. This result indicated that LvsB must exert its function primarily on the post-lysosomal compartment. Interestingly, LvsB mutants showed abnormally enlarged post-lysosomes that frequently exhibited altered acidity. Utilizing a fluid phase marker in a fusion assay we showed that, in the absence of LvsB, the terminal post-lysosomal compartments fuse inappropriately with earlier lysosomes. In agreement with this fusion assay, LvsB mutants exhibited frequent intermixing of lysosomal and post-lysosomal markers. Based on our data we propose that LvsB helps define the identity of late endosomal compartments by inhibiting their incorrect fusion with earlier compartments.

A Defect in the Metabolism of the Signaling Lipid, PI3,5P2 Causes Neurodegeneration in Mice

Y. Zhang,1 C. Y. Chow,2 S. C. Richardson,1 R. C. Piper,1 R. J. Westrick,1 M. H. Meisler,1 L. I. Weissman1; 1Department of Cell and Developmental Biology, Life Sciences Inst., University of Michigan, Ann Arbor, MI, 2Department of Human Genetics, University of Michigan, Ann Arbor, MI

The low abundance signaling lipid, phosphatidylinositol 3,5-biphosphate (PI3,5P2) is produced in the endocytic pathway. Its physiological functions are not known. PI3,5P2 is unique in that its levels change dramatically in response to specific stimuli. For example, in the yeast, S. cerevisiae, exposure to hyperosmotic shock, causes PI3,5P2 levels to transiently rise more than 20 fold within 5 minutes. The return to basal levels, even in the continued presence of esmyle, is achieved by 30 minutes. As an approach to determine the physiological roles of PI3,5P2, in mammals, we tested and found that proteins required for synthesis and turnover of PI3,5P2, are present in all tissues examined. This wide distribution suggests that PI3,5P2 plays multiple roles in signaling events that occur on internal membranes. Here we report that mice hypomorphic for the PI3,5P2, regulator, Vac14, die soon after birth. While development appears to be normal, there is massive neurodegeneration in both the central and peripheral nervous system. Cell bodies of multiple neurons are vacuolated, and large holes are present in areas where neurons should be present. Vacuolation appears specifically in neurons, however, other cell-types have the potential to form large vacuoles. That vacuoles appear first in neurons suggests that either PI3,5P2 functions in a neuronal-specific compartment and/or that neurons by virtue of their long processes are more sensitive to general defects in membrane transport. These findings strongly suggest that the general signaling lipid, PI3,5P2, is specifically essential for neuronal survival, and raise the possibility that selected human neuropathies are caused by mutations in PI3,5P2, signaling pathways.

Autophagy, Cell Death, and Development

S. Pattingre,1 Y. Wei,1 Q. Xu,1 N. Mizushima2,3 B. Levine1,4; 1Department of Internal Medicine, University of Texas Southwestern Medical Center, Dallas, TX, 2Department of Birerregulation and Metabolism, Tokyo Metropolitan Institute of Medical Science, Tokyo, Japan, 3Precursory Research for Embryonic Science and Technology, Japan Science and Technology Agency, Kawaguchi, Japan, 4Department of Microbiology, University of Texas Southwestern Medical Center, Dallas, TX

Apoptosis and autophagy are both tightly regulated biological processes that play a central role in tissue homeostasis, development, and disease. Previously, we have shown that the anti-apoptotic protein, Bcl-2, interacts with the evolutionarily conserved autophagy protein, Beclin 1. Bcl-2 binding inhibits Beclin 1-dependent autophagy and autophagy gene-dependent cell death. Moreover, the binding and dissociation of the Bcl-2/Beclin 1 complex is regulated by nutritional status. In this meeting, new data will be presented regarding the biochemical regulation of Bcl-2/Beclin 1 binding. We will also describe studies using autophagy gene null embryonic stem cells to assess the role of autophagy in programmed cell death during mammalian development. Together, our data demonstrate important interrelationships between the autophagy and apoptosis pathway in mammalian physiology and development.

Rules for Nuclear Localization Sequence Recognition by Karyopherin beta2/transportin

Y. Chook; Pharmacology, UT Southwestern Medical Center, Dallas, TX

Karyopherin beta2/transportin bind nuclear localization and export signals (NLSs and NESs) to mediates nuclear trafficking. Diversity and complexity of signals recognized by Kap2 have been previously predicted for new Kap substrates. We have solved the crystal structure of Kap2/transportin bound to the NLS of hnRNP A1, and further analyses reveal three rules for NLS recognition by Kap2: NLSs are structured disorderly in free substrates, have overall basic character, and possess a central hydrophobic or basic motif followed by a C-terminal R/H/KX(2), S/PY consensus sequence. We demonstrate the predictive nature of these rules by identifying NLSs in seven previously known Kap2 substrates and uncovering 81 new candidate Kap2 substrates in an initial bioinformatics endeavor. Of the members of this predicted group with annotated subcellular localization, ~90% are reported to be nuclear localized. We have experimentally validated all seven new NLSs of known Kap2 substrates and five new bioinformatics-predicted substrates for Kap2 recognition as well as Ran-mediated dissociation. These studies define and validate a new NLS that could not be predicted by primary sequence analysis alone. We refer to this new class of prevalent NLS as PY-NLSs. This class of signals can be further subdivided according to their central motifs into hydrophobic or hPI-NLSs and basic or bPY-NLSs. We have recently solved crystal structures of Kap2 in complex with two additional hPI-NLSs found in Kap2 substrate TAP and SAM68, as well as a bPY-NLS found in hnRNP M. The C-terminal R/H/KX(2), S/PY consensus sequence in all three additional structures are structurally conserved, explaining the importance of this key motif and its conservation through evolution for Kap2 recognition. The four Kap2-substrate structures now shows how significant diversity within PY-NLSs are accommodated by the karyopherin, and the structures also allow refinement of the NLS consensus sequences for more extensive bioinformatics prediction of new substrates.

Nanomechanical Selective Gating in the Nuclear Pore Complex

R. Y. H. Lim,1 B. Fahrenkrog,1 J. Deng,2 K. Schwarz-Herion,1 J. Köser,1 U. Aebi1; 1M.E. Müller Institute for Structural Biology, Biozentrum, University of Basel, Basel, Switzerland, 2Department of Materials Research and Engineering, Singapore, Singapore

The intrinsic surrounding the nuclear pore complex (NPC) lies in its ability to restrict or promote cargo translocation between the cytoplasm and nucleus i.e. selective gating. To come to understand the modus operandi of the selective gating mechanism necessitates a detailed knowledge of both the biochemical identities and the corresponding physical responses of the NPC machinery. In this regard, biological approaches are key in identifying the protein-protein interactions that govern cargo translocation, but provide only marginal assessments of its physical foundations. To obtain a rational understanding of the mechanical nature of the selective gate, it is pertinent to study its principal components with respect to different environmental conditions and related transport factors, at the relevant length scale i.e. nanoscale. In our laboratory, we have developed a single-hairpin, inter-implanar approach to unravel such effects. Specifically, phenylalanine-glycine (FG)-molecules are tethered to gold nanostructures designed to mimic the NPC geometry. Atomic force microscopy (AFM) measurements reveal that the thermal fluctuations of FG-molecules serve as an entropic barrier to would-be entrants to the NPC. Privileged access to the NPC is provided by transport receptors (e.g. importin-β), which negotiate the entropic barrier by causing a collapse of the FG-molecules via receptor-FG binding interactions. This striking effect is only reversed by RanGTP, which sequesters importin-β and inhibits FG-binding. Immunogold-labeling electron microscopy complement these findings by showing that the FG-domains of Kap153 are reversibly collapsed in vivo by importin-β and RanGTP. We anticipate that the receptor-driven collapse of the FG-domains defines the physical aspects of selective gating, and propose that the flux of collapsing and distending FG-domains serves to promote the translocation of receptor-cargo complexes while simultaneously maintaining the entropic barrier. In closing, we will demonstrate how the aforementioned principles of nanomechanical selective gating can be applied to the construction of a de novo designed “nanomill” NPC.
Baculovirus Infection Reveals a New Role for an Importin Alpha Isoform in Directing Integral Membrane Proteins to the Inner Nuclear Membrane

S. C. Brauneagl, S. Saksena, M. Summers 1,2,3, Texas Agricultural Experimental Station, Texas A&M University, College Station, TX, Department of Biochemistry and Biophysics, Texas A&M University, College Station, TX, Department of Entomology, Texas A&M University, College Station, TX.

Baculovirus infection produces an amplified pulse of viral integral membrane proteins directed specifically toward the inner nuclear membrane (INM) for viral envelope assembly in the nucleus. A viral INM-sorting sequence has been identified from studies of these proteins and features of this sequence are retained in mammalian INM-directed integral membrane proteins. Using the viral sequence to identify interacting proteins specific to the pathway of viral protein transit from the ER to the INM has identified a cellular, truncated, membrane-bound importin (importin α-16). Importin α-16 binds the INM-sorting sequence during protein synthesis at the junction of the translocon-associated proteins, importin α-16 remains adjacent to the INM-sorting sequence after it integrates into the ER membrane and is released from the translocon. Thus importin α-16 is the first known sorting factor that can discriminate INM-directed integral membrane proteins during translation and insertion into the ER membrane, and facilitate their transit from the ER to the INM. The identification of importin α-16 provides evidence for a new model of INM-directed protein trafficking that may include functional activity for transit across the lateral channels of the nuclear pore complex. Analyses of the six human importin α genes reveal that humans encode five unique isoforms of importin α. When tested in an in vitro translation assay followed by treatment with a chemical crosslinking reagent, one human isoform covalently crosslinks to the baculovirus INM-sorting signal sequence. These data suggest that the observations originally made with the insect importin α-16 also apply to similar isoforms generated in humans. The model of importin α-16 mediated trafficking of integral membrane proteins to the INM, and new observations made with human isoforms of importin α will be discussed.

The Nuclear Export Factor Xpo1p Regulates the Turnover of Mad1p at Kinetochores

R. J. Scott, R. W. Wozniak; Department of Cell Biology, University of Alberta, Edmonton, AB, Canada

Nuclear pore complexes (NPCs) are strategically positioned along the surface of the nuclear envelope where they control the exchange of macromolecules between the cytoplasm and the nucleoplasm. The majority of the component parts of the NPC function in transport by either directly interacting with soluble cargo proteins or establishing the structural framework of the NPC. However, there are several proteins that interact with the NPC but play no obvious role in transport suggesting that the NPC is involved in other cellular processes. Two such NPC residents are the proteins Mad1p and Mad2p, which function in the spindle assembly checkpoint (SAC). These proteins are bound to the NPC during interphase and are recruited onto mitotic kinetochores during SAC activation. We have previously shown that S. cerevisiae Mad1p dynamically associates with both NPCs and kinetochores during SAC activation and that its association with kinetochores is energy dependent. Here we will present new data showing that the cycling of Mad1p on and off kinetochores and the NPC is dependent on the GTPase Ran and the soluble nuclear export factor Xpo1p. In mutants of the yeast RanGEF, FPR20, Mad1p turnover at the kinetochores is inhibited during SAC activation. Similarly, overexpression of a dominant negative mutant of Ran incapable of GTP hydrolysis allows association of Mad1p with kinetochores but prevents its turnover. Kinetochore turnover of Mad1p is also inhibited by mutations in Xpo1p. Consistent with the hypothesis that Xpo1p is present in the nucleoplasm and at spindle pole bodies throughout the cell cycle, but is recruited kinetochores during SAC activation. Finally, the results of experiments examining the direct interactions of Mad1p with Xpo1p and the role of this export factor in regulating the SAC will be discussed.

Export of mRNA through the Nuclear Pore Complex

K. Weis, C. S. Weichr, J. P. Erzberger, J. S. Flick, J. M. Berger, J. Thorrer; Department of Molecular & Cell Biology, University of California, Berkeley, Berkeley, CA

Export of mRNAs from the nucleus is essential for eukaryotic gene expression. Mature mRNAs are packaged into export-competent mRNA-protein particles (mRNPs) in the nucleus and subsequently transported across the nuclear pore complex (NPC) to the cytoplasm. mRNA export requires the essential DExD/H-box ATPase Dbp5, however, the precise role of Dbp5 in mRNA export is unknown and how mRNAs are directionally translocated across the NPC remains poorly understood. We have identified the nuclear pore protein Gle1 as an essential cellular activator of Dbp5. While Dbp5 alone is unable to bind RNA or effectively hydrolyze ATP under physiological conditions, addition of Gle1 dramatically stimulates these activities of Dbp5. A gle1p mutation that is deficient for Dbp5 stimulation in vitro does not affect Dbp5 expression in vivo, indicating that activation of Dbp5 is an essential function of Gle1. Functional analysis of the crystal structure of Dbp5’s C-terminal domain also reveals commonalities between Dbp5 activation by Gle1 and eIF4A activation by eIF4G, suggesting that these interactions may define a general model for the regulation of cellular DExD/H-box proteins by trans-acting factors. Interestingly, Gle1 binds directly to inositol hexakisphosphate (IP6) and IP6 potentiates the Gle1-mediated stimulation of the ATPase activity of Dbp5 in an RNA-dependent manner. We have isolated novel dominant alleles of Gle1 and DBP5 that rescue mRNA export phenotypes associated with the lack of IP6 production. Importantly, the dominant Dbp5 protein variant mimics the effect of IP6 on Dbp5 activation by Gle1 in vitro. These results define specific roles for Gle1 and IP6 in mRNA export and suggest that local activation of Dbp5 at the NPC by Gle1 and IP6 is critical for mRNA export.

A Role for the Nuclear Pore Protein, Nup60p in the Localization of ASH1 mRNA

E. A. Powrie, S. Shenoy, R. Singer; Cell Biology, Albert Einstein College of Medicine, Bronx, NY

Localization of ASH1 in the budding yeast Saccharomyces cerevisiae is one of the paradigms of mRNA localization. ASH1 is very highly expressed in late anaphase and actively localized to the bud-tip where it is locally translated and selected into the daughter cell nucleus where it functions as a GATA-like transcriptional repressor of the HO endonuclease. In addition to the She proteins that were initially identified as affecting ASH1 mRNA localization, other proteins that have more subtle effects on ASH1 localization (e.g. Loc1p, Khd1p, Puf6p) have been discovered. High resolution imaging of a localizing ASH1 reporter construct under wild type and mutant conditions demonstrates that the mRNA co-localizes with the nuclear pores, suggesting a potential role for nuclear pores in localization. Viable deletion strains (of nucleoporins and nuclear periphery-associated proteins) were selectively screened for abnormal ASH1 localization by in situ hybridization. The nuclear basket protein Nup60p displayed a defect in the efficacy of endogenous ASH1 transcript localization. Characterization of the nup60p deletion defect showed that a significant proportion of the ASH1 mRNA was retained in the mother cell. Preliminary analysis using in situ hybridization techniques showed that in nup60p deletion strains, the transcription site is internalized relative to its usual position at the nuclear periphery. Whether there is a cause and effect relationship between the aberrant localization phenotype and the delocalization of the transcription site is being investigated. As the identification and understanding of how trans-acting protein factors affect ASH1 localization expands, events that occur at every part of the transcript life cycle, from transcription to translation are ultimately critical to maintaining the wild type phenotype. Supported by GM557071.

Cell Signaling by Receptor Tyrosine Kinases: From Bench to Bedside

J. Schlessinger; Department of Pharmacology, Yale University School of Medicine, New Haven, CT

Receptor tyrosine kinases (RTKs) comprise a large family of membrane receptors that control many critical cellular processes. It is now well established that various human diseases and pathologies are caused by dysfunction in RTKs or in the intracellular signaling pathways that they activate. We have used mass spectrometry and X-ray crystallography to demonstrate that tyrosine autophosphorylation of the catalytic tyrosine kinase domain of FGF-receptor-1 (FGFR1) is mediated by a sequential and precisely ordered reaction. We also demonstrate that the rate of catalysis of two FGFR substrates is enhanced by 50 to 100 fold following autophosphorylation of the first site in the activation loop while autophosphorylation of the second site in the activation loop results in 500 to 1000 fold increase in the rate of substrate phosphorylation. We propose that FGFR1 is activated by a two-step mechanism mediated by strictly ordered and regulated autophosphorylation suggesting that distinct phosphorylation states may provide both temporal and spatial resolution to receptor signaling. Genetic models in mice provide new opportunities for exploring and developing new treatments for diseases caused by dysfunctions in RTKs and in their intracellular signaling pathways. Inhibitors of tyrosine kinases have been successfully applied for the treatment of cancers driven by activated tyrosine kinases. Support of U011126 is a new grant biacis actions of several tyrrosine kinases including e-kai, PDGFR and VEGFR. Sentox has been approved by the FDA for the treatment of advanced kidney cancers, gastrointestinal stromal tumors (GIST) and Gleevec resistant GIST. Finally, a novel scaffold-based drug discovery approach will be described that enables the development of many new families of inhibitors for protein kinases and other enzymes that play a role in cell signaling.
Transactivation of Epidermal Growth Factor Receptor in Human Mammary Epithelial Cells Involves Multiple Receptor Types Operating via Distinct Signaling Modules

N. Bollinger, D. Ippolito, H. Wiley, K. D. Roldand; Biological Sciences, Pacific Northwest National Laboratory, Richland, WA

It has been established that oncogenes can induce complex, interconnected communication networks that allow cells to integrate various extracellular signals. The transactivation of epidermal growth factor receptor (EGFR) is involved in many cellular processes such as proliferation, differentiation, and migration. The overall objective of this study was to determine which receptor types and signaling pathways were involved in transactivation of the EGFR in human mammary epithelial cells (HMEC). We found that G-protein-coupled receptors (LPA receptors, purinergic receptors, and Calcium-sensing receptors), cytokine receptors (VEGF and GH receptors), IGF receptor and TNF-α receptors are all capable of initiating cross-talk measured as increased ERK phosphorylation that could be blocked by inhibiting EGFR kinase activity. In contrast, the IGF receptor appears to activate the ERK pathway independent of EGFR. We found that transactivation of the EGFR generally involves activation of membrane associated metallopeptases of either the ADAM (A Disintegrin And Metalloproteinase-) or matrix metallopeptase (MMP) families, resulting in the proteolytic cleavage of membrane-bound EGFR ligands. Specifically, our results suggest that GPCR-mediated transactivation of the EGFR in HMEC cells required activation of ADAM 17/TACE when the IGF-1 receptor used alternate metallopeptases. Analysis of the ligands responsible for transactivation in HMEC cells indicated that although amphiuregulin is the dominant ligand released by IGF receptor activation, GPCR transactivation involves multiple ligands, including TGFα and epiregulin. These data suggest that multiple pathways are responsible for the selective release of different ligands that activate the EGFR in HMEC. Understanding the various receptors and the complex mechanisms involved in EGFR transactivation may lead to identification of therapeutic targets in diverse physiological disorders, such as cancer.

Membrane Mucin Muc4 Induces Density Dependent Changes in Erk Activation in Mammary Epithelial and Tumor Cells

C. A. Carothers Carraway, V. Pino, K. Carraway; University of Miami School of Medicine, Miami, FL

The membrane mucin molecule has been shown to alter cell behavior through both anti-adhesive effects on cell-cell and cell-extracellular matrix interactions and its ability to act as an intramembrane ligand for the receptor tyrosine kinase ErbB2. The extracellular-regulated kinase (Erk) pathway is regulated by both cell-matrix and cell-cell adhesion. An analysis of the effects of Muc4 expression on Erk phosphorylation in mammary and epithelial cells which exhibit both adhesion dependent growth and contact inhibition of growth showed that the effects are density dependent, with opposing effects on proliferating cells and on contact-inhibited cells. In these cells, cell-matrix interactions through integrins are required for activation of the Erk mitogenesis pathway. However, cell-cell interactions via cadherins inhibit the Erk pathway. Expression of Muc4 reverses both of these effects. In contact-inhibited cells, Muc4 appears to activate the Erk pathway at the level of Raf-1; this activation does not depend on Ras activation. The increase in Erk activity correlates with an increase in cyclin D1 expression in these cells. This abrogation of contact inhibition is dependent on the number of mucin repeats in the mucin subunit of Muc4, indicative of an anti-adhesive effect. The mechanism by which Muc4 disrupts contact inhibition involves a Muc4-induced relocalization of E-cadherin from adherens junctions at the lateral membrane of the cells to the apical membrane. Muc4-induced abrogation of contact inhibition may be an important mechanism by which tumors progress from an early more benign state to invasiveness.

SUZ12 Mediated NF-IL6 Gene Silencing Plays a Functional Role in Tumorgenesis

C. Ko; The Institute of Basic Medical Sciences, College of Medicine, National Cheng Kung University, Tainan, Taiwan

Polycomb group (PcG) proteins function as epigenetic chromatin modifiers and involve in cancer development and also in the maintenance of embryonic and adult stem cells. Recent reports have demonstrated that PcG protein EZH2 is highly expressed in metastatic prostate cancer and lymphomas. SUZ12 is a recently identified PcG protein which binds with EZH2, a histone H3 methyltransferase (HMT), and EED to form Polycomb repressive complexes (PRC). SUZ12 has been identified as an E2F target gene and its mRNA is up-regulated in a number of different human tumors, such as tumors of the colon, breast, and liver. On the other hand, previous reports showed that NF-IL6 (human C/EBPα) induced growth arrest in breast cancer cells and was a crucial regulator of pro-apoptotic gene expression during mammary gland involution. These data suggested that NF-IL6β was a potential tumor suppressor. Kirmizis et al. has shown that knock-down of SUZ12 induced C/EBPs gene expression. From my result, it showed that SUZ12 could bind to NF-IL6β promoter region and inhibited its transcriptional activity which resulted in decreasing NF-IL6β gene expression. Moreover, NF-IL6β gene expression could be induced by treatment with DNA methyltransferase inhibitor 5-AzaC in different cancer cell lines. Taken together, these results suggested that SUZ12 might play a functional role in NF-IL6 gene silencing. In the future, I would like to identify and clarify the connection between SUZ12 and NF-IL6 gene silencing in cancer cells and whether overexpression of NF-IL6β can block the SUZ12-induced tumorigenic phenotype.

Signaling Pathway Regulating Heat Shock Responses by Hsp27 and Peroxiredoxin 6

Y. Kim, Y. Kim, J. Jeong; College of Pharmacy, Ewha Womans University, Seoul, Republic of Korea

Heat shock stress induces a wide variety of biological processes, including ROS generation, inhibition of protein synthesis, elevated expression of heat shock proteins (Hsps), and induction of thermotolerance and apoptotic cell death in a dose dependent manner. However, the exact mechanisms of these processes were not well understood. Recently, proteosome inhibitor can induce Hps and thermotolerance as well as heat shock responses. To determine whether heat shock response is occurred similar way to proteosome inhibitor, we examined the differential protein expressions with systematic way in a radiation-induced fibrosarcoma cell line (RIF) and found that Hsp27 and peroxiredoxin6 (PRX6) were highly overexpressed and heavily modified in various sites identified using nano-LC-ESI-q-TOF MS/MS/MS. Based on the results, the heat shock signaling pathways in Hsp27 and PRX6 overexpressed cells were examined in ROS generation, poly-Ub accumulation, MAPK activation, Hsp synthesis, and thermotolerance. The results demonstrate that heat-induced signaling pathways were regulated by various key proteins including Hsp27 and PRX6 in protein-specific manner. [Supported by KOSEF grant FPR05A2-480, CCS, CCS & DDR and Brain Korea 21]

Lithium Induces Mitochondrial Biogenesis Independently of Glycogen Synthase Kinase-3-Beta and Inositol Monophosphatase Inhibition

I. T. Strouweeg, C. D. Maas; GCNS, University of Kentucky, Lexington, KY

Lithium treatment of these cells led to an increase in cell size, similar to the Wnt hypertrophic effect. Along with these changes there was an increase of mitochondrial mass as evidenced by an increase in mitochondrial genomic DNA compared to nuclear DNA. This increase in mitochondrial mass was accompanied by a proportional increase in ATP production and mitochondria membrane potential indicating that there was no change in mitochondrial efficiency. This increase of mitochondrial biogenesis was due to an increase in the mRNA and protein levels of oxidative phosphorylation components, which was triggered by an increased expression of the transcription factors NRF1 and 2 and the mitochondrial transcription factor TFAM. Though lithium also increased the levels of the inactive Phospho-S9-GSK3β, these changes were not a result of GSK3β inhibition as these effects were not reproduced with other GSK3β inhibitors, valproate and indirubin, or by expression of the inactive K85R-GSK3β. Although lithium also affects the inositol pathway by inhibiting inositol monophosphatase (IMPase), these effects could not be reversed with the addition of myo-inositol to restore the inositol intracellular pool. Together our results suggest a novel effect of lithium on mitochondrial biogenesis that is independent of GSK3β and IMPase inhibition and reveal a new target pathway for lithium that might be relevant to Wnt signaling.
1431 Hypoxia Inducible Factor-1 Is a Determinant of Hepatic Oxygen Consumption In Vivo

K. Tsukada, 1 T. Tajima, 1 T. Kawamura, 1 N. Goda, 1 R. S. Johnson, 2 M. Suematsu 2; 1Department of Biochemistry & Integrative Medical Biology, Keio University, Tokyo, Japan, 2Molecular Biology Section, Division of Biological Sciences, College of Veterinary Medicine, The Ohio State University, Columbus, OH, USA

Hypoxia-inducible factor (HIF)-1α is an oxygen-sensing transcriptional factor that dictates expression of erythropoietin, TGF-β and gas-generating enzymes such as NO synthase-2 and heme oxygenase-1. Since the gene disruption causes embryonic lethality, the roles of HIF-1α in adult mice remain largely unknown. To determine the role of HIF-1α in liver, we have herein generated mice harboring a floxed HIF-1α allele, and employed the albumin-Cre transgenic line to inactivate the gene site-specifically in hepatocytes. Intravital observation of the hepatic microcirculation combined with phosphorescence-assisted local oxygen measurements revealed that no difference in the local oxygen tension was evident in portal and central veins between HIF-KO and control mice. However, because of a higher erythrocyte velocity in microvasculature, the net oxygen consumption in the lobules appeared to be greater in HIF-KO mice than in the controls. The greater oxygen consumption in the HIF-KO liver appeared to result from an increase in the consumption at the hepatocellular level, so far as judged from measurements of the oxygen consumption in primary cultured hepatocytes. Although the whole mechanism remains unknown, the current results suggest a crucial role of HIF-1α in modulation of cellular oxygen consumption.

1432 Endosomal NADPH Oxidase Regulates c-Src Activation Following Hypoxia/Reperfusion Injury

Q. Li, 1 Y. Zheng, 1 W. Zhou, 1 J. Engelhardt 2; 1Anatomy and Cell Biology, The University of Iowa, Iowa City, IA, 2The Center for Gene Therapy, The University of Iowa, Iowa City, IA

As a tyrosine kinase, c-src has been shown to activate NFkappaB following hypoxia/reoxygenation (H/R) and ischemia/reperfusion (I/R) by directly phosphorylating IkappakBAlpaha. Our previous studies (J Clin Invest, 2004, 113(5): 746-55) have suggested that reactive oxygen species (ROS) are required for c-Src activation following H/R and I/R injuries in hepatocytes. In the present study, we investigated potential sources of ROS required for c-Src activation following H/R with the hypothesis that NADPH oxidases were involved. Our results demonstrate that following H/R injury, c-Src movement from the plasma membrane to intracellular vesicles was associated with enhanced NADPH-dependent superoxide production in isolated endosomes. Blocking endocytosis, by expressing a dominant negative mutant of dynamin, inhibited activation of NADPH oxidase, c-Src activation, and the ability of c-Src to tyrosine-phosphorylate IkappakBAlpaha in endomembranes following H/R. Quenching intra-endosomal ROS by loading newly formed endosomes with SOD1 and catalase, inhibited c-Src activation and its ability to tyrosine-phosphorylate of IkappakBAlpaha, without affecting c-Src recruitment into endosomes. These findings suggest that NADPH oxidase derived ROS are important for c-Src activation but not subcellular relocalization following I/R injury. Using reductant and adenoviral mediated expression of GPx-1, we demonstrate that hydrogen peroxide appears the key ROS required for c-Src activation following H/R. This finding suggests that NADPH oxidase derived superoxides are the source of endogenous hydrogen peroxide required for H/R activation of c-Src. Using siRNA mediated knockdown of Rac1 (a small GTPase and required co-activator of NADPH oxidases), we also demonstrate that Rac1 is required for both the endocytosis and reoxidation-mediated activation of c-Src. Inhibition of Rac1 also prevented H/R-induced ROS production by the endosomal compartment. In summary, our data suggest that Rac1-dependent NADPH oxidases play a critical role in activating c-Src following H/R injury. This may be a useful therapeutic target for I/R related disease.

1433 C/EBPβ mRNA Is Stabilized by UV Radiation Via Activation of the p38 MAP Kinase Pathway and HuR

B. Li, J. DeWille; Department of Veterinary Biosciences, College of Veterinary Medicine, The Ohio State University, Columbus, OH, USA

Inhibition of c-Src by treatment of A549 adenocarcinoma cells with the tyrosine kinase inhibitor, PP1, or treatment with Schisandrin B (SchB), both known to disrupt TGF-β signaling, led to a decrease in C/EBPβ mRNA levels. Treatment of cells with UV radiation induced an increase in C/EBPβ mRNA levels which was also blocked by the participation of the transcription factor, HuR. These findings suggest that UV radiation-induced stabilization of C/EBPβ mRNA is regulated by cellular proteins that bind to the C/EBPβ mRNA 3' UTR AU rich elements (ARE). In this study we treated HC11 mouse mammary epithelial cells with UVB or Anisomycin (AN) and demonstrated increased activation (phosphorylation) of p38 MAP kinase and increased C/EBPβ mRNA stability. Treatment with SB203580, a p38 MAP kinase inhibitor resulted in a decrease in C/EBPβ mRNA stability. UV radiation induces the nuclear -> cytoplasm translocation of HuR, an ARE-binding protein that functions in mRNA stability. We show that UV radiation-induced HuR translocation is also blocked by SB203580. Furthermore, repression of HuR by HuR siRNA treatment led to inhibition of C/EBPβ mRNA stability by UV radiation. HuR immunoprecipitation analysis demonstrated that HuR can bind to C/EBPβ mRNA in vivo after UV treatment. These results suggest that UV radiation activates p38 MAP kinase leading to nuclear/cytoplasmic shuttling of HuR and subsequent stabilization of C/EBPβ mRNA. Finally, previous studies from our lab have demonstrated that increased C/EBPβ expression dramatically reduces the growth of human breast cancer cell lines. The results from the present study suggest that pharmacological interventions aimed at activation of the p38 MAP kinase pathway may increase C/EBPβ mRNA stability and promote growth arrest and/or programmed cell death of breast cancer cells.

1434 Inhibition of ATR Protein Kinase Activity by Schisandrin B during DNA Damage Response

H. Nishida, 1 N. Tatewaki, 1 T. Magara, 1 Y. Nakajima, 1 K. M. Ko, 1 Y. Hamamori, 1 T. Konishi, 1 Applied Life Sciences, Niigata University of Pharmacy and Applied Life Sciences, Niigata, Japan; 2Biochemistry, Hong Kong University of Science and Technology, Hong Kong, China, 3Cardiology, Baylor College of Medicine, Houston, TX

Inhibition of DNA damage checkpoint genes, such as ATR, reduces cell growth and interrupts cell cycle progression (J Biol Chem, 2003, 278: 35515-22). In addition, knockdown of ATR, caused growth arrest (Cancer Lettre, 2003, 202: 281-90). We previously reported that treatment of Schisandrin B (SchB) significantly reduced the A549 adenocarcinoma cell viability after UV exposure. Of importance, SchB treatment also disrupts G2/M checkpoint in the UV-exposed cells. In vitro immunoprecipitation protein kinase activity assay of ATR was clearly decreased by increased concentration of SchB. Consistent with potential inhibition of ATR by SchB, UV-induced phosphorylations of ATR effectors such as p53 and Chk1 are remarkably reduced by SchB in ATM-deficient cells (AT patient derived AT2KY cells and siATM treated cells) but not in siATR-treated cells. SchB does not affect an activity of another protein kinase, ERK (p44/p42). Taken together these findings suggest that SchB specifically inhibits ATR protein kinase in cells following DNA damage.

1435 Arsenic-induced p53-DNA Binding and Activity in Epithelial Cells

M. Sandrowal, 1 M. Morales, 1 A. OrtegA, 1 P. Ostrosky-Wegman, 1 E. López-Bayghen 1; 1Genética y Biología Molecular, Cinvestav, Mexico DF, Mexico, 2Genética y Toxicología Ambiental, Instituto de Biología, UNAM, Mexico DF, Mexico

Exposure to arsenic is associated with an increased incidence of skin pathologies as hyperkeratosis and cancer. Arsenic effects include genotoxicity, cell-proliferation changes, alterations in DNA repair and methylation patterns. Proliferation and differentiation coordinated expression of structural and regulatory proteins, is probably lost in arsenic-associated-skin pathologies. We evaluated whether the changes in epithelial cells including human keratinocytes after arsenic exposure, are mediated through modifications in the activity of the tumor suppressor p53, a potent mediator of responses against genotoxic damage, and a pivotal proliferator-control. We tested if arsenic modulates the abilities of p53 as a transcription factor in epithelial cells treated with increasing concentrations of sodium arsenite for up to 24h, using a p53-consensus sequence in EMSAs. A time and dose-dependent response in p53-DNA binding occurs under arsenic exposure. We test if changes in the proliferation and differentiation process during arsenic exposure can be mediated by modifications in the expression levels of p53 and human involucrin, an important differentiation marker in cornified envelope of terminally differentiated keratinocytes. Significantly, using concentrations higher than 0.5μM, we noticed a decrease in proliferation and increased levels of involucrin in keratinocytes, supporting the idea that arsenic activates p53 (C33-A). An increase in proliferation, in cells under treatment is accompanied by an increase in cyclin D1 promoter activity. Signaling events include PI3 kinase and Protein Kinase B activation for an activated p53 pathway, favouring the notion that p53-controlled transcriptional mechanisms are important to understand modifications in the proliferation-differentiation balance severely impaired during skin carcinogenesis.
1436 Tobacco Carcinogens Stimulate Different Signal Pathways in Breast Cancer M. W. Hance,1 M. S. Dhar,1 H. K. Plummer; 1Pathobiology, University of Tennessee, Knoxville, TN, 2Pathobiology and Large Animal, University of Tennessee, Knoxville, TN

Breast cancer is a leading cause of new cancers in women, and smoking is a controversial risk factor. However, the tobacco-specific metabolite (3-aminomethyl-3-pyridyl)-1-butanone (NNK) has been identified as a high affinity agonist for β-adrenergic receptors. Our previous data suggests a joint role of G-protein inwardly rectifying potassium channel 1 channels and β-adrenergic signaling in the growth regulation of some breast cancers. In addition, polyacrylic polyacrylic hydrocarbons (PAH) from cigarette smoke and other sources induce breast cancer. In the present studies, we investigated the effects of the PAH 7,12-dimethylbenz[a]anthracene (DMBA) and NNK on β-adrenergic signaling using the estrogen receptor (ER) [ER+] cell line MDA-MB-453 and the ER (-) cell line MDA-MB-361. DMBA decreased β-adrenergic protein levels, but neither 10 nM nor 100 nM NNK increased β-adrenergic levels in MDA-MB-453 cells. However, in the MDA-MB-361 cells, DMBA increased β-adrenergic protein expression, and neither 10 nM nor 100 nM NNK had effects on β-adrenergic expression. We then studied the cAMP-PKA-CREB signaling pathway since binding of agonists to β-adrenergic receptors may activate this pathway. Treatment of the MDA-MB-361 cell line with 100 nM or 10 nM NNK or 5 μM DMBA did not lead to PKA phosphorylation at times ranging from 5 minutes to 2 hours. In addition, DMBA decreased cAMP levels while the β-adrenergic agonist formoterol stimulated cAMP production indicating that DMBA affects stimulation of cAMP differently than β-adrenergic stimulation. However in the MDA-MB-453 cell line, both 100 nM and 10 μM NNK treatment led to PKA phosphorylation at all time periods. DMBA had no effect on PKA phosphorylation in MDA-MB-453 cells. This collective data indicates that DMBA and NNK have different effects on the β-adrenergic signaling pathway, including different effects based on ER expression. Supported by Philip Morris USA Inc./Philip Morris International and University of Tennessee Center of Excellence.

1437 The Effects of Insulin on Serum Deprivation-induced Cell Death of SK-N-BE(2) Cells That Cannot Produce Insulin-induced ROS C. Yeo, J. Lim, J. Kim, K. Hur; Department of Life Sciences, Ewha Womans University, Seoul, Republic of Korea

Insulin can suppress serum deprivation-induced cell death in most cell lines. However, upon insulin stimulation, serum deprivation-induced cell death is accelerated in SK-N-BE(2) neuroblastoma cells while it is suppressed in SK-N SH neuroblastoma cells. Moreover, SK-N-BE(2) cells are more resistant to serum deprivation compared to SK-N-SH cells. SK-N-BE(2) cells cannot produce reactive oxygen species (ROS) in response to insulin while SK-N-SH cells can. We examined the time course of Akt activation, in order to address the molecular mechanisms for opposing oxygen species in these cells. In SK-N-SH cells, Akt activation occurred up to 48 hrs only in the presence of insulin. In SK-N-BE(2) cells, Akt activation was gradually increased up to 48 hrs upon serum deprivation even in the absence of insulin. Moreover, the levels of active Akt was lower in the presence of insulin than in the absence of insulin in SK-N-BE(2) cells. Similarly, the production of ROS was gradually increased upon serum deprivation and the increase of ROS production was suppressed by insulin. The resistance of SK-N-BE(2) cells to serum deprivation-induced cell death was abolished when cells were treated with N-acetylcysteine. These results suggest that the increase of ROS levels in SK-N-BE(2) cells in serum-free condition is a major reason for the abnormal response to insulin.

1438 Microarray Analysis of Diabetic Rat Wounds Treated with Either V.A.C.® Therapy or Moist Wound Healing K. Derrick, A. McNulty, K. Norbury, K. Kieswetter; KCI, Inc., San Antonio, TX

Vacuum Assisted Closure® Therapy (V.A.C.® Therapy) is extensively used to treat both acute and chronic wounds. Use of this therapy is widely known to help promote wound healing. Whole-genome studies were designed to gain insight into the biological processes which V.A.C.® Therapy may affect. Three cm wounds were made dorsally on 8 diabetic rats (one wound per animal). Wounds were treated with either V.A.C.® Therapy (125mm Hg, continuous negative pressure) using V.A.C.® Gammagraf® Dressing or with Tegaderm™. After 2 days of treatment, wound tissue was harvested. The Applied Biosystems microarray platform was used to assess gene expression for all 16 pieces of tissue (8 normal from wound creation, 8 wound from day 2). A total of 8,445 unique genes (p<0.05) experienced fold changes in gene expression between day 0 and day 2 post wounding in the 2 treatment groups. This was divided into 7,359 genes changed in V.A.C.® Therapy treated tissue vs. 4,563 genes changed in Tegaderm™ treated tissue. After differential analyses, data were entered into the PANTHER classification system (www.pantherdb.org) to assess biological processes which were differentially affected by V.A.C.® Therapy. For V.A.C.® Therapy treated tissue, significantly more signal transduction related genes were expressed than expected (p=1.85x10^-10). Significantly more genes related to intracellular signaling were also differentially expressed during the two days of therapy (p=2.74x10^-7). Cell motility related genes were also overexpressed in V.A.C.® Therapy treated animals (p=1.77x10^-14). These data show that, in studied rats, V.A.C.® Therapy influenced specific biological processes during wound healing, which may account for some of the benefits of this therapy.

1439 Helicobacter pylori VacA Enhances PGE2 Production through the Induction of COX-2 Expression via p38 MAP Kinase/ATF-2 Cascade in AZ-521 Cells T. Hirayama,1 J. Hisatsune,1 E. Yamasaki,1 A. Wada,1 K. Yahiro,2 J. Moss2; 1Dept. of Bacteriology, Nagasaki University, Nagasaki, Japan, 2Pccm, nhlbi, National Institutes of Health, Bethesda, MD

Helicobacter pylori produces a vacuolating exotoxin, VacA, which causes vacuolation and gastric injury. We investigated whether VacA affected cyclooxygenase-2 (COX-2) expression in AZ-521 cultured gastric epithelial cells, resulting in the production of prostanooids from arachidonic acid. Treatment of AZ-521 cells with VacA increased amounts of COX-2 mRNA in time- and dose-dependent process. Inhibitor of p38 MAP kinase, SB203580, almost completely blocked the elevation of COX-2 mRNA levels, whereas an MKK inhibitor, PD98059, which is known to block the Erk1/2 signal cascade partially suppressed it. VacA-induced accumulation of COX-2 mRNA was reduced in AZ-521 cells overexpressing a dominant-negative p38 MAP kinase construct, suggesting that VacA increased COX-2 expression in AZ-521 cells through a signaling pathway that included p38 MAP kinase. In agreement, PI-PLC, which inhibited VacA-induced p38 MAP kinase activation, blocked VacA-induced COX-2 expression, whereas two inhibitors (NPPB and bafilomycin A1) of VacA-induced vacuolation, had no effect on p38 MAP kinase activation and COX-2 expression in AZ-521 cells, suggesting that P3MAP kinase activation was independent of the vacuolating activity of VacA. In parallel with COX-2 expression, VacA increased PGE2 production by AZ-521 cells, which was remarkably inhibited by SB203580 as well as NS-398, a COX-2 inhibitor. In addition, VacA-induced PGE2 production was markedly attenuated in AZ-521 cells stably expressing dominant-negative p38 MAP kinase. VacA increased COX-2 transcription by more than 2.5-fold in AZ-521 cells transfected with WTCOX-2(-327/+59) promoter, whereas VacA had no activation effect in AZ-521 cells transfected with a mutated CRE site, but not with mutated NFκB or NF-IL6 sites, suggesting direct involvement of the ATF-2/CREB-binding region in VacA-induced COX-2 promoter activation. These results show that VacA enhances PGE2 production in AZ-521 cells through the induction of COX-2 expression via the p38 MAP kinase/ATF-2 cascade.

1440 Photomechanical and Biochemical Characterization of LOV2 Mutant Domains of Arabidopsis thaliana H. Kim,1 E. Baik,1 K. Im,1 S. Choi,1 Y. Yoo,1 I. Han; 3; 1Korea Science Academy, Busan, Republic of Korea, 2IRC, University of Ulsan, Ulsan, Republic of Korea, 3Biological Science, University of Ulsan, Ulsan, Republic of Korea

The LOV domains are the photoreceptive modules of the phototropins and related chroomoproteins. LOV domain fusion proteins purified from E. coli are highly fluorescent and undergo a formation of a helical adduct between the FMN chromophore and a conserved active-site Cys residue. However, the molecular and structural basis of LOV domains regulate the activity of phototropin is not well understood. In order to investigate photomechanical activity of LOV domain, we have used three mutant oat LOV2 domains (C39A/K77E, C39A/V67A, and C39A/T53P) obtained from LOVC39A, of which fluorescence and absorption properties are very similar to those of wild type LOV domain, by using PCR-driven random mutagenesis method. Amino acid substitution of Trp 53 with proline had deleterious effect on fluorescent activity of LOV domain. Compared to C39A, C39A/V67A exhibited only two-thirds of fluorescent activity, whereas two inhibitors (NPPB and bafilomycin A1) of VacA-induced vacuolation, had no effect on p38 MAP kinase activation and COX-2 expression in AZ-521 cells, suggesting that P3MAP kinase activation was independent of the vacuolating activity of VacA. In parallel with COX-2 expression, VacA increased PGE2 production by AZ-521 cells, which was remarkably inhibited by SB203580 as well as NS-398, a COX-2 inhibitor. In addition, VacA-induced PGE2 production was markedly attenuated in AZ-521 cells stably expressing dominant-negative p38 MAP kinase. VacA increased COX-2 transcription by more than 2.5-fold in AZ-521 cells transfected with WT COX-2(-327/+59) promoter, whereas VacA had no activation effect in AZ-521 cells transfected with a mutated CRE site, but not with mutated NFκB or NF-IL6 sites, suggesting direct involvement of the ATF-2/CREB-binding region in VacA-induced COX-2 promoter activation. These results show that VacA enhances PGE2 production in AZ-521 cells through the induction of COX-2 expression via the p38 MAP kinase/ATF-2 cascade.

1441 Regulation of Arabidopsis thaliana Ku Gene Expression by Abscisic Acid P. Liu, W. Chang, Y. Wang, R. Pan; Life Science, National Tsing Hua University, Hsinchu, Taiwan

Ku antigen (Ku70/Ku80) is a regulatory subunit of DNA-dependent protein kinase (DNA-PK), which participates in the regulation of DNA replication, cell cycle and telomere maintenance. The plant hormone abscisic acid (ABA) plays a central role in stress responses and is described as a plant growth inhibitor. In this study, we aimed to find out whether Arabidopsis thaliana Ku
genes (At.Ku) were regulated during ABA inducing slow growth in 3-week-old seedlings. Firstly, some ABA responsive elements of At.Ku promoters are predicted from PlantCARE (http://www.plantcare.com/) and PLACE (http://www.dna.nic.go.in/PLACE/) websites and At.Ku promoter-GUS (β-Glucuronidase) analysis in transgenic Arabidopsis indicated that activity of At.Ku promoter was inhibited by ABA. In addition, real time quantitative PCR analysis showed their repression in a time-and concentration-dependent manner. Moreover, ABA-mediated inhibition of At.Ku gene expression was confirmed by inhibitor treatment and mutant analysis of ABA biosynthesis. Furthermore, At.Ku gene repression under ABA responses may be regulated through the pathway of Ca²⁺/phospholipase D alpha (PLDα) mitogen-activated protein kinase (MAPK) and some transcription factors, abf1 and abf2. Finally, our results revealed an interaction between ABA, auxins and GA for modulating At.Ku gene expression. Taken together, these results demonstrated that At.Ku gene is presumably regulated by ABA.

Identification of a New Gene Required for Cell Wall Separation in Corynebacterium glutamicum

Y. Tagne, M. Imi, H. Yakuwa; Research Institute of Innovative Technology for the Earth, Kyoto, Japan, Nara Institute of Science and Technology, Nara, Japan

Corynebacterium glutamicum is a gram-positive bacterium extensively used in industrial amino acid production. This bacterium exhibits a unique cell division system called snapping division, completely different from model microorganism like Escherichia coli or Bacillus subtilis. However, the detailed mechanism of this division system is mostly unknown. Elucidation of the cell division mechanism of this bacterium may contribute to higher amino acids productivity, given that C. glutamicum secretes bulk of its amino acids when cell division is arrested. Of 2990 genes of C. glutamicum, we focused on cws1. This gene consists of deduced 610 amino acid residues with a 50-residue signal peptide. Insertional inactivation of cws1 resulted in a 3-fold elongation of the cell compared to the wild type. Multiple lines were observed on the cell under light microscopy. Complementation of the G2/M checkpoint proteins cyclin B and cdk1 was not decreased if nuclear Ca²⁺ was buffered, but the mitotic index was increased by 47% in these cells, and virtually all mitotic cells were in early prophase and failed to undergo centrosome duplication. Knockdown of the Ca²⁺-binding protein centrin-2 had a similar effect; BrdU uptake was decreased by 75% in these cells, there was a 48% increase in mitotic index, and nearly all mitotic cells were in early prophase and failed to undergo centrosome duplication. These findings show that cell growth is regulated by nuclear rather than cytosolic Ca²⁺ signals and suggest that the specific role of nuclear Ca²⁺ is to permit progression through early prophase, by centriole-mediated centrosome duplication.

Mechanisms Underlying the P35-mediated Prevention of Adriamycin-induced Apoptosis and Polyploidy/Multinucleation

Y. Lin, F. Wang; The Institute of Biochemistry and Molecular Biology, National Yang-Ming University, Taipei, Taiwan

The p53 tumor suppressor executes its function either by maintaining the cell survival through arresting cell cycle progression for DNA damage repair or eliciting apoptosis, and has long been regarded as a key therapeutic target for cancer treatment. Adriamycin is a topoisomerase II inhibitor widely used in the treatment of a variety of cancers. To explore the cytoprotective function of p35 on adriamycin treated cells, we established clones of H1299 cells stably expressing the temperature-sensitive p53 mutant, tsp53V143A, previously shown to activate the genes related to the p53 tumor-suppressor pathway. Adriamycin leads to the down-regulation of p21 Waf1/Cip1 after p53 activation, while the role of p21 Waf1/Cip1 in mediating the cytoprotective function of p53 was not known. We found that p21 Waf1/Cip1 is required for suppression of the adriamycin-induced polyploidy/multinucleation. Together our findings suggest that the cytoprotective action of p53 against adriamycin induced cell death requires the expression of p21 Waf1/Cip1 in vitro, indicating the importance of this gene in p53-mediated cancer chemotherapy.

Investigation of the Role of Conserved H59 and H157 for the Functionality of Pin1

M. L. Bailey, C. J. Brandl, D. W. Litchfield, B. H. Shilton; Biochemistry, University of Western Ontario, London, ON, Canada

Pin1 catalyzes the cis to trans isomerization of peptide-polyglycine bonds preceded by a phosphorylated serine or threonine residue, and has emerged as an important regulator of cell division. Pin1 consists of two domains: a WW domain that binds phosphorylated proteins and an isomerase (PPIase) domain; however, the precise catalytic mechanism and how isomerase activity relates to the catalytic mechanism is unknown. is a conserved histidine residues (H59 and H157) found in the Pin1 active site that were initially proposed to play critical roles in the catalytic mechanism. Interestingly, mutation of H59GQG still yielded a functional protein in yeast complementation assay. Similarly, substitution of the nearby H157GQG produced a functional protein. However, it was most surprising to find that a non-functional H595L mutant of Pin1 could be rescued by substitution of H157 with L. To examine this finding further, both H59 and H157 were mutated to multiple amino acids to determine their role in the mechanism of Pin1. This work provides evidence that H59 and H157 are not as critical to Pin1 catalysis as originally suggested and that the current catalytic mechanism for this protein may need to be refined.

Down-regulation of γ-tubulin Inhibits Cell Proliferation and Induces Apoptosis in Human Breast and Prostate Cancer Cells

A. Banerjee, R. F. Ludueña; Department of Biochemistry, The University of Texas Health Science Center, San Antonio, TX

γ-tubulin is a member of the tubulin superfamily and plays a very important role in the mechanism of mitotic spindles. Although the major function of γ-tubulin is to nucleate mitotic spindles, recent studies have implicated its role in the regulation of cell cycle. In human system, γ-tubulin isoforms, namely γ1 and γ2 tubulin, are expressed. We have studied the expression of these two isoforms in MCF-7 breast cancer cells by RT-PCR. We find that γ1 is the major isoform while γ2 is expressed in trace amounts in MCF-7 cells. In an effort to study whether targeted depletion of γ-tubulin may affect cell growth, antisense phosphorothioate oligodeoxycytidine nucleotides (ODNs) targeted to human γ1 and γ2 tubulin mRNA were prepared. Transfection of human breast and prostate cancer cells showed that both antisense ODNs inhibited cell growth in a dose-dependent manner. Western analysis of the cell extracts from antisense-transfected cells showed significant reduction in the level of γ-tubulin, while the same treatment with scrambled ODN had no effect. TUNEL staining of cells indicated that antisense-transfected cells underwent significant apoptosis as compared to the untreated cells. Supported by a DOD BCRP grant DAMD17-98-1-8244 to AB, the Welch Foundation grant AQ-0726 and a DOD BCRP grant W81XWH-05-1-0238 to RFL.
Tetraploidy and Cell Cycle Progression Revised
A. M. Kryzwicz-Racka, G. Sluder; Cell Biology, University of Massachusetts Medical School, Worcester, MA
Cleavage failure is believed to be dangerous to the organism because the meiotic and mitotic divisions are coupled. Normal human cells do not have a tetraploidy checkpoint (Uetake and Sluder, J. Cell Biol. 2004;165(5):609–15), which characterizes the long term practical consequences of cytokinesis D induced cleavage failure in RPE1 cells expressing GFP centrin 1 to tag the centrosomes. Lineage analysis from time lapse records reveals that 60% of binucleate cells progress through the first interphase to mitosis, and approximately 70% assemble bipolar spindles due to centrosome bundling. Even though diploid control cells in the same preparations continue proliferating, more and more of the progeny of tetraploid cells arrest in interphase at each cell cycle. None divide a fourth time even when all mitoses were bipolar. To gain insight into this phenomenon, we induce cleavage failure and 60-180 min. after exit from mitosis, we microscopically cut each tetraploid cell between the nuclei to produce two mononucleate cells. Since the centrosomes often cluster between the nuclei, we produce cells that have 0, 1, or two centrosomes at G1. We find more than 50% such mononucleate cells continue to proliferate for at least 4-7 cell cycles (depending on movie duration and confluence). Also, tetraploid cells generated by the fusion between a G1 cell from which the centrosome was removed and a control G1 cell never divided more than twice. These results indicate that the eventual arrest of tetraploid cells is due to the extra genomic content, not to cell size or inappropriate centrosome number. Thus, cleavage failure per se is not sufficient to produce a proliferating population of genomically unstable cells at risk for transformation.

Plk Interacts with Cdc14A and Is Essential for Orchestrating Faithful Chromosome Segregation
K. Yuan,1 H. Hu,2 R. Hsu,2 G. Fu,2 B. Liu,1 Z. Zhu,1 X. Yao,2 Hefei National Laboratory, Hefei, China, 2Fudan University School of Medicine, Shanghai, China, 3Shanghai Second Medical University, Shanghai, China
Chromosome segregation in mitosis is orchestrated by protein kinase and phosphatase signaling cascades. Previous studies showed that overexpression of human phosphatase Cdc14A, an antagonist of CDK1, affects several aspects of cell division. However, the molecular mechanism underlying this regulation has remained elusive. To identify the proteins that participate in Cdc14A signaling in mitosis, we carried out proteomic search for mitotic proteins associated with Cdc14A. To this end, mitotic extracts from HeLa cells stably expressing FLAG-Cdc14A were purified using a FLAG antibody-affinity chromatography. The proteins selectively bound to Cdc14A were removed from the gel and analyzed by LC-MS/MS. Of several known proteins selectively bound to Cdc14A, the presence of a polo-like protein (PLK) was novel and particularly exciting. Polo-like kinases are key regulators of mitosis, regulating many aspects of the cell cycle, including mitotic entry, chromosome segregation, mitotic exit, and cytokinesis. Interestingly, this PLK interacts with and phosphorylates Cdc14A. Our mass spectrometric analysis of Cdc14A revealed that Cdc14A is phosphorylated by the PLK in vitro and in vivo. To examine the functional relevance of such phospho-regulation of Cdc14A, phospho-mimicking mutant of Cdc14A was expressed in HeLa cells. Importantly, overexpression of the phospho-mimicking and non-phosphorylatable mutants caused aberrant chromosome alignment with a prometaphase delay and aberrant chromosome segregation into daughter cells, suggesting the temporal regulation of Cdc14A phosphorylation and activity is critical for orchestrating mitotic events. Currently, we are employing biosensor to monitor the spatio-temporal profile of Cdc14A activation and illustrate how the kinase-phosphatase interplay orchestrates mitotic exit.

Microcephalin (MCPH1) Is Required for Cell-Cycle Progression in the Early Drosophila Embryo
J. L. Rickmyre, A. Y. Frist, L. A. Lee; Cell and Developmental Biology, Vanderbilt University Medical Center, Nashville, TN
Mutations in human MCPH1 result in a form of autosomal recessive primary microcephaly, a disorder of fetal brain growth characterized by a severely reduced cerebral cortex and head size with mental retardation. Both human and Drosophila MCPH1 contain BRCA1 C-terminal domains (BRCT domains), which are found in many proteins that function in DNA repair and cell cycle control. To date, no animal models for primary microcephaly due to mutations in MCPH1 have been reported. We have identified maternal-effect lethal mutations in the Drosophila homolog of human MCPH1. Early Drosophila embryogenesis consists of rapid S-M cell cycles driven by stockpiles of maternal RNA that occur without gaps or cytokinesis. These streamlined cycles as well as the genetic tractability of Drosophila offer ideal conditions in which to study cell-cycle regulation during development. Embryos from mutant MCPH1 females undergo mitotic arrest in the early syncytial divisions and contain short, rounded spindles that lack centrosomes. We have genetically determined that this is a secondary effect due to triggering of the centrosome inactivation pathway, a Checkpoint kinase 2 (Chk2)-mediated response following DNA damage or incomplete DNA replication in early Drosophila embryos. Current efforts are directed towards elucidation of the mechanism by which mutation of MCPH1 leads to Chk2 activation as well as placement of MCPH1 within a molecular framework.

An RNAi Screen for Genes That Are Synthetically Lethal with san-l(ok1580)
T. Yamamoto, R. Kitagawa; Molecular Pharmacology, St. Jude Children’s Research Hospital, Memphis, TN
Chromosome segregation in mitosis is orchestrated by protein kinase and phosphatase signaling cascades. Previous studies showed that overexpression of human phosphatase Cdc14A, an antagonist of CDK1, affects several aspects of cell division. However, the molecular mechanism underlying this regulation has remained elusive. To identify the proteins that participate in Cdc14A signaling in mitosis, we carried out proteomic search for mitotic proteins associated with Cdc14A. To this end, mitotic extracts from HeLa cells stably expressing FLAG-Cdc14A were purified using a FLAG antibody-affinity chromatography. The proteins selectively bound to Cdc14A were removed from the gel and analyzed by LC-MS/MS. Of several known proteins selectively bound to Cdc14A, the presence of a polo-like protein (PLK) was novel and particularly exciting. Polo-like kinases are key regulators of mitosis, regulating many aspects of the cell cycle, including mitotic entry, chromosome segregation, mitotic exit, and cytokinesis. Interestingly, this PLK interacts with and phosphorylates Cdc14A. Our mass spectrometric analysis of Cdc14A revealed that Cdc14A is phosphorylated by the PLK in vitro and in vivo. To examine the functional relevance of such phospho-regulation of Cdc14A, phospho-mimicking mutant of Cdc14A was expressed in HeLa cells. Currently, we are employing biosensor to monitor the spatio-temporal profile of Cdc14A activation and illustrate how the kinase-phosphatase interplay orchestrates mitotic exit.

Cell Cycle Dependent Changes in Mitochondrial Morphology
K. Mitra, J. Lippincott-Schwartz; NICHD, NIH, Bethesda, MD
Mitochondria are highly dynamic in morphology, but little is known about the significance of this dynamic nature. Here, we investigate whether mitochondrial dynamics is linked to changes in energy production during the cell cycle. Using live cell imaging approaches employing GFP-tagged mitochondrial marker, we found that mitochondrial morphology is highly regulated during the cell cycle. Cells arrested at the G1/S boundary had very long mitochondria that formed a network with a single continuous matrix based on Fluorescence Recovery After Photobleaching (FRAP) results. Time-lapse imaging of mitochondria and an S-phase-specific marker, PCNA, revealed that the network formed specifically at late G1 and persisted through early S phase, gradually breaking apart as the cell progressed through later stages of S phase. Interestingly, this PLK interacts with and phosphorylates Cdc14A. Our mass spectrometric analysis of Cdc14A revealed that Cdc14A is phosphorylated by the PLK in vitro and in vivo. To examine the functional relevance of such phospho-regulation of Cdc14A, phospho-mimicking mutant of Cdc14A was expressed in HeLa cells. Importantly, overexpression of the phospho-mimicking and non-phosphorylatable mutants caused aberrant chromosome alignment with a prometaphase delay and aberrant chromosome segregation into daughter cells, suggesting the temporal regulation of Cdc14A phosphorylation and activity is critical for orchestrating mitotic events. Currently, we are employing biosensor to monitor the spatio-temporal profile of Cdc14A activation and illustrate how the kinase-phosphatase interplay orchestrates mitotic exit.

The Role of Yeast NDR Kinase Chkl in Polarized Morphogenesis
C. Kuriscik,1 P. Nazarov,1 C. Zhang,2 K. M. Shokat,2 F. C. Luca; 1Department of Animal Biology, University of Pennsylvania, Philadelphia, PA, 2Department of Cellular and Molecular Pharmacology, University of California, San Francisco, San Francisco, CA
Mitochondria are highly dynamic in morphology, but little is known about the significance of this dynamic nature. Here, we investigate whether mitochondrial dynamics is linked to changes in energy production during the cell cycle. Using live cell imaging approaches employing GFP-tagged mitochondrial marker, we found that mitochondrial morphology is highly regulated during the cell cycle. Cells arrested at the G1/S boundary had very long mitochondria that formed a network with a single continuous matrix based on Fluorescence Recovery After Photobleaching (FRAP) results. Time-lapse imaging of mitochondria and an S-phase-specific marker, PCNA, revealed that the network formed specifically at late G1 and persisted through early S phase, gradually breaking apart as the cell progressed through later stages of S phase. Currently, we are employing biosensor to monitor the spatio-temporal profile of Cdc14A activation and illustrate how the kinase-phosphatase interplay orchestrates mitotic exit.
During cell, tissue and organ development, conserved signaling networks coordinate multiple processes associated with cell growth and proliferation. The NDR protein kinase family was implicated in regulating cellular morphogenesis, maintenance of cell integrity and cell cycle progression in a variety of cell types, however the molecular functions of NDR kinases are unknown. We previously established that the Saccharomyces cerevisiae NDR kinase Cbk1 functions in a conserved signaling network that is essential for maintaining cell integrity and controlling daughter specific gene expression (Weiss et al., 2002; Neill et al., 2002; Kurischko et al., 2005). To elucidate the essential role of Cbk1, we investigated the consequence of Cbk1 inhibition in synchronized cells. We found that Cbk1 kinase inhibition delayed bud emergence and growth. Cytological analyses revealed Cbk1 inhibition disrupted endocytosis and exocytosis but did not interfere with actin polarity establishment. Moreover, Cbk1 kinase inhibition triggered the Swi1-dependent cell cycle checkpoint, indicating that Cbk1 is important for coordinating polarized growth with cell cycle progression. Collectively, these data suggest that NDR kinases control cellular morphogenesis and development via regulating polarized secretion.

Rfp1 and Rfp2, RING Finger Proteins with a SUMO-Interacting Motif, Regulate Chromosome Segregation in Fission Yeast
H. Sun, Salk Institute for Biological Studies, La Jolla, CA
Small ubiquitin-like modifier (SUMO) is conjugated to target proteins through a pathway similar to ubiquitylation. Most SUMOylation targets function in nucleus. The mechanism through which SUMOylation regulates cellular processes may lie in the interaction between SUMO-binding proteins and the SUMOylated targets. We have identified two proteins in Schizosaccharomyces pombe, named Rfp1 and Rfp2, each with an N-terminal SUMO-interacting motif (SIM) and a C-terminal RING domain. Consistent with their similarity in amino acid sequence, rfp1 and rfp2 compensate for each other genetically. Together they are essential for cell growth. Spores with both rfp1 and rfp2 genes missing survive for only a limited number of cell divisions and fail to grow into visible colonies. Viable strains of double null mutant cells show slow growth, elongated cell bodies, and aberrant nuclear segregation. The growth defect of double mutant cells can be rescued by expression of either wild-type Rfp1 or Rfp2, but not their SIM or RING domain mutants. Rnf4, a mammalian protein with significant sequence similarity to Rfp1 and Rfp2, appears to be their functional homologue, as it also rescues the rfp1/rfp2 double null phenotype. Nevertheless, while Rnf4 can act as a ubiquitin E3 ligase, presumably through its RING domain, we did not detect any ubiquitin or SUMO ligase activity with Rfp1 or Rfp2. When fluorescent protein-tagged forms are expressed under a mid-strength nmt promoter, both Rfp1 and Rfp2 appear as multiple nuclear spots. However, an Rfp2 mutant without SUMO-interacting motif, but not the comparable Rfp1 mutant, appears as only a single nuclear spot that is positioned next to a nucleus marker. We conclude that Rfp1 and Rfp2 as SUMO-interacting proteins may be involved in regulating chromosome segregation and progression through mitosis.

Role of MicroRNAs in Drosophila Germ Line Stem Cells That Can Induce Their Own Niche
H. T. Ruohola-Baker, E. Ward, H. Scherberbata, S. Reynolds, S. Hatfield, J. Yu, K. Fischer; Biochemistry, University of Washington, Seattle, WA
A critical question in stem cell biology is how stem cell division is controlled; too little disturbs tissue homeostasis, too much can result in cancer. We have shown the necessity of microRNA pathway for germ line stem cell (GSC) function. Analysis for GSCs mutant for dicer-1 (dcr-1), the dRNAseII essential for miRNA biogenesis, revealed a dramatic reduction in the rate of germ line cyt production. Based on cell cycle markers and genetic interactions, we conclude that dcr-1 GSCs are delayed in the CDK-inhibitor p21/p27/Dacapo-dependent G1 to S transition. We show that GFP from Dacapo3’UTR-sensor construct is up-regulated in dcr-1 mutant GSCs that lack functional microRNAs, revealing that Dacapo 3’UTR is responsive to functional miRNAs. Work is in progress to identify the microRNAs critical for stem cell division. Stem cells are maintained and retain their capacity to continue dividing due to the influence of a microenvironment, termed a niche. Niche is important to maintain ‘stemness’ in a wide variety of tissues, the mechanism by which niches are maintained is unknown. We show that Notch activation can induce the expression of niche cell markers even in an adult fly. Delta over-expression in the germ line, or expression of cNotch in the somatic cells, results in extra somatic cells expressing niche cell markers. In turn, these ectopic niche cells induce ectopic GSCs, a sign of active niche. Conversely, when GSCs do not produce functional Delta and Serrate ligands, the TGF-beta pathway is not activated in the GSCs, the GSCs differentiate and the niche is lost. Importantly, Notch activity is not required in GSCs but in the somatic cells. These data show that a feedback loop exists between the stem cells and niche cells and may provide insight into how cancer can spread throughout an organism via populations of cancer stem cells.

Cytokines Maintain Lymphocyte Homeostasis through the Activity of Cdc25A
C. Kittaparin, 1 W. Li, 1 S. Durum, 1 A. R. Khaleed, 1 Biomolecular Science Center, University of Central Florida, Orlando, FL, 2National Cancer Institute, NIH, Frederick, MD
Homeostasis of the peripheral immune system is maintained through signals transduced by cytokines like interleukin-7 (IL-7). In the absence of IL-7 cells undergo apoptosis, while excess IL-7 leads to proliferation. However, the mechanisms by which IL-7 regulates these life and death processes are poorly understood. We observed that expressing an anti-apoptotic protein, such as BCL-2 or inhibiting a pro-apoptotic protein, such as BAX, protected cells from death but did not support growth, suggesting the existence of previously unrecognized IL-7 dependent proliferative factors. To identify these factors, we examined cell cycling in cytokine-dependent lymphocytes and found that the G1-to-S phase progression was not solely dependent on the synthesis of cyclin-dependent kinases (cdks) and cyclins or the inactivation of inhibitors. Rather it was the removal of inhibitory phosphorylations on cdks by the phosphatase, Cdc25A, that primarily transduced cytokine-mediated growth signals. We determined that cytokine deprivation led to cell cycle arrest by inducing the activity of the stress kinase, p38 MAP kinase (MAPK), which in turn phosphorylated and destabilized Cdc25A. As a result, the substrates of Cdc25A, phosphorylated cdks, remained inactive, retinoblastoma (Rb) protein was hypophosphorylated, and cells arrested prior to induction of apoptosis. Inhibiting p38 MAPK or expressing a mutant Cdc25A, in which two p38 MAPK target sites, Ser75 and Ser123, were substituted for alanines, rendered cells resistant to cytokine withdrawal, driving the cell cycle independent of a cytokine growth stimulus. Cells expressing the Cdc25A mutant, in the absence of cytokines, actively synthesized DNA, expressed hyperphosphorylated Rb protein, maintained glucose uptake and did not undergo apoptosis, even in the presence of elevated levels of the inhibitor, p27kip. Cdc25A is thus a novel transducer of cytokine-mediated growth signals and regulation of its activity through phosphorylation by p38 MAPK is a means by which cytokines, like IL-7, can control lymphocyte proliferation.

Linking Epidermal Proliferation and Differentiation: A Novel Phenomenon in Skin Homeostasis
L. Barnes, 1 2 J. Zanet, 1 M. Dumas, 1 A. Gandarillas, 2 LVMH Recherche, Saint Jean de Braye, France, 3Laboratoire Dermatologie Moleculaire, Université Montpellier 1, Montpellier, France
Human epidermis is a frequent target of hyperproliferative alterations and abnormal differentiation processes. However, the mechanisms that link cell growth and differentiation and maintain epidermal homeostasis are not understood. We have previously shown that primary differentiating keratinocytes continue DNA synthesis and become polyplloid in the absence of cell division (endoreplication). Cell growth, cell cycle, differentiation and genomic stability are thus dynamically linked. This phenomenon might have a physiological importance in keeping correct stem cell function and differentiation. We have now unravelled and studied this phenomenon in normal human epidermis in situ. To this aim, we have applied to human skin up-to-date techniques for the study of cell cycle regulation, DNA replication and genome amplification. All these investigations converge on the importance of endoreplication in normal human epidermis. This novel epidermal phenomenon may have a central role in co-ordinating proliferation with differentiation, thus maintaining skin homeostasis.

Establishment of Radiosensitive Non Small Cell Lung Cancer Cell Line and Expression Profiles of the Radiodifference-related Genes
Y. Lee, 1 M. Mollah, 1 B. Kim, 1 C. Kim, 1 Y. Seo, 1 J. Park, 1 M. Cho, 1 J. Lee, 1 Department of Dermatology, College of Medicine, Chungnam National University, Daejeon, Republic of Korea, 2Department of Radiation Oncology, College of Medicine, Chungnam National University, Daejeon, Republic of Korea
Non-small cell lung cancers commonly develop resistance to radiation and chemotherapy. To gain an insight into the molecular mechanism underlying radiosensitivity, we established radiosensitive cell line using a human non small cell lung cancer cell line H460. H460 cells were irradiated with X-rays by an accumulated dose of 40 Gy over 10 weeks. After this treatment, we got radiosensitive cells and named H460R. To assess the susceptibility to radiation, we compared the several characteristics of H460 and H460R cells. These include morphological features, clonogenic ability, radiosensitivity, and cell growth kinetics. We then performed DNA microarray to examine the differences in gene expression profiles between mother and radiosensitive cells. In radiosensitivity test, H460R cells showed marked increase in radiosensitivity as compared with H460 cells. In addition, H460R cells also showed resistance to UVB and camptothecin (CPT), suggesting that these cells acquired resistance against broad range of external death stimuli. The radiosensitivity of H460R cells were repeatedly confirmed by clonogenic assay and FACS analysis. Primary cell culture, cell cycle, apoptosis, DNA repair, cell communication, cell death regulation and development. Our results suggest that many of biological characteristics were affected during the process of establishing radiosensitivity, and provide important clues for the future investigations on molecular events underlying radiation response.
1458 Blm-s, a Novel Proapoptotic Molecule, Induces Apoptosis in a Bax-dependent Manner

W. Liu, H. Huang* (equal contribution), S. Chen, S. Hou, P. Huang; Graduate Institute of Pathology, College of Medicine, National Taiwan University, Taipei, Taiwan. Department of Pathology, School of Medicine, National Taiwan University Hospital, Taipei, Taiwan. Molecules mediating neuronal apoptosis during embryonic development have long been research focus. In this study, we report a novel Bcl-2 family member enriched in mouse embryonic nervous system, Blm-s (Bcl-2-like molecule-gmnl transcript). Northern blotting reveals Blm-s expression is limited to a later developmental stage in mice, when CNS morphogenesis and physiological neuronal death occur. Blm-s contains three Bcl-2 homology (BH) domains and an ER membrane retention signal. In transfected cells, we demonstrated overexpression of Blm-s kills by apoptosis via a common mitochondrial pathway. Additionally, BH domains are required for Blm-s-mediated apoptosis. Blm-s interacts selectively with Bcl-2 and counteracts Bcl-2 antiapoptotic activity. Although not directly interacting with Bax, Blm-s induces apoptosis in a Bax-dependent manner. Furthermore, RNA in situ hybridization on γ-irradiation-treated E15.5 mice reveals such double strand break stress activates transcription of Blm-s. In summary, Blm-s is a novel Bax-dependent proapoptotic molecule and can be up-regulated after DNA damage.

1459 Rotkitamycin Induces Mitochondria Defect and Caspase-dependent Apoptosis

T. Shinomiya, M. Fukui, Y. Nagahara; 1Radioisotopes, National Research Institute of Child Health and Development, Tokyo, Japan, 2Biotecnology, Tokyo Denki University, Tokyo, Japan [Objective] Macrolides are a well-known family of antibiotics. We examined whether various macrolides induce any cytotoxic effects to human lymphoma cell lines (Jurkat and HL-60), and studied the effect of thirteen macrolides on the cell viabilities. After 40 hr incubation with 10μM or 40μM of macrolides, respectively, Rotkitamycin (RKM) exhibited strong cytotoxic effect by a MTT colorimetry assay. So we investigated whether the observed lymphoma cell death involved any particular apoptotic pathways, in further detail. [Methods and Results] RKM-treated Jurkat cells showed DNA ladders on agarose gel electrophoresis and sub-G1 DNA content cells on flow cytometric analysis. RKM-treated cells were detected in the activations of caspase 3 and 9 by the western blot analysis using anti-caspase 3 or anti-caspase 9 antibodies. Pre-treated with caspase inhibitor z-VAD-fmk, the DNA degradation and the caspases activation were blocked. DNA fragmentation and caspases activation estimated the progression of apoptosis. We went on to investigate mitochondrial membrane potentials in RKM-treated cells by the DiOC6(3) staining and flow cytometric analysis. RKM reduced the mitochondria membrane potential in the cells. Furthermore, mitochondria were prepared from Jurkat cells and incubated with none or 10μM RKM for 30 min at 37°C. Mixtures were incubated with 50 nM DiOC6(3) for 15 min then the membrane potential was analyzed by flow cytometry. Isolated mitochondria incubated with RKM resulted decreased mitochondrial membrane potentials. By the western blot analysis using anti-cytochrome c antibodies, the RKM-treatment revealed the concentrations of cytochrome c, decreased in mitochondria particles and increased in mitochondrial supernatants, respectively. [Conclusions] We concluded that RKM directly affected the mitochondria, decreased mitochondrial membrane potential, released cytochrome c from mitochondria into cytosol, activated caspase 9 and 3 and induced apoptosis in Jurkat and HL-60 cells.

1460 Scaffold Protein Intersectin-1s (ITSN-1s) Regulates Mitochondrial-dependent Apoptosis

S. A. Predescu, D. N. Predescu, I. Knezevic, A. B. Malik; Pharmacology, University of Illinois at Chicago, Chicago, IL. Intersectins (ITSNs) are multidomain adaptor proteins that have been implicated in endocytosis, regulation of actin polymerization, and Ras/ MAP kinase signaling. We have previously shown by in vitro biochemistry and protein overexpression studies that ITSN-1s expression is required for caveolea fission and internalization in cultured endothelial cells (ECs). In this study, using the RNAi approach to knock down ITSN-1s protein expression followed by morphological and biochemical analysis of ECs deficient in ITSN-1s, we demonstrate a novel role of ITSN-1s as an anti-apoptotic protein. Down-regulation of ITSN-1s expression in ECs by siRNA triggered the mitochondrial pathway of apoptosis as determined by specific morphological and biochemical changes such as genomic DNA fragmentation, extensive mitochondrial fission, blebbing of the mitochondrial membrane, widening of the narrow tubular cristae, swollen and unstacked Golgi apparatus and activation of the pro-apoptotic proteins BAK and BAX, resulting in cytochrome c efflux from mitochondria. Moreover, Bcl-X1 expression prevented BAX activation and inhibited the apoptotic ECs death caused by down regulation of ITSN-1s expression, consistent with a novel role of ITSN-1s in regulation of signaling pathways required for cell survival.

1461 Activation of Dual Apoptotic Pathways by E2F4 in Human Intestinal Crypt Epithelial Cells

H. Gameau, L. Alvarez, M. C. Paquin, C. Lussier, N. Rivard; Anatomy and Cell Biology, University of Sherbrooke, Sherbrooke, PQ, Canada. The E2F transcription factors control cell cycle progression. The localization of E2F4 in intestinal epithelial cells is cell cycle-dependent, being cytoplasmic in quiescent differentiated cells but nuclear in proliferative cells. Objective. To investigate the impact of constitutive nuclear expression of E2F4 in normal intestinal epithelial cells. Methods. Adenoviruses expressing fusion proteins between GFP and either E2F4 wild-type (E2F4wt) or E2F4-NLS containing a strong NLS from SV40LgT were used to infect non immortalized human intestinal epithelial cells (HIEC). Survival regulatory proteins were analyzed by Western blot. Caspase activities were analyzed with fluorogenic substrates. Cell death was analyzed by trypan blue exclusion assay and electron microscopy. Results. 1- Examination of living cells revealed that HIEC-expressing E2F4-NLS acquired a fibroblastic morphology few hours after infection, in contrast to non-infected epithelial HIEC or HIEC-expressing E2F4wt. 2- Two days after infection, HIEC-expressing E2F4-NLS died and detached; no exploded cells or flocculent densities in organelles or cytosol that would signal necrosis were observed. 3- An induction of p35 (5.5-fold), PUMA (3.5-fold), FAS (2-fold), BAX (2-fold) and RIP (4-fold) was also observed in HIEC-expressing E2F4-NLS comparatively to cells-expressing E2F4wt, by contrast, E2F1 protein expression remained unaltered. 4- The lentiviral infection of a sRNA which specifically knocked-down p53 expression significantly attenuated cell death induced by E2F4-NLS expression. 5- Caspase-3, 8 and 9 activities were enhanced by respectively 12, 3 and 2-fold in HIEC-expressing E2F4-NLS. 6- The caspase inhibitor z-VAD-fmk (100 μM) abolished caspase activities but only 60% reduced death induced by E2F4-NLS. 7- Inhibition of calcines (E6-d, 50 μM) and caspases prevented death of HIEC-expressing E2F4-NLS. 8- Chromatin margination, but not nuclear fragmentation, is noted in cells expressing E2F4-NLS. Conclusion. Persistent nuclear localization of E2F4 induces apoptosis of normal intestinal epithelial cell by at least two mechanisms: a p53/caspase-dependent pathway and a caspase-independent pathway involving calcines.

1462 Aquaporins 8 and 9 Translocate to the Plasma Membrane during Apoptosis and in Response to Trypsin or Collagenase and Likely Involve Integrin Signaling and Myosin IIs

W. K. Braddy, B. L. Gragg, J. S. Coley, R. L. Ross, C. M. Yengo, N. A. McConnell, G. E. White, F. M. Hughes; 1Biological, University of North Carolina at Charlotte, Charlotte, NC, 2Oncology, University of Wisconsin at Madison, Madison, WI, 3Biological and Environmental Sciences, Longwood University, Farmville, VA. Early during apoptosis cells detach from the substratum and round up. Subsequent efflux of K+ then drives the Apoptotic Volume Decrease (AVD). We have shown that during the AVD the water leaves through aquaporins (AQPs) and that the expression level of AQPs directly affects the rate of cell death. In the present study we investigated the cellular localization of AQP8 and AQP9 during apoptosis. Surprisingly, immunoreactivity in nondegrading rat ovarian granulosa cells and the uterine cancer cell line RUCA-1 was intracellular but translocated to the plasma membrane following induction of apoptosis, logically to increase the water permeability and allow the cell to die as quickly as possible. Using RUCA-1 cells we further demonstrated translocation in response to multiple apoptotic signals suggesting it is a signal-independent phenomenon. Interestingly, cell detachment by trypsin also stimulated translocation, as demonstrated by coimmunolocalization with TNF-R1 and Western blotting of isolated plasma membrane and vesicles, suggesting that cleavage of cell adhesion proteins will stimulate this event. Plating cells on collagen, we observed translocation of an AQP9-GFP fusion protein (but not a GFP-only control) in response to collagenase, implicating the disturbance of integrin signaling as a trigger for translocation. In addition, cytochalasin D prevented translocation while colchicine had no effect, suggesting that translocation takes place along microfilaments. Finally, immunolaosilated AQP9-containing vesicles contained the actin motor proteins myosin IIA, IIB and IIC by Western blot, although myosin IIC was highly enriched. Together, the results demonstrate translocation of AQP9 and 9 to the plasma membrane during apoptosis, logically to increase the rate of death, and implicating cleavage of integrins and a cessation of their signaling in stimulating this translocation. Furthermore, we identified three non-muscle myosins (IIA, IIB and IIC) associated with AQP9 vesicles which may be important in vesicular movement to the plasma membrane and/or within the cell.

1463 Mathematical and Experimental Analysis of Effector Caspase Amplification in the Death Receptor Network in Single-Cells

A proposed mechanism of ligand-induced single-cell rapid-all-or-none death is positive feedback in the apoptotic network. However, we experimentally show in HeLa cells that this hypothesis is not supported. We derive an experimentally verified mass-action ODE model of apoptosis. Model simulations indicate that in single HeLa cells, the mitochondrial death pathway is responsible for rapid, all-or-none apoptosis. We use singular perturbation techniques for model reduction, enabling us to find a theoretical threshold parameter that, when crossed, initiates fast, all-or-none mitochondrial cell death. Moreover, our model theoretically predicts, and we experimentally verify, that Bcl-2 over-expressing and XIAP knock-down cells produces "undead" single cells, that is, partially cleaved PARP in single cells that do not apoptose. Finally, we experimentally show that these undead cells proliferate, thus theoretically suggesting a mechanism of creating and/or perpetuating DNA-damaged cells.

1464 Histone Deacetylase Inhibitors Induce Apoptosis in Both Type I and Type II Endometrial Cancer Cells J. Li; S. Jiang; S. Dowdy; X. Meng; K. Podrata; S. Jiang; Department of Obstetrics and Gynecology, Mayo Clinic, Rochester, MN; 2Shandong Provincial Hospital, Jinan, China; 3Department of Pharmacology, Mayo Clinic, Rochester, MN

Objective. To investigate the inhibitory effects of histone deacetylase inhibitors on Type I and Type II apoptotic endometrial cancer cell proliferation. To characterize the molecular pathway involved in cell apoptosis induced histone deacetylase inhibitors. Methods. ARK2, Ishikawa, and AN3 cells cell lines representing both Type I and Type II endometrial cancers were treated with various concentrations of oxamflatin and HDAC inhibitor-1. Cell apoptosis was determined by flow cytometry, nuclear staining, Western blotting, and mitochondrial membrane potential assays. Results. Compared to controls, there was a 95% reduction in the growth of ARK2 cells following administration of histone deacetylase inhibitors and this response was dose-dependent. These agents also caused profound morphologic changes and loss of mitochondrial membrane potentials consistent with the induction of apoptosis. Cleavage of PARP, caspase-9, and caspase-8 was detected, indicating the activation of apoptotic cascades in endometrial carcinoma cells. This effect was present in both serous and endometrioid cell types. Conclusion. These results suggested that oxamflatin and HDAC inhibitor-1 has potent cytotoxicity in endometrial cancer cells by inducing cell apoptosis. Histone deacetylase inhibitors may be potentially useful chemotherapeutic drugs for women diagnosed with different types of endometrial carcinomas.

1465 Ultrasensitive Immunooassays for Cleaved PARP as an Indicator of Apoptosis W. Zheng, C. Foutain, J. DeSimone, J. Wang, K. J. Reagan; Signal Transduction Assay R&D, BioSource, Invitrogen Corporation, Camarillo, CA

Poly (ADP-Ribose) Polymerase (PARP) is a 116 kDa nuclear protein and a classic indicator of apoptosis. PARP is activated by cleavage by ICE family members, such as caspase-3 and -7, between amino acids Asp214 and Gly215 to yield a 85 kDa fragment. We report sensitive and quantitative cell-based methods (both an ELISA and Luminex bead based immunoassay) to analyze the amount of PARP p85 fragment as an indicator of the extent of apoptosis in cell lysates and tissue homogenates. In this study, Jurkat cells were grown in 96-well plate and treated with staurosporine at different doses and time intervals to induce apoptosis. In comparison to a caspase-3 protease assay, the PARP p85 specific immunooassay can quantitate apoptosis with a least 10 times the sensitivity. The assay can detect apoptosis in as few as 20-50 cells. The Luminex assay can be combined with other signaling markers of pro or anti-apoptotic activity.

1466 Mcl-1 Protein Binds to an Immediate Early Gene, IEX-1, and Modulates Apoptosis Signaling S. Yoon; S. M. Ryu; K. Lee; Y. Kang; M. Won; D. C. Lee; S. J. Kim; S. Y. Lee; J. J. Ko; J. Bae; 2Graduate School of Life Science and Biotechnology, CHA Research Institute, Seongnam, Republic of Korea; 3Comprehensive Gynecologic Cancer Center, Bundang CHA General Hospital, Pochon CHA University, Seongnam, Republic of Korea; 4Department of Life Science, College of Natural Science, Chung-Ang University, Seoul, Republic of Korea

Mcl-1 (myeloid cell leukemia 1) is a distinguished member of anti-apoptotic Bcl-2 family protein, and studies have been demonstrated pivotal roles of Mcl-1 protein in controlling cell death and survival under various conditions. To further understand the signaling pathway of Mcl-1 protein, we have screened 3 x 10^6 independent clones of human ovarian cDNA library using yeast two-hybrid system. We have identified IEX-1 (immediate early response gene X-1), also known as IER3, Dif-2, gly96 or p22/PRG-1, as a Mcl-1-interacting protein and investigated the two-hybrid system. We have identified IEX-1 (immediate early response gene X-1), also known as IER3, Dif-2, gly96 or p22/PRG-1, as a Mcl-1-interacting protein and investigated the possible roles of IEX-1 and Mcl-1 in their apoptosis signaling pathways. IEX-1 is a stress- and growth-induced gene up-regulated under various conditions, but the functional role of IEX-1 in the circumstances aforementioned has not been clearly understood yet. In the current study we confirmed the association of Mcl-1 with IEX-1 in the ovarian cell line SK-OV-3 as assessed by immunoprecipitation. Further, IEX-1 induced apoptosis of different cell lines as determined by cell viability assay and FACS analysis. Overexpression of Mcl-1 effectively attenuated IEX-1-induced cell killing effect, and IEX-1-mediated cell death effect was further augmented in a Mcl-1 knock downed stable cell line. In addition, IEX-1, itself, was able to block Mcl-1-mediated cell survival effect. Therefore, the current study reports that Mcl-1 and IEX-1 inhibit each other’s function by the direct association and suggests them as regulators in apoptosis signaling pathways.

1467 Ceramide Induces p38 MAPK and JNK Activation through a Mechanism Involving Thioredoxin-interacting Protein-regulating Pathway C. Chen, C. Lin, Y. Lin; Microbiology and Immunology, National Cheng Kung University Medical College, Tainan, Taiwan

Ceramide has been demonstrated as a second messenger, which is generated from sphingolipid metabolism by sphingomyelin hydrolysis or de novo synthesis pathway in various apoptotic stimuli. However the transcriptional regulation of ceramide on apoptotic signaling remains unclear. Here, using microarray analysis, we showed that ceramide induced the transcription of thioredoxin-interacting protein (Txnip), an endogenous inhibitor of thioredoxin. The increased Txnip mRNA and protein expression was further confirmed by RT-PCR, Western blotting, and confocal microscopy. Ceramide-upregulated Txnip co-localized with thioredoxin and reduced thioredoxin activity. Because thioredoxin might inhibit apoptosis-regulating signal kinase 1 (ASK1) and downstream p38 MAPK and JNK, we therefore investigate the effect of ceramide on ASK1, p38 MAPK, and JNK activation. Ceramide first activated ASK1 by inhibiting PKB-mediated inhibitory residue Ser-83 phosphorylation and increasing the activating residue Thr-845 phosphorylation. Ceramide further caused p38 MAPK and JNK activation time-dependently. Treatment with p38 MAPK inhibitor, SB203580, or JNK inhibitor, SP600125, partially reduced ceramide-induced cell apoptosis. Interestingly, ceramide-induced p38 MAPK and JNK phosphorylation was significantly inhibited by actinomycin D and Txnip siRNA treatment, which indicated that ceramide may act through Txnip-mediated transcriptional mechanism to regulate p38 MAPK and JNK phosphorylation. Taken together, our results show that ceramide exhibits a transcriptional regulation via Txnip-thioredoxin signaling to activate ASK1, which then trigger p38 MAPK and JNK activation leading to apoptosis.

1468 The Expression of Retinoblastoma Binding Protein 6 in Correlation to P53 in Lung Cancer L. R. Motadi, Z. Dlamini, K. D. Bhoola; 1MCB, Wits University, Johannesburg, South Africa; 2Centre for Allergy, Asthma and Respiratory Disease, University of the Western Australia, Perth, Australia

Tumor of the lung is the main cause of cancer related deaths and the incidence of such tumors shows a continuous. Apoptosis also known as programmed cell death (PCD), which is a genetically controlled mechanism essential for the maintenance of tissue homeostasis, proper development, and the elimination of unwanted cells. Defect in apoptosis signaling have been reported to contribute to resistance to tumour cells including lung cancer. Retinoblastoma binding protein 6 (RbBP6) gene, located on chromosome 16p21 encodes for RbBP6 protein 13kDa which consist of only the domain (DOMAIN) and RbBP6 protein which contains several other domains including Zinc finger and p53 binding domain which is believe to be involved in p53 dependent pathway. The aim of this study was to establish the relationship between apoptosis levels and RbBP6 expression in A549 cell lines, MRC5 cell lines and lung cancer tissues. A total of 98 histologically confirmed cases of various lung cancers were analyzed for protein expression of RbBP6 and p53 regulators of apoptosis. RT-PCR revealed that the levels of the transcripts of RbBP6, p21, Bax and Bcl2 were variable and that there was no direct correlation between them. The ratio of Bcl2/Bax was around 1.5 which indicated increased levels of antiapoptotic molecules at the transcript level. The protein expression levels of Bcl2, Bax and RbBP6 ranged from negative to positivity. Immunostaining showed cytoplasmic expression with Bcl2 showing basal positivity whereas RbBP6 showed some nuclei expression. From this small analysis of various lung cancers, it appears that the balance is in favour of anti-apoptosis which is predominantly determined by the Bcl2/Bax ratio.

Alpha-Crystallins Modulate p53 Phosphorylation Status to Attenuate UVA-induced Apoptosis

J. Liu, J. Qin, Q. Yan, D. W. Li; Biochemistry & Molecular Biology, University of Nebraska Medical Center, Omaha, NE, College of Life Sciences, Hunan Normal University, Changsha, China

UV-induced apoptosis is linked to cataractogenesis of the ocular lens. The ocular lens normally guards apoptosis of the lens epithelial cells through the function of the lens structure proteins, alpha-crystallins. In our previous studies, we have demonstrated that alpha-crystallins can negatively regulate UVA-induced apoptosis through suppression of the ERK-mediated pathway and activation of the AKT signaling pathway. In the present study using UVA irradiation, Western blot analysis and apoptosis assays, we present evidence to show that alpha-crystallins can modulate the phosphorylation status of the tumor suppressor, p53 to antagonize UVA-induced apoptosis. Thus, our results demonstrate that alpha-crystallins can regulate UVA-induced apoptosis through different mechanisms. Supported by NIH/NEI IR01 EY115765 and the Lotus Professorship Funds from Hunan Province Government.

A Zinc Finger Containing Protein, P99 Induces Cell Death

D. Kang, J. Kim, J. Lim, J. Yu; Korea Basic Science Institute, Chunchon Center, Chunchon, Republic of Korea

We show here functional study of p99, a new anaphase promoting complex/cyclosome (APC/C) substrate using imaging tools such as three dimensional colocalization technique, long-term live imaging and FRET (fluorescence resonance energy transfer) method. APC/C is known to have important roles during cell cycle. The evidence that these complexes are related with a variety of cellular events such as neural cell differentiation and genetic stability beyond cell cycle is rising. We adopted small pool expression screening to find new substrates of APC/C with some modifications. We isolated many interesting candidates as APC/C substrates. Among them, a zinc finger containing protein, p99 was selected to investigate the functional consequences of its degradations. We show a full length p99 is ubiquitinated in vitro. Interestingly, p99 is expressed in a nucleus as speckles and co-localized with SC-35, a marker of IG (interchromatin granule cluster). Over-expression of p99 disturbed normal cell cycle progression. Live fluorescence imaging show p99 induces cell death in dose dependent manners. The physiological function of p99 and meaning of its degradation is under investigation.

Molecular and Celluar Characteristics of Apoptosis and Cell Growth in Cervical Cancer Cells Following RNAi Mediated Knockdown of Survivin, Cdc2 and Eg5

Resistance to apoptosis is a hallmark of cancer cells. The ability to regulate apoptosis, holocytochrome c is released from mitochondria and associates with Apaf1 and procaspase 9, forming a complex called the apoptosome. Apoptosome formation results in activation of caspase 9 initiating a proteolytic caspase cascade and the ultimate demise of the cell. The analysis of cytochrome c release is important in determining the commitment to apoptosis in model signaling systems. Widely employed cellular fractionation strategies for determination of cytochrome c release generally involve mechanical disruption of cells resulting in incomplete or excessive rupturing of cells and mitochondria. Subsequent analysis of subcellular fractions by Western blot can only be regarded as qualitative, reflecting the quality of the fractionation procedure. We have developed a fluorescent assay for determination of mitochondrial cytochrome c localization on a per cell basis. The assay relies on the selective permeabilization of the cellular membrane for release of cytosolic components while leaving the mitochondrial membrane intact. Cytochrome c is detected with a monoclonal antibody by flow cytometry or fluorescent microscopy. To determine the usefulness of the assay in measuring apoptotic cell death, Jurkat cells were treated with Actinomycin D and cytochrome c release was determined by flow cytometry. In parallel, samples were processed for annexin V binding, DNA fragmentation (TUNEL), and propidium iodide staining. Cytochrome c release was detected at earlier time points of the cell death response when compared to the TUNEL based assay and propidium iodide staining. Furthermore, unlike annexin V staining, the cytochrome c stained cells are fixed making the assay amenable to mult-paramater analysis of apoptotic cells as well as convenient storage of cells for future analysis. Unlike traditional cellular fractionation protocols, the assay may be useful for high throughput screening as well as the analysis of scarce samples such as primary cells.

Soft Substrate Induces Apoptosis by the Disturbance of Ca2+ Homeostasis in Renal Epithelial LLC-PKI Cells

W. Chiu, Y. Wang, M. Tang, M. Shen; Institute of Basic Medical Sciences, National Cheng-Kung University, Tainan, Taiwan, Department of Pharmacology, National Cheng-Kung University, Tainan, Taiwan

Different rigidities of adhesive substrate affect cellular functions in different ways. Here, we cultured a renal epithelial cell line (LLC-PKI) and a tumor cell line (HeLa) on substrates of different rigidities and compared the cell type-specific responses. The culture dish was coated with a very thin layer of collagen gel (control group) or overlaid with collagen gel (soft substrate). LLC-PKI cells contracted as they grew on collagen gel and the apoptotic bodies obviously appeared with time. The protein levels of procaspase-12 and its downstream target procaspase-3 were decreased when LLC-PKI cells cultured on collagen gel. µ-calpain was activated on collagen gel. In contrast, there was no significant change in cytochrome c reduction, mitochondrial membrane potential, and the protein levels of procaspase-8 and procaspase-9. Moreover, soft substrate caused elevated cytosolic Ca2+. Ca2+ overload in ER and upregulation of capacitative calcium entry. Ca2+ chelator or channel blocker partially rescued the collagen-gel induced apoptosis by inhibiting µ-calpain activation. In contrast, for HeLa cells cultured either on...
Molecular Determinants of Mob1 Localization at the Spindle Poles, Kinetochores, and Central Spindle of Dividing Cells

L. J. Wilneth, J. Rashe, S. Shrestha, C. B. Shuster; Biology, New Mexico State University, Las Cruces, NM

Maintenance of chromosomal ploidy requires chromosome segregation and cytokinesis be precisely coordinated in space and time. We have focused on the localization dynamics of Mob1 family members, which are required for activation and localization of the NDR family kinases, and are essential for mitotic progression in yeast. There are 4 human Mob1 isoforms, and to discriminate between these highly similar proteins, Mob1-A-D were fused to EGFP. Transient expression of all four isoforms in HeLa cells revealed partially redundant localization patterns through mitosis and cytokinesis. Mob1 proteins were found on interphase centrosomes, with enrichment late in G2 and remaining through cytokinesis. Spindle pole localization was microtubule-independent, suggesting that Mob1 is a true centrosomal protein. Additionally, Mob1 recruitment to kinetochores could be detected in control cells from prophase until anaphase onset, as well as in cells arrested with nocodazole or monastrol. Upon anaphase onset, Mob1 was found at the spindle poles and central spindle, with equatorial localization maintained throughout cytokinesis. Mob1 localization at metaphase and cytokinesis is suggested to be microtubule-dependent, because Mob1A localization was examined in cells depleted of INCENP and PLK1 by siRNA. INCENP depletion resulted in lagging chromosomes during anaphase and cytokinesis failure, and while Mob1A localization at the centrosomes was unaffected, kinetochore- and central spindle localization was lost. Conversely, PI3 depletion, did not affect kinetochore localization, although spindle pole localization was reduced. Together, these results suggest that there may be multiple regulatory inputs determining Mob1 localization, including the possibility that Mob1 functions downstream of the chromosomal passenger complex. Supported by P200R016480 and S06GM008136.

NEK2A Regulates the Interaction of Hecl with CENP-H and the Attachment of Spindle Microtubules to the Kinetochore

A. Jimenez-Dalmaroni, M. Théry, V. Racine, F. Julicher, M. Bornens; 1Max Planck Institute for the Physics of Complex Systems, Dresden, Germany, 2UMR 144, Institut Curie, Paris, France

Chromosome segregation in mitosis is orchestrated by the interaction of the kinetochore with spindle microtubules. Our recent study shows that NEK2A interacts with MAD1 at the kinetochore and possibly functions as a novel integrator of the spindle checkpoint signaling. However, it is unclear how NEK2A regulates kinetochore-microtubule attachment in mitosis. Here, we report that NEK2A modulates the interaction of Hecl with CENP-H and the attachment of spindle microtubules to the kinetochore during mitosis. Hecl1 interacts with CENP-H in vitro and in vivo via extended coiled-coil domains located in the middle of the two molecules, respectively. Our immunofluorescence study revealed that Hecl1 is localized at the metaphase kinetochore exterior to CENP-H with the globular domain oriented toward microtubule plus end. NEK2A phosphorylates Hecl1 at Ser165 during mitosis while such phosphorylation regulates Hecl1-CENP-H interaction in vitro and in vivo. Interestingly, phosphorylation of Ser165 is not essential for assembly of Hecl to kinetochore as non-phosphorylatable mutant Hecl1S165A is localized to the kinetochore. Moreover, Hecl1 interacts with kinetochore microtubules. However, there was a significant increase in attachment errors, including syntelic attachment and monotelic attachment. In addition, these Hecl1S165A-overexpressing cells display a chromosome-bridge phenotype with sister chromatids inter-connected. These findings reveal a key role for the NEK2A-mediated phosphorylation of Hecl1 in governing proper kinetochore-microtubule attachment and support a notion by which NEK2A integrates kinetochore-microtubule attachment into spindle checkpoint signaling. Using fluorescence resonance energy transfer measurements in living cells, we are evaluating how NEK2A orchestrates the Hecl1-CENP-H interactions in kinetochore assembly and chromosome segregation.

B-Raf Is Required for Spindle Formation and Chromosome Congregation in Human Somatic Cells

M. E. B. Brooks, T. Gandaglio, J. V. D. M. Molecular Oncology, Moffitt Cancer Center and Research Institute, Tampa, FL

B-Raf is a member of the Raf family of serine/threonine protein kinases that serves a prominent role in regulating cell proliferation. The cellular mechanisms through which B-Raf mediates cell proliferation remain poorly understood. Here we report a novel role for B-Raf in regulating spindle formation in somatic cells. We show by epifluorescence and confocal microscopy that B-Raf localizes at the mitotic spindle and spindle-associated structures during the stages of mitosis. A detergent-insensitive pool of B-Raf is tightly associated with the centrospheres throughout the cell cycle. Furthermore, phospho-state specific antibodies detect phospho-B-Raf (Thr599/Ser602) at the centrioles, kinetochores, and outer regions of chromosomes during prometaphase, metaphase, and anaphase, and at the midbody during cytokinesis. To determine the functional significance of B-Raf localization at the spindle apparatus, RNA interference was used to down-regulate B-Raf in human cells. Reduction of B-Raf resulted in pleiotropic effects on the mitotic spindle and chromosome alignment in over 80% of mitotic cells. Similar results were observed using a second siRNA that targeted a different exon in B-Raf. In contrast, reduction of C-Raf (Raf-1) had no effects on spindle formation or chromosome alignment suggesting that B-Raf, and not Raf-1, is critical for regulating the mitotic spindle. Additionally, we showed that depletion of B-Raf disrupts spindle pole focusing in Xenopus egg extracts, a system in which B-Raf is activated exclusively during mitosis. In summary, our results demonstrate that B-Raf is required for proper mitotic spindle assembly and chromosome alignment in human somatic cells.

Theoretical and Experimental Description of Mitotic Spindle Orientation

A. Jimenez-Dalmaroni, M. Théry, V. Racine, F. Julicher, M. Bornens; 1Max Planck Institute for the Physics of Complex Systems, Dresden, Germany, 2UMR 144, Institut Curie, Paris, France

The architecture and adhesiveness of cell microenvironment is a critical factor regulating spindle orientation in vitro. It has been shown that the orientation of the spindle during HeLa cell division in vitro depends on the spatial distribution of adhesive cell contacts. It has also been demonstrated, that minus-end directed cortical force generators exert forces on astral microtubules. Here we show that the observed spindle orientation in HeLa cells can be understood as the result of the action of cortical force generators interacting with astral microtubules. We assume that these force generators are activated by cortical signals which are associated with retraction fibers connecting the mitotic cell body to its adhesive microenvironment. The force generators exert a torque on the spindle which depends on its relative orientation with respect to the microenvironment geometry and leads to spindle rotation. We developed a simple physical description of this spindle mechanics which allows us to calculate angular profiles of the torque acting on the spindle and the angular distribution of spindle orientations. Our model could account for the spindle orientations observed in a large variety of different adhesive patterns. Remarkably it also describes the shape transition from symmetrical to asymmetrical orientation observed for pattern of similar type. Our results suggest that a slight modification of cell microenvironment is sufficient to provide either main polarizing signals and stimulate symmetrical orientation or a single polarizing signal and stimulate asymmetrical orientation of the spindle. It supports the hypothesis that, in vivo, niche architecture is established so as to embed stem cells in a geometrical configuration close to this transition. 1. Fuchs, E. et al. Cell (2004). 2. Thery, M. et al. Nat Cell Biot (2005). 3. Grill, S. W. et al. Science (2003).

Bod1, a Novel Kinetochore Protein Required for Chromosome Biorientation

I. M. Porter, G. A. Khoudels, J. S. Anderson, J. W. Bow, J. R. Swedlow; 1Division of Gene Regulation and Expression, University of Dundee, Dundee, United Kingdom, 2Division of Biochemistry and Molecular Biology, University of Southern Denmark, Odense, Denmark

Through proteomic analysis of Xenopus chromosomes and a secondary RNAi live cell imaging screen we have identified a novel protein required for proper chromosome alignment during mitosis that we have named Bi-orientation defect 1 (Bod1). Bod1 is a small 22 kDa protein that is a member of a family of three closely related proteins that appear to have arisen due to gene duplication. GFP tagged Bod1 localised to centrosomes throughout the cell cycle and also localised to kinetochores from prometaphase through to anaphase. We performed time-lapse microscopy of HeLa cells expressing GFP tagged Bod1 and observed that Bod1 was not recruited to the centromeres of chromosomes until prometaphase. Bod1 recruitment to centromeres was not mitosis-dependent, suggesting that Bod1 is a microtubule associated protein. Co-localisation studies indicate that the majority of these attachments are stable suggesting that the kinetochores are intact. Together, these results suggest that Bod1 is a novel protein required for the maintenance of chromosome biorientation at metaphase.
A Conserved Role of Kinesin-14 Family Proteins HSET/XCTK2 in Controlling Spindle Morphology

S. Cai, S. C. Ems-McClung, C. E. Walczak, C. Biochemistry Program, Indiana University, Bloomington, IN; Medical Sciences Program, Indiana University, Bloomington, IN

Kinesin-14 family proteins are minus-end directed motors, which drive microtubule movements and play key roles during mitosis. We showed previously that the Xenopus Kinesin-14 XCTK2 is regulated by Ran via the association with importin alpha/beta to a bipartite NLS in the tail of XCTK2. Binding of importin alpha/beta to XCTK2 inhibits its association with microtubules and blocks its ability to cross-link microtubules during spindle formation. Whether Ran-regulation of the Kinesin-14 family is conserved in vertebrate cells is not known. We found that knockdown of the human Kinesin-14 HSET by RNAs resulted in shorter spindles, and overexpression of HSET increased spindle length. These results are consistent with the role of HSET in microtubule cross-linking and sliding in the spindle. To ask whether HSET is regulated by Ran, we identified the NLS in the tail of HSET and generated NLS mutants. Transfection of NLS-mutated-HSET caused an accumulation of HSET in the cytoplasm, which resulted in strong microtubule bundling, suggesting that one role of the NLS is to sequester HSET from cytoplasmic microtubules. In mitosis, overexpression of the NLS-HSET mutants also caused spindle defects, consistent with its role in microtubule cross-linking. To compare HSET with XCTK2, we generated full-length XCTK2 with a mutated NLS. Addition of a 5-10 fold molar excess of NLS mutant XCTK2 over endogenous levels to extracts disrupted spindle assembly by causing excessive microtubule sliding. This effect is additive with expression of wild-type XCTK2, which resulted in enhanced spindle formation. Our results are consistent with a model in which Ran regulates the association of XCTK2/HSET with importin alpha/beta to prevent aberrant cross-linking and bundling of microtubules and to sequester XCTK2/HSET in the nucleus. Upon NLS, XCTK2/HSET is released from importin alpha/beta in the vicinity of chromosomes to facilitate microtubule cross-linking and organization of the spindle.

Organization and Dynamics of the Budding Yeast Metaphase Spindle

H. Qi, Y. Ding, L. Zhu, U. Rath, J. Girtton, K. M. Johansen; Biochemistry, Biophysics & Molecular Biology, Iowa State University, Ames, IA

The concept of a spindle matrix has long been proposed based on theoretical considerations of the requirements for force production to help organize and stabilize the microtubule spindle during mitosis. However, molecular evidence corroborating its existence and function has been elusive. In *Drosophila* we have recently identified four nuclear proteins, Skeleton, Chromator, Megator, and EAST that interact with each other and that redistribute during prophase forming a fusiform spindle structure that persists in the absence of polymerized tubulin. Two of these proteins, Skeleton and Chromator, are localized to chromosomes during interphase whereas the other two, Megator and EAST, occupy the intranuclear space surrounding the chromosomes. Megator is a 260 kD protein with a large NH-terminal coiled-coil domain that is capable of self-assembly when expressed in S2 cells indicating that Megator has the necessary molecular properties to serve as the structural basis for the spindle matrix complex. To further analyze Megator's role in spindle function we used EMS mutagenesis to generate 43 new alleles that reduced adult survival rates by more than 50% when heterozygous with the null Megator allele. The new Megator alleles fall into three distinct complementation groups possibly reflecting an essential role of Megator in three different cellular contexts. Currently, we have identified one allele from complementation group I, 22-6, with clear mitotic spindle defects. In 22-6 the ipMTs are misaligned, incompletely formed, and with abnormal congression and segregation of chromosomes. In mutant brains (n=9) 317 out of 346 neuroblasts examined had such phenotypes versus only 13 out of 265 neuroblasts in control brains (n=12) (χ² test). These results strongly suggest that Megator mutations can result in severe chromosome segregation defects as well as in spindle abnormalities and support the hypothesis that Megator plays a functional role in mitosis. (Supported by NSF grant MCB0445182).

Role of the Bipolar Kinesin-5, KLP61F, in Poleward Flux and Spindle Elongation in *Drosophila* Embryos

I. Brust-Mascher, D. Cheemanthatham, P. Shroff, J. M. Scholky; Molecular and Cell Biology, University of California, Davis, Davis, CA

Mitosis involves a highly choreographed sequence of motility events that depend upon the action of microtubule (MT)-based force generators, namely MT polymer ratchets, kinesins and dyneins. Here we focus on the role of KLP61F during the metaphase-anaphase A steady state and during anaphase B spindle elongation. In previous studies we proposed that the bipolar kinesin KLP61F (Sharp et al, 2000, MBC 11:241) persistently slides dynamically unstable ipMTs outward, while the depolymerase KLP10A (Rogers et al, 2004 Nature 427:364) acts at the poles to convert ipMT sliding to flux before anaphase B. The inhibition of this depolymerization at anaphase B onset suppresses flux and allows ipMT sliding to drive spindle elongation (Brust-Mascher and Scholky, 2002, MBC, 13:3967, Brust-Mascher et al, 2004, PNAS 101:15493). The proposal that KLP61F slides ipMTs during both the steady state and during spindle elongation predicts that this motor contributes to poleward flux within ipMTs. To test this we are using Fluorescence Speckle Microscopy and time lapse confocal microscopy to measure flux and spindle pole movement in the syncytial embryo. Injection of an antiKLP61F function blocking antibody produces a gradient of defects. The most severe defect occurs during prometaphase and spindle pole movement in the syncytial embryo. Tracking kinetochore-proximal chromosome tags further allows us to measure and compare the dynamics of individual kinetochore microtubules in wild type and mutant cells, which has revealed that kinetochore proteins are key regulators of kinetochore microtubule dynamics.
The Endocytic Coat Protein ARH Associates with Motor and Centrosomal Proteins and Is Involved in Mitosis

S. Lehtonen, R. Nielsen, N. Iino, J. J. Ryan, H. Zhou, M. G. Farquhar; Department of Cellular and Molecular Medicine, University of California San Diego, La Jolla, CA; Ludwig Institute for Cancer Research, University of California, La Jolla, CA; Department of Cellular and Molecular Medicine and Ludwig Institute for Cancer Research, University of California San Diego, La Jolla, CA

ARH is an endocytic adaptor protein that is essential for LDL receptor mediated uptake of LDL in hepatocytes and which we found is required for uptake of ligands by megalin (Nagai, MBC 14: 4984-4996, 2003). This binds clathrin and AP2, and the NPXY sequence present in the cytoplasmic tail of LDLR superfamily members. Here we report novel and unexpected findings showing that ARH is a core centrosomal protein. Moreover, we found localization of ARH to be regulated in a cell-cycle dependent manner: When cells entered mitosis, ARH was recruited to kinetochores and spindle poles where it co-localizes with the motor protein cytoplasmic dynein and dynactin. Furthermore, during cytokinesis ARH was detected in the midbody of HeLa cells. By co-IP followed by mass spec analysis ARH was found to form a complex with y-tubulin complex proteins and dynine. Centrosomes are involved in several cell cycle regulatory events in addition to serving as microtubule nucleation sites and dynein, a microtubule-based molecular motor, participates in cell division and vesicular trafficking. Depletion of ARH with siRNA in Rat-1 cells caused a G1 delay, and immuno/fluorescence showed that microtubules seem to be organized more randomly in ARH depleted cells compared to control cells. These data suggest that ARH has structural and/or functional roles that are needed for normal progression of mitosis.

The ENDO Network Couples Cyclin Stability to the Assembly of the Mitotic Spindle and Checkpoint Activation

K. H. Ban, J. Z. Torres, J. J. Miller, A. Mikhailov, M. V. Nachury, J. J. Tung, C. L. Rieder, P. K. Jackson; Program in Cancer Biology, Stanford University, Stanford, CA; Department of Pathology, Stanford University, Stanford, CA; Genentech, Inc., South San Francisco, CA; Program in Molecular Pharmacology, Stanford University, Stanford, CA; Division of Molecular Medicine, Wadsworth Center, Albany, NY

The activation of cyclin-dependent kinase 1 (CdK1) drives chromosomal and microtubule organization, and at a later time downregulates its own activity by initiating the ubiquitination and destruction of cyclin B by the Anaphase Promoting Complex/Cyclosome (APCC) E3 ligase. Studies to date have emphasized the role of checkpoint signaling at the kinetochore to provide the critical delay for APC/C activation. However, recent work has demonstrated an additional role for checkpoint-independent mechanisms in restraining APC/C activation in early mitosis when kinetochores are not yet competent to generate the necessary APC/C inhibitory signals. Here, we show that a novel regulatory pathway, called the ENDO (Emi1/NuMA/Dynein-dynactin) network, forms a critical APC/C inhibitory mechanism on spindle poles in human tissue culture cells. We demonstrate that a specialized pool of the APC/C inhibitor Emi1 (~15%) persists in early mitosis and binds to the APCC on the mitotic spindle poles from prophase to anaphase. This organization is driven by the minus-end directed motor dynein-dynactin and the spindle protein NuMA. We find that Emi1 binds directly to the microtubule binding domain of NuMA and this interaction anchors the Emi1-APCC complex to the spindle pole. Inactivation of Emi1 in mitosis leads to the loss of pole-associated cyclin B due to the premature activation of APC/C at the poles. Because NuMA function requires Cdk1 activity, this premature destruction of cyclin B disrupts NuMA-dependent anchorage of microtubules at the poles thus resulting in pole fragmentation and aberrant spindle formation. Surprisingly, we find that perturbing the END network abolishes the recruitment of checkpoint proteins to the kinetochores, suggesting that cyclin B/Cdk1-dependent organization of the spindle pole is linked to the activation of the kinetochore-directed spindle checkpoint. We propose that the END network functions to couple localized cyclin stabilization to both spindle assembly and checkpoint activation following prophase.

Identifying the Kinetochore-derived “Wait Anaphase” Signal of the Mitotic Checkpoint

A. Kulukian, D. W. Cleveland; Biology, University of California, San Diego, La Jolla, CA; Ludwig Institute for Cancer Research, University of California, San Diego, La Jolla, CA

The mitotic checkpoint is the major cell cycle control mechanism for maintaining diploid chromosome content. Prevention of premature anaphase onset requires the production by unattached kinetochores of a diffusible “wait anaphase” inhibitor that is thought to function by inhibiting the ability of Cdc20 to activate the APC/C, the E3 ubiquitin ligase that targets mitotic regulators such as cyclin B and securn for degradation. The exact composition of this inhibitor(s) has not been established, although the mitotic checkpoint components BubR1 and Mad2 can bind Cdc20 directly and have, along with Bub3, been implicated as potential components of this inhibitor. In addition, Mad1 and Bub1, stably bound components of unattached kinetochores, have also been shown to play a role in the generation of the checkpoint signal, potentially through the recruitment of diffusible components (including Mad2 and BubR1) to the mitotic spindle and the possible modification of those components upon recruitment. To identify the kinetochore-derived anaphase inhibitor, we have attempted to reconstitute mitotic checkpoint signaling in vitro from purified components. Using cyclin B ubiquitination as an assay for APC/C activity, purified recombinant checkpoint proteins Mad2, Bub3, and BubR1 are demonstrated to act synergistically to inhibit APC/C/Cdc20, with the combination at least four times more potent than each alone. Moreover, purified chromosomes (with unattached kinetochores) amplify, by a further 10 fold, the overall generation of a Cdc20-specific APC/C inhibitor. Fluorescently labeled Mad2 is shown to localize to kinetochores as further proof of its role as part of a kinetochore-generated inhibitory signal. This provides an assay for identifying the kinetochore-derived mitotic checkpoint inhibitor and determining how unattached kinetochores catalyze the production of this inhibitor.

Mechanisms of Poleward Chromosome Movement

E. L. Grishchuk, M. L. Molotskov, J. S. Spirodnov, A. K. Yetefromov, F. I. Atullakhakovov, J. R. McIntosh; MCB Biology, University of Colorado, Boulder, CO; National Research Center for Hematology, Moscow, Russian Federation

Poleward chromosome movement during mitosis is dependent upon the activities of minus-end directed, microtubule-dependent motors, and it requires the depolymerization of microtubules. To learn the relative roles of these factors in the process, we have undertaken two experimental approaches. Microtubule depolymerization is studied in a novel experimental system, which allows the direct measurement of the depolymerization force. By conjugating glass microbeads to microtubules through strong inert linkages, and by using laser tweezers we have shown that depolymerization of microtubules can exert a brief tug on an attached bead (Grishchuk et al, Nature 2005). Analysis of these interactions with a molecular-mechanical model of microtubule (Molodtsov et al, PNAS 2003) suggests that a single disassembling microtubule can generate about ten times the force that is developed by a motor enzyme. Thus, this mechanism might be the primary force for chromosome motion. This experimental system is being applied to analyze force production by depolymerizing microtubules that are linked to cargo via processive couplers. We are also studying the roles of minus-end directed motors in poleward chromosome motions in vivo using fusion yeast (Grishchuk and McIntosh, submitted). This organism has three such motors: dynein and two kinesin-14s, Pkl1p and Klp2p. The maximum rate of poleward chromosome movement was unaffected by the deletion of any of these motors, suggesting that microtubule depolymerization can cause such movements in vivo. However, Klp2p, which localizes to kinetochores, contributed to the effectiveness of poleward movement by promoting the shortening of kinetochore fibers. Pkl1p and dynein were required for efficient chromosome bi-orientation. In pkl1a, whose product normally localizes to the spindle poles, the checkpoint that monitors chromosome bi-orientation was defective, leading to premature anaphase. Electron microscopy suggests that Pkl1p contributes to error-free bi-orientation by promoting the normal organization of spindle poles, while dynein helps to anchor microtubule minus ends.

Cytoplasmic Dynein Drives Fast Poleward Motion during Kinetochore Attachment in Vertebrates

Z. Yang, C. Rieder; Laboratory of Cell Regulation, Division of Molecular Medicine, Wadsworth Center, New York State Department of Health, Albany, NY; Biomedical Sciences, SUNY School of Public Health, Albany, NY

During mitosis in vertebrates kinetochores become attached to the forming spindle as they interact with dynamic microtubules growing from the separating centrosomes. Due to the random nature of this process it is not unusual for one kinetochore to become attached to the spindle before its sister does. Under this condition the chromosome “monoorient” and rapidly moves towards the pole it is attaching to (C.L. Rieder and S.P. Alexander. J. Cell Biol., 110:81-95, 1990). Although this rapid motion is through to be mediated by kinetochore-associated cytoplasmic dynein, there is no direct evidence that this is so. To examine this in detail we tracked kinetochore motion during nuclear envelope breakdown in live human U2OS CENP-B-GFP cells after knocking down zw10 by siRNA. This approach allowed us to selectively deplete kinetochores of cytoplasmic dynein, without inhibiting normal bipolar spindle assembly. As expected, we found that shortening of numerous kinetochores exhibited a rapid poleward motion up to 5 minutes after nuclear envelope breakdown, some with rates > 20 μm/min. However, after zw10 siRNA treatment the number of rapid poleward kinetochore motions was greatly reduced, the normal dynamics of chromosome congression was perturbed, and the duration of prometaphase was considerably prolonged. From our data we conclude that cytoplasmic dynein is involved in the initial rapid poleward motion of attaching chromosomes, and also in normal congression movements. We are currently exploring the role of dynein in anaphase poleward motion.

A Change in the Distribution of Microtubule Plus Ends Contributes to the Anaphase B Switch in Drosophila Mitotic Spindles

D. K. Cheeresarabathur, G. Civelękoglu-Scholey, J. Braut-Mascher, P. Sommi, A. Mogilner, J. Scholey; MCB, University of California, Davis, Davis, CA

Spindle elongation during anaphase B in Drosophila embryos is initiated by the inhibition of minus end depolymerization within microtubules (MTs), which allows the sliding apart of interolar (ip) MTs to exert forces that drive spindle pole separation. Here we monitored the dynamics of the plus ends of MTs within the spindle during mitosis by using time lapse microscopy of the GFP-labeled plus end tip tracker protein EB1. Analysis of EB1 revealed a change in the distribution of growing MT plus ends, which are localized throughout the spindle prior to anaphase B, but concentrate in the overlap region of ipMTs at the equator at anaphase B onset. This change in plus end distribution during the transition is reflected in MT polymer dynamics measured using fluorescence recovery after photobleaching (FRAP) of GFP-tubulin. Our studies reveal that spindle MTs display very high dynamicity (recovery half time, 5-10 sec) at all stages of mitosis on all subsets of MTs. However, the fractional recovery of spindle MTs becomes spatially non-uniform at the onset of anaphase B, with MTs proximal to the poles recovering to a significantly lower extent (~ 45%) than elsewhere (80-90%), indicating the emergence of a stable subset of MTs near the poles. Quantitative modeling suggests that this depends on the establishment of a spatial gradient in MT dynamic instability parameters, with MT plus end catastrophe frequencies being highest at the poles and decreasing toward the equator. The resulting redistribution of growing MT plus ends to the ipMT overlap zone, together with the suppression of ipMT depolymerization at the poles, constitutes a mechanical switch that initiates spindle elongation.

Kinesin-14 and the Dam1 Complex Ensure Microtubule-dependent Kinetochore Transport Towards Spindle Poles by Distinct Mechanisms

K. Tanaka, E. Kitamura, Y. T. U. Tanaka; School of Life Sciences, University of Dundee, Dundee, United Kingdom

To ensure high-fidelity chromosome segregation, kinetochores must be properly captured by spindle microtubules. Kinetochore are initially captured by the lateral sides of single microtubules and subsequently transported towards spindle poles. Poleward kinetochore transport is especially crucial when kinetochores are located at a distance from the mitotic spindle. We found that at least two mechanisms are involved in microtubule-dependent poleward kinetochore transport in Saccharomyces cerevisiae. First, Kar3, a kinesin-14 family member and a microtubule minus-end directed motor, localizes at kinetochores and drives poleward kinetochore sliding along the lateral surface of microtubules. Second, following capture by microtubule lateral sides, kinetochores are tethered at the distal ends of microtubules and pulled poleward as microtubules shrink. The first mode of kinetochore transport is often converted to the second one, but the opposite conversion rarely happens. The second mode leads to more processive kinetochore transport and crucially depends on the Dam1 complex. The Dam1 complexes accumulate at the microtubule plus ends as microtubules shrink, providing evidence that the complex forms rings encircling microtubules in vivo, as reported in vitro. We suggest that the Dam1 complex plays an essential role in converting microtubule depolymerization into the poleward kinetochore-pulling force. Thus Kar3 and the Dam1 complex ensure microtubule-dependent kinetochore transport by distinct mechanisms.

The Kinesin-13 Family Member, KLP59D, Contributes to Both Poleward Flux and Pacman-based Chromosome Motility in Drosophila S2 Cells

U. Rath, G. C. Rogers, D. J. Sharp; 1Department of Physiology and Biophysics, Albert Einstein College of Medicine, Bronx, NY, 2Department of Biology, University of North Carolina, Chapel Hill, NC

Kinesin-13 family members destabilize microtubules and perform important and conserved roles during mitosis. Previously, we reported that Drosophila contain three distinct Kinesin-13s, termed KLP10A, KLP59C, and KLP59D. In embryos, two of these, KLP10A and KLP59C depolymerize microtubule minus- and plus-ends, respectively, to drive Anaphase A by a “Pacman-Flux” mechanism. Here, we assess the mitotic functions of KLP59D. Our data reveal that KLP59D targets to outer kinetochores and centrosomes. Following KLP59D knockdown in S2 cells using RNAi, the rate of anaphase A decreases by ~50%. Similar results were obtained following KLP59D antibody injections into embryos. Photobleaching experiments performed in S2 cells expressing fluorescently labeled microtubules and chromosomes reveal that KLP59D exerts its impact on anaphase by inducing the depolymerization of both ends of kinetochore associated microtubules. Specifically, knockdown of KLP59D results in a ~80% reduction in plus-end depolymerization along with a 20% reduction in microtubule minus-end depolymerization during anaphase. Thus, KLP59D is uniquely important for chromosome segregation in Drosophila cells.

Production of a Human Artificial Chromosome with a Conditional Centromere

Kinesin-13 family members destabilize microtubules and perform important and conserved roles during mitosis. Specifically knockdown of KLP59D results in a ~80% reduction in plus-end depolymerization along with a 20% reduction in microtubule minus-end depolymerization during anaphase. Thus, KLP59D is uniquely important for chromosome segregation in Drosophila cells.

Identification of Genes Involved in Centromeric Chromatin Formation

C. M. Betts, S. Erhardt, B. Mellone, M. H. Karpen, A. F. Straight; 1Biochemistry, Stanford University, Stanford, CA, 2Genome Biology, Lawrence Berkeley National Lab, Berkeley, CA

Accurate chromosome segregation is essential for maintenance of genomic stability. Attachment of the chromosomes to the spindle apparatus is mediated by kinetochores assembled on the chromosome's centromere. All eukaryotic centromeres require the replacement of histone H3 in the nucleosomes of centromeric chromatin with the histone variant CENP-A. Thus, to understand how the site of centromere formation is determined it is necessary to understand how CENP-A is specifically incorporated into centromeric chromatin. Although many centromere proteins have been biochemically identified, the mechanisms of centromeric chromatin formation have yet to be elucidated. To identify factors involved in centromere determination, we used an RNAi based approach to screen the entire Drosophila genome for defects in centromeric chromatin formation. Cultured Drosophila cells were treated with double stranded RNAs corresponding to each gene in the Drosophila genome to deplete the messenger RNA encoded by each gene. Cells were fixed and immunofluorescence was performed to localize cdc (the Drosophila CENP-A homologue), HP1 (a marker for heterochromatin), and the DNA intercalating dye DAPI. We acquired fluorescent images of each depletion using an automated microscope and we developed conditions to screen the entire Drosophila genome for defects in centromeric chromatin formation. Cultured Drosophila cells were treated with double stranded RNAs corresponding to each gene in the Drosophila genome to deplete the messenger RNA encoded by each gene. Cells were fixed and immunofluorescence was performed to localize cdc (the Drosophila CENP-A homologue), HP1 (a marker for heterochromatin), and the DNA intercalating dye DAPI. We acquired fluorescent images of each depletion using an automated microscope and we developed...
computational methods to rapidly analyze the image data and identify genes that disrupted Cenp-A localization. We have identified 17 genes that were not previously implicated in centromere formation but that cause a loss in Cenp-A incorporation into centromeres.

Centromere Specification Requires a Conserved Myb Domain-containing Protein Family

P. S. Maddox, J. Menon, F. Hyndman, K. Oegema, A. Desai; LICR, UCSD, La Jolla, CA

Nucleosomes containing the histone H3 variant CENP-A create the structural foundation for kinetochores - the primary chromosomal attachment sites for spindle microtubules which mediate chromosome segregation during cell division. The mechanisms that selectively load CENP-A nucleosomes and maintain their restricted distribution, while largely unknown, are critical for genomic stability. To identify factors required for CENP-A loading, we utilized a functional genomics approach in the nematode C. elegans. Secondary analysis of a gene set defined by a genome-wide RNA interference (RNAi) screen identified 4 proteins whose depletion recapitulates the "kinetochore-null" (KNL) phenotype observed following depletion of CENP-A. Of these, only one protein, KNL-2, is required to load CENP-A nucleosomes onto chromatids. This function is specific, as KNL-2 is not required to load histone H3-containing nucleosomes. Consistent with a close functional interaction on chromosomes, KNL-2 and CENP-A co-localize at centromeres, and are coordinately required for kinetochore assembly, mitotic chromosome structure, and chromosome segregation. Biochemical isolation of KNL-2 associated chromatin specifically enriched CENP-A relative to histone H3 indicating close physical proximity of these two proteins on DNA. KNL-2 is a member of a conserved and previously uncharacterized sub-family of the Myb domain-containing protein superfamily. Analysis of human KNL-2 (Hsk2NL-2) revealed a conserved function in centromere assembly. Hsk2NL-2 localizes to centromeres and is required for localization of CENP-A to centromeres and kinetochore assembly. These results implicate a novel protein class, known to interact with DNA as well as histones, in centromeric chromatin assembly, a critical event in segregation of the genome during cell division.

Assembly of Centromeric Chromatin Requires DNA Repair by Ung2

S. G. Zeitlin,1 C. Tai,2 B. R. Chapados,1 G. Shuphang,1 B. Kavl1,1 J. J. Y. Wang3; 1Cellular and Molecular Medicine, UCSD, La Jolla, CA, 2Biology, UCSD, La Jolla, CA, 3Molecular Biology, TSRI, La Jolla, CA, 4Faculty of Medicine, NTNU, Trondheim, Norway, 5Moores Cancer Center, UCSD, La Jolla, CA

CENP-A is an essential histone H3 variant found in all eukaryotes examined to date. Previously, we showed that the incorporation and removal of uracil from DNA by the nuclear uracil DNA glycosylase, Ung2, are required for CENP-A assembly into sperm chromatin in cell-free Xenopus egg extracts. Here we examine whether such DNA modifications are also important for CENP-A assembly in mammalian cells. To distinguish new CENP-A assembly from maintenance of existing CENP-A in chromatin, we generated stable inducible cell lines that express CENP-A-GFP upon addition of tetracycline. Both siRNA against Ung2 and expression of Vpr, which induces Ung2 degradation, produced a consistent loss of detectable Ung2 and CENP-A-GFP protein, without detectably affecting pre-existing untagged CENP-A. These results suggest that Ung2 is required for assembly of newly synthesized CENP-A, but is not required for maintenance of CENP-A that is already assembled at centromeres.

Structural Alterations and Conformational Rigidity Conferred to Centromeric Nucleosomes by the CENP-A Targeting Domain (CATD)

B. E. Black,1,2 L. E. T. Jansen,3 D. R. Foltz,7 P. S. Maddox,1 D. W. Cleveland2; 1Biochemistry and Biophysics, University of Pennsylvania School of Medicine, Philadelphia, PA, 2Ludwig Institute for Cancer Research, UCSD, La Jolla, CA

CENP-A targets the chromosomal region of its own propagation is not understood. Here we show, using fluorescent pulse-chase experiments that CENP-A remains stably associated with centromeres through multiple cell divisions and is equally partitioned among sister centromeres generated during S phase. Strikingly, loading of new CENP-A on replicated centromere DNA does not take place until after cells have entered the next G1 phase. We further show that passage through mitosis, proceeding normally or by artificially bypassing the mitotic checkpoint, is required for CENP-A assembly into centromeric chromatin. These findings demonstrate a direct coupling between cell cycle progression through mitosis and the assembly of the next generation of centromeres.”

1501

Propagation of Centromeric Chromatin Requires Exit from Mitosis

L. E. T. Jansen, B. E. Black, D. R. Foltz, D. W. Cleveland, Ludwig Institute for Cancer Research, La Jolla, CA

Centromeres direct chromosomal inheritance by providing the foundation for the assembly of the kinetochore, a large multi-protein complex required for spindle microtubule attachment at cell division. CENP-A, a histone H3 variant, assembles with histone H3, independent of DNA template. Substitution of the CATD into histone H3 generates the same more rigid nucleosome as does CENP-A. In human cells, while depletion of CENP-A is lethal, recruitment of normal levels of kinetochore proteins, centromere-generated microtubule attachment, and viability can be rescued by this chimeric H3 containing the CATD. The CATD is confined to the structured “core” of the nucleosome, comprised of the loop 1 and alpha-2 helix of the CENP-A histone fold domain, demonstrating that much (if not all) of the essential features of CENP-A are within the rigid core of the nucleosome. Together, these data support a model of centromere identity maintained by a unique nucleosome structure that serves to distinguish the centromere from the rest of the chromosome.

1502

Mapping the Assembly Pathways That Specify Formation of the Trilaminar Kinetochore Plates in Human Cells

S. Liu,2 J. Rittere,7 S. Jablonski,1 J. Famulski,1 G. Chan,7 T. Yen1; 1Cellular and Molecular Medicine, UCSD, La Jolla, CA, 2Biology, UCSD, La Jolla, CA, 3Molecular Biology, TSRI, La Jolla, CA, 4Faculty of Medicine, NTNU, Trondheim, Norway, 5Moores Cancer Center, UCSD, La Jolla, CA

While the physical nature of the epigenetic mark defining the location of the centromere on the chromosome is not known, nucleosomes in which CENP-A replaces histone H3 are at the foundation of the centromeric chromatin. Hydrogen/deuterium exchange mass spectrometry is now used to show that assembly into nucleosomes imposes stringent conformational constraints, reducing solvent accessibility in almost all histone regions by >3 orders of magnitude. Nucleosomes assembled with CENP-A are substantially more conformationally rigid than those assembled with histone H3, independent of DNA template. Substitution of the CATD into histone H3 generates the same more rigid nucleosome as does CENP-A. In human cells, while depletion of CENP-A is lethal, recruitment of normal levels of kinetochore proteins, centromere-generated microtubule attachment, and viability can be rescued by this chimeric H3 containing the CATD. The CATD is confined to the structured “core” of the nucleosome, comprised of the loop 1 and alpha-2 helix of the CENP-A histone fold domain, demonstrating that much (if not all) of the essential features of CENP-A are within the rigid core of the nucleosome. Together, these data support a model of centromere identity maintained by a unique nucleosome structure that serves to distinguish the centromere from the rest of the chromosome.

Understanding the Arrangement of Structural Kinetochore Proteins within a Kinetochore-Microtubule Attachment Site in Budding Yeast

A. Joglekar, D. Bouck, J. Molk, K. Bloom, E. Salmon; University of North Carolina, Chapel Hill, NC

The eukaryotic kinetochore is a complex protein structure comprised from more than 60 different proteins. Understanding the mechanism by which this protein assembly regulates microtubule polymerization dynamics and generates force requires knowledge of the three dimensional architecture of kinetochore proteins within the kinetochore-microtubule attachment. Budding yeast with only one microtubule attachment per kinetochore provides an ideal model system for studying the kinetochore-microtubule attachment. Using quantitative fluorescence microscopy of representative proteins from each essential kinetochore protein complex in budding yeast, we have counted the copy number of each protein complex within a kinetochore-microtubule attachment. We find that the attachment site is composed of a standardized number of structural proteins, which ranges from one or two for inner kinetochore proteins such as Mtr2p (hCENP-C) to more than 16 for the outer kinetochore complex DAM/DASH. To determine the localization of these proteins within the attachment, we are currently adapting the Simultaneous High Resolution Colocalization (SHREC) technique for use in vivo. SHREC is used to measure nanometer scale distances between two fluorophores emitting different wavelengths by simultaneous two-color imaging and subsequent localization of each fluorophore with high resolution. Yeast cells expressing two kinetochore proteins tagged with GFP and mCherry can be arrested in mid-anaphase for two-color imaging of single kinetochores. We will use SHREC imaging and analysis to localize the centroid of each of the two kinetochore protein clusters with nanometer scale accuracy. This will allow us to measure the relative axial localization of kinetochore proteins within a kinetochore-microtubule attachment. Combined
with biochemical and structural data, the copy numbers and localization data for structural kinetochore protein complexes will allow us to compile a high resolution structural description of the protein assembly interfacing centromeric DNA and a microtubule plus-end.

1504

The CENP-H/I Complex Proteins Are Required for Faithful Chromosome Segregation in Vertebrate Cultured-Cells and Are Essential for Early Development in Mice

T. Fukagawa,1 M. Okada,1 I. M. Cheeseman, 2 T. Hori1; 1Department of Molecular Genetics, National Institute of Genetics, Mishima, Shizuoka, Japan, 2Ludwig Institute for Cancer Research, La Jolla, CA

Chromosome segregation in eukaryotes requires a multi-protein structure termed the kinetochore, which assembles on centromeric DNA to mediate the binding of spindle microtubules to chromosomes and chromosome movement. Several components of the kinetochrome, including CENP-A, CENP-C, CENP-H, CENP-I, and the Mis12 complex proteins, have been identified. However, comparison to budding yeast kinetochores, where more than 60 kinetochore proteins have been identified, suggests that other components of the vertebrate kinetochore remain to be isolated. To identify additional vertebrate kinetochore components, we utilized two parallel biochemical strategies to isolate a multi-subunit complex, which includes the established kinetochore components CENP-H and CENP-I and nine other proteins (CENP-K, -L, -M, -N, -O, -P, -Q, -R, -50), from both human and chicken cells (Okada et al., Nature Cell Biol., 2006). Here, we present data for these proteins using chicken and human DT40 knockout and RNA interference analysis in human cells. Our results demonstrate that the CENP-H1 complex can be divided into three functional sub-complexes, each of which is required for chromosome alignment and faithful chromosome segregation. Interestingly, DT40 knockout of one sub-complex (CENP-O class) were not lethal: however, our live cell observations found that the time for these knockout cells to complete mitosis is longer than that for wild-type cells. We also observed severe mitotic defects in these knockouts with apparent premature sister chromatid separation when the mitotic checkpoint was activated, indicating that CENP-O class proteins are required for recovery from spindle damage. To examine the function of CENP-O class proteins in the organismal context, we generated knockout mice of CENP-50, a member of CENP-O class proteins. Surprisingly, CENP-50 gene-disrupted mice could not survive beyond day 7.5 postcoitus due to accumulation of mitotic errors. Thus, although CENP-50-deficient DT40 cells are viable, CENP-50 is essential for centromere function during early embryogenesis.

Biological and Functional Analysis of Human CENP-H/CENP-I and CENP-H Kinetochore Complexes

S. E. McClelland1, S. Borusu2, P. Meraldi2, A. D. McAins2; 1Chromosome Segregation, Marie Curie Research Institute, Oxted, United Kingdom, 2Institute for Biochemistry ETH Zurich, Zurich, Switzerland

A fundamental challenge in cell biology is to determine by which mechanisms kinetochores assemble on centromeric DNA, capture microtubules and ultimately regulate subsequent chromosome movement during cell division. Human kinetochores are complex molecular machines that are 80-100-nm thick, 0.5-1.0-µm in diameter and mediate the coordinated attachment to ~30 microtubules. The sequence of events including centromere attachment and spindle checkpoint signaling. As a first step, we have determined the biophysical properties of multiple kinetochore proteins using gel-based gradient centrifugation and size-exclusion chromatography. From these experiments we have determined that kinetochores are comprised of diverse sub-complexes, including the previously characterized NDC80 and MIND/Mis12 complexes, which are required for microtubule attachment and force generation respectively. We have also determined that the recently identified nucleosome-associated complex (NAC) is assembled from a set of smaller sub-complexes. These include a 100KDa CENP-H containing complex, an 89KDa Sim4R-Fta1R complex and a Chl4R dimer. Consistent with these findings, inactivation of Chl4R or CENP-H by RNAi-mediated protein depletion leads to distinct mitotic defects. Thus, the Chl4R and CENP-H sub-complexes represent distinct functional units within the kinetochore which implies that the NAC can modulate multiple kinetochore functions during chromosome segregation.

1506

Analysis of Cenp-h Function in Kinetochore Assembly

B. Moree, A. Straight; Biochemistry, Stanford University, Stanford, CA

During mitosis, kinetochores function as a molecular scaffold physically linking chromosomes to the dynamic microtubules of the mitotic spindle apparatus. Assembly of functional kinetochores requires localization of more than 60 proteins to the centromere, yet the coordination of the events necessary for kinetochore assembly is poorly understood. The centromere, a specialized chromatin domain on each chromosome, serves as the assembly substrate for the loading of diverse kinetochore protein complexes essential for mitotic checkpoint activity, microtubule binding, and chromosome segregation. Central to building functional kinetochores is the loading of the essential centromere protein CENP-H at centromeres. CENP-H constitutively associates with centromeres in somatic cells and functions as a molecular bridge between centromeric chromatin and the microtubule binding proteins of the kinetochore. To determine the role of CENP-H in centromeric chromatin formation and mitotic kinetochore assembly, we are using Xenopus laevis egg extracts to follow kinetochore assembly in vitro. Xenopus egg extracts are arrested at metaphase of meiosis II and assemble functional meiotic spindles when sperm chromatin is added to the extract. Cenp-h is present in Xenopus egg extract by western blot but does not localize to centromeres of meiosis II chromosomes suggesting that it may be dispensable for kinetochore function in meiosis II. When sperm chromatin is added to extracts made from mitotically activated Xenopus eggs, Cenp-h is assembled at centromeres. These results suggest that Cenp-h is assembled only on mitotic centromeres and may reflect fundamental differences in the composition of meiotic and mitotic kinetochores.

Structural and Functional Analysis of the Human Zw10 Interacting Protein, Hzwint-1

L. J. Vos, G. K. T. Chan; Oncology, University of Alberta, Edmonton, AB, Canada

The human hzw10 interacting protein, hzwint-1, is a novel kinetochore protein originally identified in a yeast 2-hybrid screen for interactors of Zw10 (Starr et al. 2000). Hzw10 and hrod form a complex which recruits dynein/dynactin to the kinetochore and is essential components of the mitotic checkpoint (Chan et al. 2000). Hzwint-1 localizes to the kinetochore in prophase, prior to hzw10 localization, and remains at the kinetochore until anaphase, after hzw10 has dissociated. In addition to hzw10, we have found that hzwint-1 interacts with hHec1, a component of the conserved Ndc80 complex, and hMis12, a conserved inner kinetochore protein, in yeast 2-hybrid assays. As well as interacting with hHec1 and hMis12, hzwint-1 has similar dynamics as examined by fluorescence recovery after photobleaching. As such we propose that hzwint-1 is a structural protein to which hzw10 binds. To test this hypothesis, we are performing mutagenesis based domain mapping to determine which regions of hzwint-1 are necessary for kinetochore localization and which are required for the interaction with hzw10, hHec1 and hMis12. We have produced 16 truncation mutants, 23 random-insertion mutants and 25 site-directed mutants. By transferring these mutants into a green fluorescent protein fusion vector and transiently transfecting HeLa cells, we have determined that the N-terminal of hzwint-1 is crucial for kinetochore localization. By employing the mutants in a yeast 2-hybrid assay we are mapping the hzw10, hHec1 and hMis12 interaction domains. Yeast 2-hybrid results are confirmed with GST pull-down assays. We are analyzing the effect of these hzwint-1 mutants have on kinetochore assembly, chromosome segregation and the mitotic checkpoint in cells that have reduced level of endogenous hzwint-1 proteins by siRNA knockdown.

HZW10 Response to the Loss of Tension Is Dependant on Aurora B Kinase Activity

J. K. Famulski, G. K. T. Chan; Oncology, University of Alberta, Edmonton, AB, Canada

Faithful chromosome segregation depends on the bi-polar attachment of microtubules (MTs) at kinetochores leading to chromosome alignment at the metaphase plate. The mitotic checkpoint is thought to monitor both kinetochore-MT attachments as well as tension across sister kinetochores by accumulating checkpoint proteins at kinetochores. Here we report the finding that human Zeste White 10 (hzw10), a known mitotic checkpoint protein, accumulates on kinetochores in response to the loss of tension. Using immunofluorescence, we established that once chromosomes align at the metaphase plate, and are therefore under equal tension, hzw10 signal is diminished at kinetochores. However, when HeLa cells were treated with low dose Taxol which is known to inhibit MT dynamics and therefore prevent tension across sister kinetochores (Lampson et al. 2005), we observed an accumulation of hzw10 at metaphase kinetochores. We have verified this finding through time-lapse microscopy using a stable HeLa cell line expressing EGFP-hzw10 treated with low dose taxol. Furthermore, we have observed that EGFP-hzw10 kinetochore dynamics are retarded in cells treated with low dose taxol. Hzw10R1 is an Aurora B checkpoint protein that is also known to accumulate at kinetochores lacking tension and its accumulation has been shown to be dependent on Aurora B kinase activity (Hauf et al. 2003; Ditchfield et al. 2003). We have tested how the Aurora B kinase activity, whether Aurora A kinase activity or Aurora B kinase activity, plays a role in the response of hzw10 to the loss of tension. Interestingly, we find that inhibition of Aurora B, by treatment with ZM447439, prevents the accumulation of hzw10 at kinetochores in the presence of low dose taxol. This suggests that Aurora B function is required for Hzw10R1 and hzw10 accumulation at kinetochores in response to the loss of tension. We therefore conclude that hzw10 accumulates at kinetochores lacking tension in an Aurora B kinase dependent manner.
Structural and Functional Analysis of the Kinetochore Protein, hZwilch

S. Shoba, 1 S. Cheng, D. McDonald, 2 H. Cho, 3 G. Chan, 3 Department of Oncology, Faculty of Medicine & Dentistry, Edmonton, AB, Canada; 3Department of Biochemistry & Chronic Inflammatory Disease for Research Center, Ajou University School of Medicine, Suwon, Republic of Korea.

During mitosis, the kinetochore interacts with the microtubules and mediates chromosome movement to ensure accurate chromosome segregation. The kinetochore is also important in mitotic regulation as a docking site for mitotic checkpoint components. hZwilch localizes to kinetochores during metaphase as expected. Using transient transfection and fluorescence microscopy to analyze the Zwilch mutants, we found that both the N and C-terminal regions are important for kinetochore localization.

Molecular Dissection of Mammalian Kinetochore Proteins Identifies a Novel CENP-E-interacting Protein, Cenp-V, Essential for Mitotic Checkpoint

J. Du, 1 S. Hua, 1 X. Cai, 1 D. Liu, 1 Z. Guo, 1 J. Li, 1 X. Zhou, 2 A. Shaw, 2 M. Zhu, 1 S. Liang, 3 Z. Cheng, 1 D. Cleveland, 1 X. Yao, 2 1Cellular Dynamics, Heifei National Laboratory, Heifei, China; 2Physiology, Morehouse School of Medicine, Atlanta, GA; 3Proteomics, Human Normal University, Changsha, China; 4Cell Biology, Ludwig Institute for Cancer Research, La Jolla, CA.

Our previous studies show that mitotic kinesin CENP-E represents a link between attachment of spindle microtubules and the mitotic checkpoint signaling cascade (NCB 2: 484-491). However, the molecular mechanism underlying CENP-E-mediated spindle checkpoint signaling remains elusive. To identify the proteins that participate in the CENP-E-mediated spindle checkpoint signaling, we carried out proteomic search for kinetochore proteins associated with CENP-E. To this end, mitotic extracts from HeLa cells stably expressing FLAG-CENP-E were purified using a FLAG antibody-affinity chromatography. The proteins selectively bound to CENP-E were removed from the gel and analyzed by LC-MS/MS. Of several known proteins selectively bound to CENP-E, the presence of a 59 kDa previously uncharacterized protein was novel and particularly exciting. Our immunofluorescence microscopic analysis shows that this protein co-distributes with CENP-E to the kinetochore of HeLa cells during early prometaphase and departs from kinetochores upon the metaphase alignment. We therefore designated it as CENP-V (centromere-associated protein V). Using immunoelectron microscopy, CENP-V is shown to target to the outermost region of the developing kinetochores upon the nuclear envelope breakdown. Throughout chromosome congression, CENP-V is a constituent of the corona fibers, extending up to 90 nm away from the kinetochore outer plate. Our yeast two hybrid assay revealed that the C-terminal tail of CENP-E binds to CENP-V, which was confirmed by a pull-down assay using bacterially recombinant proteins. Significantly, depletion of CENP-V abrogates the localization of CENP-E to the kinetochore and results in chromosome mis-segregation. Real-time analyses show that elimination of CENP-V caused a substantial mitotic arrest. In addition, the tension across the sister kinetochore is reduced in the absence of CENP-V, suggesting that CENP-V links spindle microtubules to kinetochores. Taken together, our studies strongly support a model in which CENP-V functions together with CENP-E in spindle checkpoint signaling cascades at the kinetochore.

Tripin Is a New Inner Centromere Protein That Recruits MCAK and Prevents Aberrant Kinetochore Attachments

H. Huang, 1 J. Feng, 1 J. Famulski, 1 J. Rattner, 2 S. Liu, 1 G. Kao, 1 R. Muschel, 1 G. Chan, 1 T. Yen, 1 Fox Chase Cancer Center, Philadelphia, PA; 1Dep. of Experimental Oncology, Cross Cancer Institute, University of Alberta, Edmonton, AB, Canada; 3Dep. of Cell Biology & Anatomy, Faculty of Medicine, University of Calgary, Calgary, AB, Canada.

In eukaryotes, nuclear pore complexes (NPCs) are evolutionarily conserved structures, which allow bidirectional transport of macromolecules between the cytoplasm and the nucleus. NPCs are composed of proteins termed nucleoporins, often organized in complexes. Among them, the Nup107-160 complex, which is composed of 9 nucleoporins in metazoans, plays an important role in NPCs reassembly at the end of mitosis. We previously demonstrated that a fraction of the Nup107-160 complex is targeted to kinetochores at the onset of mitosis. However, the molecular mechanisms involved in this targeting as well as the biological relevance of this mitotic-specific localization remained uninvestigated. Here, we show that one of the Nup107-160 complex subunits, Nup133, interacts with CENP-F and that CENP-F partially contributes to the targeting of the Nup107-160 complex to kinetochores. In addition, siRNA experiments revealed that the Ndc80 complex plays a key function in the recruitment of the Nup107-160 complex to kinetochores. We further demonstrate that specific mislocalization of the Nup107-160 complex from kinetochores induces a checkpoint-dependent mitotic delay. These cells showed impaired chromosome congression, reduced tension and less stable kinetochore-microtubule attachment. Current studies are underway to identify the downstream effectors of the Nup107-160 complex that may mediate its function at kinetochores.

Targeting and Function of the Nup107-160 Complex at Kinetochoreksites

M. Zuccolo, 1 A. Alves, 1 S. Bolhy, 1 J. Sibarita, 1 T. Fukagawa, 1 T. Yen, 1 X. Yao, 2 1Umr144-CNRS, Institut Curie, Paris, France; 2National Institute of Genetics and SOKENDAI, Mishima, Shizuoka, Japan.

Our previous studies show that mitotic kinesin CENP-E represents a link between attachment of spindle microtubules and the mitotic checkpoint signaling cascade (NCB 2: 484-491). However, the molecular mechanism underlying CENP-E-mediated spindle checkpoint signaling remains elusive. To identify the proteins that participate in the CENP-E-mediated spindle checkpoint signaling, we carried out proteomic search for kinetochore proteins associated with CENP-E. To this end, mitotic extracts from HeLa cells stably expressing FLAG-CENP-E were purified using a FLAG antibody-affinity chromatography. The proteins selectively bound to CENP-E were removed from the gel and analyzed by LC-MS/MS. Of several known proteins selectively bound to CENP-E, the presence of a 59 kDa previously uncharacterized protein was novel and particularly exciting. Our immunofluorescence microscopic analysis shows that this protein co-distributes with CENP-E to the kinetochore of HeLa cells during early prometaphase and departs from kinetochores upon the metaphase alignment. We therefore designated it as CENP-V (centromere-associated protein V). Using immunoelectron microscopy, CENP-V is shown to target to the outermost region of the developing kinetochores upon the nuclear envelope breakdown. Throughout chromosome congression, CENP-V is a constituent of the corona fibers, extending up to 90 nm away from the kinetochore outer plate. Our yeast two hybrid assay revealed that the C-terminal tail of CENP-E binds to CENP-V, which was confirmed by a pull-down assay using bacterially recombinant proteins. Significantly, depletion of CENP-V abrogates the localization of CENP-E to the kinetochore and results in chromosome mis-segregation. Real-time analyses show that elimination of CENP-V caused a substantial mitotic arrest. In addition, the tension across the sister kinetochore is reduced in the absence of CENP-V, suggesting that CENP-V links spindle microtubules to kinetochores. Taken together, our studies strongly support a model in which CENP-V functions together with CENP-E in spindle checkpoint signaling cascades at the kinetochore.
algorithm to find the centroids of kinetochore fluorescent speckle images to determine how the Ndc80 complex is oriented within the kinetochore at dimensions beneath the 200 nm Abbe limit of resolution in the light microscope. Metaphase HeLa cells were fixed and labeled with 9G3 to Hecl and a polyclonal antibody to Spc24. Green and red fluorescent images of secondary antibodies were collected using spinning-disk confocal microscopy and 200nm optical sections. For in-focus sister kinetochore pairs, the centroid of the Hecl fluorescent label was always outside the centroid of the Spc24 label by an average distance delta = 43±4 nm (N=120). At metaphase, sister kinetochores become pulled apart to 1-2 μm from a separation of about 0.6 μm in prophase. At metaphase, delta was independent of this two-fold variation in centromere separation indicating that under tension, all Ndc80 complexes in the kinetochore are stiff and oriented with their long axes parallel with the kMT-centromere axis. Preliminary analysis of the Hecl marker relative to GFP-CENP-A at centromeric DNA shows an average separation at metaphase sister kinetochores of 85nm, being smaller at lower and higher at lower values of centromere stretch (range: 50-110nm). This suggests that the protein linkage between CENP-A and the Ndc80 complex is compliant and tension-sensitive. Supported by NIH GM24364 and NIH GM60678.

NudC Is Required for Plk1 Targeting to the Kinetochore and Chromosome Congression
M. Nishino, Y. Kurawa, B. R. Brinkley, S. Lin, L. Yu-Lei; Department of Cell Biology, Baylor College of Medicine, Houston, TX. Program in Cell and Molecular Biology, Baylor College of Medicine, Houston, TX. Department of Cell Biology, Baylor College of Medicine, Houston, TX. Department of Molecular Pathology, The University of Texas M.D. Anderson Cancer Center, Houston, TX
The equa distribution of chromosomes during mitosis is crucial for maintaining the integrity of the genome. Essential to this process are the capture of spindle microtubules by kinetochores and the congression of chromosomes to the metaphase plate. Polo-like kinase 1 (Plk1) is a mitotic kinase that has been implicated in microtubule-kinetochore attachment, tension generation at kinetochores, tension-responsive signal transduction, and chromosome congression. The tension-sensitive substrates of Plk1 at the kinetochore are unknown. Here, we demonstrate that human nuclear distribution protein C (NudC), a 42 kDa protein initially identified in Aspergillus nidulans and shown to be phosphorylated by Plk1, plays a significant role in regulating kinetochore function. Plk1-phosphorylated NudC co-localizes with Plk1 at the outer plate of the kinetochore. Depletion of NudC reduced end-on microtubule attachments at kinetochores and resulted in defects in chromosome congression at the metaphase plate. Importantly, NudC-deficient cells exhibited mislocalization of Plk1 and the Kinesin-7 motor CENP-E from prometaphase kinetochores. Ectopic expression of wild-type NudC, but not NudC containing mutations in the Plk1 phosphorylation sites, recovered Plk1 localization at the kinetochore and rescued chromosome congression. Thus, NudC functions as both a substrate and a spatial regulator of Plk1 at the kinetochore to promote chromosome congression.

1516
BubR1 and APC/EB1 Cooperate to Maintain Metaphase Chromosome Alignment
J. Zhang, Y. Mao; Cell Biology and Pathology, Columbia University College of Physicians and Surgeons, New York, NY
Accurate segregation of generic material in mitosis requires dynamic attachment of chromosomes to spindle microtubules, which is mediated largely by kinetochores. A major question has been how kinetochores capture and maintain interactions with dynamic microtubules. Using immunodepletion from and antibody addition to Xenopus egg extracts, we show that the kinetochore protein Arc21 and the APC/EB1 tumor suppressor BubR1 forms a complex with two microtubule associated proteins (MAPs) APC (adenomatous polyposis coli) and EB1, which localizes to the ends of microtubules embedded in kinetochores. We further demonstrate that both APC and EB1 are essential for metaphase chromosome congression. These findings support a model in which BubR1 kinase may directly regulate APC/EB1 functions involved in stable kinetochore microtubule attachment.

The Role of Baculovirus WASP-like Protein P78/83 in Viral Replication
T. Ohkawa, E. D. Goley, J. Mancuso, W. E. Cande, J. A. D'Alessio, J. B. Woodruff, L. E. Volkman, M. D. Welch; Molecular and Cellular Biology, University of California, Berkeley, CA, Plant and Microbial Biology, University of California, Berkeley, CA
Of the many pathogens that exploit the actin cytoskeleton during infection, baculoviruses are remarkable for the unique actin rearrangements they require for replication. Early in infection, baculovirus nucleocapsids induce actin cable formation in the cytoplasm of the host cell, a process hypothesized to mediate efficient translocation to the nucleus, which is the site of viral replication. Later, baculoviruses induce the polymerization of actin within the nuclei of infected cells, an apparently novel phenomenon that is essential for nucleocapsid assembly. We report that actin filaments in the nuclei of cells infected with Autographa californica Multiple Nucleopolyhedrovirus (AcMNPV) are highly dynamic, turning over with a half-life similar to filaments at the leading edge of motile cells. We demonstrate that dynamic nuclear actin polymerization by AcMNPV depends on its p78/83 protein, which functions as a WASP-like activator of Arp2/3-mediated actin polymerization. Both p78/83 and Arp2/3 complex translocate into the nucleus during infection, coincident with the presence of nuclear actin filaments. Mutations in p78/83 that abolish its in vitro nuclear-polymerizing activity prevent both nuclear actin polymerization and virus progeny production. Furthermore, silencing the expression of an Arp2/3 subunit by RNA interference results in a significant drop in viral titer. Using electron microscopy, we show that defects in p78/83 and Arp2/3-mediated actin polymerization result in aberrant nucleocapsid morphogenesis and envelopment and packaging of virions. Actin nucleation by Arp2/3 complex and p78/83 in the nucleus is therefore essential for AcMNPV virion assembly and replication. We anticipate that further study of this novel mode of pathogenesis will reveal elusive regulation and function of nuclear actin and actin regulatory factors in both pathogenic and normal cellular conditions.

Regulation of the Proteasome by Yin6/int6 and an Actin Regulatory Protein, Arc21
R. Cabrera, J. Suo, E. C. Chang; Molecular and Cellular Biology, Baylor College of Medicine, Houston, TX
The “int” genes were originally identified as loci where mouse mammary tumor virus (MMTV) integration induces breast tumor formation. Nearly all “int” genes have well characterized molecular functions that are critical for oncogenesis; in contrast, the role of int6 in tumorigenesis remains largely unknown. In order to better understand how int5 can mediate cancer formation, we have recently uncovered a highly conserved function of int6 by characterizing the int6 ortholog, named yin6, in the genetic model system fission yeast. Our data suggest that yin6 regulates localization and assembly of the proteasome. Inactivation of int6 weakens the proteasome leading to chromosome instability and abnormal mitosis. To further decipher how int6 regulates proteasome localization and assembly, our lab performed a screen to isolate S. pombe CDNAs that, when overexpressed, rescue the growth defect of yin6 null (yin6Δ) cells. This study focuses on arc21, encoding a potential subunit of the Arp2/3 complex, which has been implicated in the regulation of actin polymerization. Our data suggest that arc21 is an essential gene and its inactivation is associated with loss of cell polarity. Furthermore, our data show that an Arc21-GFP fusion protein colocalizes with F-actin, a pattern that can be disrupted by the actin polymerization inhibitor Latrunculin A. These results support the hypothesis that Arc21 binds actin and regulates actin function. Overexpression of Arc21 can rescue the proteasome defects observed in yin6Δ cells. Additionally, yin6Δ cells show an aberrant localization of Arc21-GFP, and, like many mutants defective in F-actin, are hypersensitive to actin polymerization inhibitors. These data suggest a model in which yin6 mediates proteasome localization and assembly by acting via arc21 and the actin cytoskeleton.

Actin Bundling Protein Fascin Promotes Cancer Metastasis
D. Vignjevic, M. Schoumacher, K. Janssen, F. elMarjou, D. Louvard, S. Robine; Institute Curie, Paris, France, Technische Universität, München, Germany
Cancer cells become metastatic by acquiring a motile and invasive phenotype. This step requires remodelling of the actin cytoskeleton and the expression of exploratory, sensory organelles known as filopodia. Efficient bundling of actin filaments within filopodia, is critical for filopodia function. Fascin was the only actin bundling protein found to be localized along the whole length of all filopodia and its targeted depletion by siRNA lead to the substantially reduced number of filopodia. Using qRT-PCR and immunohistochemistry, we found that fascin expression was significantly increased in human and mouse intestinal tumors compared with normal epithelium, in tumor stage depended manner. Expression was unchanged in benign lesions and early tumor stages, but significantly upregulated in invasive and metastatic lesions. A possible role of fascin on the cell growth of human adenocarcinoma cells HT29 were tested: 1) ex vivo, in cell culture assays and 2) in vivo, by subcutaneous injection of cells into SCID mice. In both cases cell proliferation was not altered by fascin expression. Next, we tested whether fascin can promote invasion and migration: 1) in vitro, in matrigel coated trans-filter assays and 2) in vivo, by tail vein injection of cells into SCID mice. Fascin expressing cells had higher migrational potential in vitro; and in vivo led to more frequent distant metastasis in the lungs. Moreover, mice injected with fascin positive cells developed severe paralysis, which was caused by invading tumors along the spine. To be able to follow all the steps of metastasis in vivo, we designed transgenic mouse metastasis model that express active form of K-ras, mutated form of APC and fascin in the intestine. In conclusion, we propose that up-regulation of fascin, by promoting the formation of filopodia, could be a significant component in the acquisition of invasive phenotype in carcinomas.
Aip/ Deletion in Mutant Actin Yeast Strains

M. McKane, K. Wen, P. Rubenstein; Biochemistry, University of Iowa College of Medicine, Iowa City, IA

Proper eukaryotic cellular function requires careful regulation of actin cytoskeletal assembly and disassembly. This regulation requires a fine balance between filament stabilization and fragmentation or severing. A major F-actin severing protein is cofilin. Yeast cofilin is a relatively poor severing protein whose activity is somehow activated by Aip1. We constructed yeast/muscle hybrid actins in which muscle actin-specific residues were substituted for their yeast counterparts in subdomains 1 and 2. These substitutions cause yeast phenotypes that seem to arise from enhanced filament fragmentation. If true, decreasing severing protein activity may rescue the phenotypes caused by the mutant actins. To test this hypothesis, we introduced into an aip1 strain a mutant yeast actin 3A/casubl1 which carries all 18 muscle-specific subdomain 1 residues except with 3 instead of 4 acidic N-terminal residues normally found in muscle actin. This F-actin fragments much more readily than WT actin. With this actin, Aip1 deletion partially rescues polarized actin structures and the endocytosis defect associated with the actin, and makes the cells sensitive to growth at 37°C instead of 37°C-lethal. Repetition of the experiment in an aip1/Δ background with the additional insertion of the three subdomain 2 substitutions into 3Ac/casubl1 actin caused cell death. Thus, increased F-actin instability can be at least partially overcome by decreased filament severing. We repeated the experiment with H372R actin. The original H372R strain is characterized by thickened actin cables, loss of mitochondrial function and mitochondrial DNA, and hypervacuolated vacuoles. We thought deletion of Aip1 in the H372R strain might be lethal because of what appeared to be the enhanced stability of the actin. Interestingly, with this actin, aip1/Δ prevents loss of mitochondrial function. There are aggregated actin patches, and abnormal vacuole morphology persists. This result implies a role for Aip1 other than as a facilitator of yeast cofilin function.

Overexpression of Nebulin Fragments in Spreading Embryonic Cardiomyocytes

Z. Panavici, X. Deng, M. Esham, C. L. Moncman; Molecular & Cell Biochemistry, University of Kentucky, Lexington, KY

Nebulin is a large actin binding protein that in concert with tropomodulin plays an important role in regulating the lengths of thin filaments in vertebrate skeletal muscle. Since its identification in the 1970s, nebulin was thought to be expressed only in skeletal muscle; however, in recent years there is a growing body of evidence that indicate the expression of nebulin isoforms in vertebrate cardiac tissue. To investigate the role of nebulin during myofibrilligenesis in spreading cardiomyocytes, we have expressed fragments of the nebulin cDNA tagged with the jellyfish green fluorescent protein (GFP) in chicken embryonic cardiomyocytes. Nebulin fragments from both the superrepeats and single repeats were expressed minus and plus the nebulin linker region. Expression and incorporation of the nebulin fragments was monitored by confocal microscopy over a three day timecourse post transfection and compared with the distribution of cardiac sarcomeric protein by immunolabeling. We find that expression of nebulin modules derived from the superrepeats displayed a diffuse to punctate distribution. Occasional cells exhibited alignment of the recombinant protein along the myofilaments at early timepoints. By 3 days postdaylighting, the majority of the expressing cells contained the nebulin superrepeat along the thin filaments, but not within the Z-line. Nebulin modules from the single repeats incorporate into the cardiac myofilaments at the level of the Z-line. Expression of the nebulin superrepeat conjoined with the nebulin linker did not alter the punctate distribution of the modules. However expression of the single repeats abutted to the nebulin linker resulted in both a B-band and Z-line distribution. The expression of the superrepeats and the single repeats resulted in disruption of the myofilament network. These data indicate that nebulin fragments, like nebulin, alter myofilament organization.

Functional Analysis of Cyclase-associated Proteins in Caenorhabditis elegans

K. Ono, S. Ono; Pathology, Emory University, Atlanta, GA

Cyclase-associated protein (CAP) is a conserved actin monomer-binding protein that is also implicated in mediating several signal transduction pathways to the actin cytoskeleton. CAP promotes ADF/cofilin-dependent actin filament turnover by enhancing dissociation of actin monomers from ADF/cofilin and recycling actin monomers for polymerization. Unicellular organisms have only one CAP gene. However in mammals, two CAP isoforms, CAP1 and CAP2, are present, but their functional difference is not understood. The nematode Caenorhabditis elegans has two CAP genes, cas-1 and cas-2, on separate chromosomes. CAS-1 and CAS-2 proteins are 42 % identical in their amino acid sequences and show 25-38 % identity with CAP proteins from other species. In particular, CAS-1 and CAS-2 exhibit high degrees of similarity to other CAP proteins in their C-terminal halves, which contain a proline-rich sequence and an actin-binding site. cas-1 knockout animals are homozygous lethal, while cas-2 knockouts are homozygous viable. Further phenotypic characterization revealed that the cas-2 mutant has disorganized rachis, which is the actin-rich structure in the core of hermaphroditic gonad. They have relatively normal rachis as young adults. However, as they become gravid adults, the actin-rich lining of the rachis was progressively diminished, and large actin rods were formed inside the rachis. UNC-60A, a non-muscle ADF/cofilin isoform, was expressed in the rachis and localized to small aggregates in wild-type, while in the cas-2 mutant, UNC-60A was associated with the large actin rods. These results suggest that CAS-2 promotes dissociation of actin from UNC-60A and regulates actin dynamics in the gonad, and that CAS-1 and CAS-2 may have distinct in vivo functions.

Interactions of APC with the Actin Cytoskeleton and Direct Regulation by the Microtubule Plus End Tracking Protein EB1

J. B. Mosley, F. Bartoloni, K. Okada, Y. Wen, G. G. Gundersen, B. L. Goode; Anatomy and Cell Biology, Columbia University, New York, NY

Adenomatous polyposis coli (APC) is a 310 kDa multi-domain protein that is truncated in most colorectal cancers, indicating that functions associated with its C-terminals are required for tumor suppression. The C-terminals mediate binding to microtubules and the microtubule plus-end tracking protein EB1, and APC localizes to microtubule plus ends in living cells. In addition, APC has been localized to actin-rich regions of cells, but the mechanism and functional significance of this localization has remained unclear. Here, we show that human APC binds directly to filamentous F-actin and characterize the dynamic exchange of APC between the actin and microtubule cytoskeletons. In biochemical assays, a C-terminal fragment of human APC (APC-basic) directly associates with and bundles F-actin, while CAP1 and CAP2, are present, but their functional difference is not understood. The nematode Caenorhabditis elegans has two CAP genes, cas-1 and cas-2, on separate chromosomes. CAS-1 and CAS-2 proteins are 42 % identical in their amino acid sequences and show 25-38 % identity with CAP proteins from other species. In particular, CAS-1 and CAS-2 exhibit high degrees of similarity to other CAP proteins in their C-terminal halves, which contain a proline-rich sequence and an actin-binding site. cas-1 knockout animals are homozygous lethal, while cas-2 knockouts are homozygous viable. Further phenotypic characterization revealed that the cas-2 mutant has disorganized rachis, which is the actin-rich structure in the core of hermaphroditic gonad. They have relatively normal rachis as young adults. However, as they become gravid adults, the actin-rich lining of the rachis was progressively diminished, and large actin rods were formed inside the rachis. UNC-60A, a non-muscle ADF/cofilin isoform, was expressed in the rachis and localized to small aggregates in wild-type, while in the cas-2 mutant, UNC-60A was associated with the large actin rods. These results suggest that CAS-2 promotes dissociation of actin from UNC-60A and regulates actin dynamics in the gonad, and that CAS-1 and CAS-2 may have distinct in vivo functions.

A Role for Tropomodulin 3 in Polarization and Junction Formation in Epithelial Cells

K. L. Weber, R. B. Nowak, R. S. Fischer, V. M. Fowler; The Scripps Research Institute, La Jolla, CA

The function of an epithelial monolayer is dependent on the transformation of individual cells into a polarized epithelial sheet, within which each cell has a tall, cuboidal morphology with clearly defined apical and basal surfaces, and lateral membranes which form junctions with neighboring cells. Cell junctions ultimately integrate the cytoskeletons of adjacent cells via the thin filaments, but not within the Z-line. Nebulin modules from the single repeats abutted to the nebulin linker resulted in both a B-band and Z-line distribution. The expression of the superrepeats and the single repeats resulted in disruption of the myofilament network. These data indicate that nebulin fragments, like nebulin, alter myofilament organization.

Bcr-Abl Alters Cellular Adhesion and Actin Dynamics during Development in Drosophila melanogaster

T. L. Stevens, 1 K. D. Miller, 1 N. B. Artabazon, 1 S. E. Tittermary, 1 M. Peifer 1; 1Biology, Randolph-Macon College, Ashland, VA; 2Biology, University of North Carolina at Chapel Hill, Chapel Hill, NC

Bcr-Abl is an activated fusion protein that has been linked to leukemia in humans. Bcr-Abl results from a reciprocal translocation between chromosomes 9 and 22 that fuses sequences of the bcr gene to the abl gene. Relative to its normal, cellular counterpart c-Abl, Bcr-Abl has increased tyrosine kinase activity. The exact cellular events that lead to cancer are unclear, but studies in culture suggest that altered actin dynamics and aberrant cell movement in cells expressing Bcr-Abl may be key events in promoting leukemia. In order to examine the effects of Bcr-Abl in the context of an organism, we used transgenic flies carrying the bcr-abl oncogene. We found that Drosophila embryos expressing Bcr-Abl in the epithelium die with defects in processes that require cell shape changes, migration, and regulated cellular adhesion. Time-lapse studies revealed that expression of Bcr-Abl drastically altered actin-based projections in migrating epithelial cells. Fewer filopodia were observed in cells that express Bcr-Abl; they were replaced with lamellipodia, and these lamellipodia persisted for longer periods of time. We hypothesize that some of the effects of Bcr-Abl may be through the phosphorylation of targets that regulate actin dynamics and cellular adhesion and that phosphorylation regulates their function. In support of this, Bcr-Abl localized primarily to cell junctions, where overall levels of tyrosine phosphorylation were increased. One substrate of Ab1 tyrosine kinase activity that is altered by the presence of Bcr-Abl is the actin regulator, Enabled (Ena). In embryos expressing Bcr-Abl, we observed increased tyrosine phosphorylation of Ena and other proteins that associate with Ena. Furthermore, Ena was mis-localized from cell junctions and from the leading edge of migrating cells in embryos expressing Bcr-Abl. These results suggest that at least some of the effects of Bcr-Abl on cell migration may be through the actin regulator Ena.

Sulfur mustard (SM, bis-2-chloroethyl sulfide) produces large, debilitating blisters at the epidermal-dermal junction of human skin. It also produces corneal keratopathy and disruption of airway epithelium, typically after a clinical latent phase of 8-24 hours. Almost 90 years after SM was first used as a chemical weapon in WW I, we are beginning to detect and understand the earliest structural lesions and mechanisms that precede this latent expression of clinical pathology. Using cultures of human epidermal keratinocytes (HEK), corneal epithelial cells (HCEC-3), and techniques of multiphoton microscopy, immunofluorescent imaging, and gene-array analysis, we have shown that exposure to SM (400 μM x 5 min) induces early (≤ 1 h) progressive disruption in the organization of cytoskeletal F-actin. Results from 3 HEK postexposure profiles confirm that the early effects on F-actin and on related changes in specific mRNA expression are remarkably and statistically reproducible. Multidimensional scaling of Affymetrix gene-chip results showed that SM induces a disparate and progressive increase in abnormal gene expression that begins gradually in the first hour then accelerates dramatically in the second hour. Image-based searches showed that abnormal F-actin polymerization precedes significant 2-h decreases in the mRNA signals for Cdc42, a small GTP-binding protein that impacts F-actin polymerization. Early changes in F-actin were, however, coincident with significant changes in mRNA signals for some “upstream activators” (guanine nucleotide exchange factors) and some “downstream targets” of Cdc42 like PEX-β (ARIGEF-7), and an occasional stress related gene, e.g., PAK-2. Our results indicate that early effects of SM disrupt structural and functional feedback loops in an F-actin/Cdc42/PIX-β signaling pathway.

F-actin Column Chromatography as a Tool to Analyze Modification of Actin-binding Proteins

A. G. Terasaki, 1 S. Sakamoto, 1 J. Suzuki, 1 H. Suzuki, 1 H. Hashimoto, 1 K. Ohashi; 1Graduate School of Science and Technology, Chiba University, Chiba, Japan, 2Faculty of Science, Chiba University, Chiba, Japan

F-actin affinity chromatography has been used to analyze proteins associated with the actin cytoskeleton. We found previously identified actin-binding proteins such as Arp2/3 complex and novel actin binding proteins (e.g., lasp-2) were enriched in eluates column eluents of chicken brain (Terasaki et al., 2002 and Terasaki et al., 2004). Lasp-2 has putative phosphorylation sites and some components of Arp2/3 complex also have been suggested to exist as phosphorylated form. The modification would affect their activities and complex formation. In this approach, we analyzed isoellectric points of lasp-1, lasp-2, p34-Arc, and p21-Arc in F-actin column eluates because proteins in any modification or specific isoforms might have high affinity to actin and bind to the column specifically. 2D electrophoresis and immunoblotting analysis revealed that all of the proteins showed multiple isoellectric points in chicken brain and specific spots of each protein increased in F-actin column eluates. These findings suggest that the F-actin binding column would be a tool to analyze relationship between modification and activity of actin-binding proteins.

Anthrax Lethal Toxin Paralyses Actin-based Motility by Blocking Phosphorylation of Hsp 27

R. During; Medicine/Infectious Disease, University of Florida, Gainesville, FL

The Bacillus anthracis lethal toxin (LT) blocks the host’s immune response permitting fatal bacteremia. We have discovered that LT paralyzes human neutrophils, preventing them from reaching the site of anthrax infection. LT accomplishes this task by blocking the formation of actin filaments required for the shape changes associated with amoeboid movement. Similarly, when HeLa cells are exposed to LT the ability of the intracellular pathogen Listeria monocytogenes to induce actin filament branching through the Arp2/3 complex is markedly impaired. To identify the involvement SPIN90 in the regulation of dendritic actin networks. Activation of SPIN90 by aluminium fluoride promotes the formation of lamellipodia and its association with cytoskeleton components. SPIN90 can directly bind to F-actin which is mediated via end of C terminus, stimulate actin polymerization, and induce actin filament branching through the Arp2/3 complex. Furthermore, deletion of F-actin binding region on failed to localize at the membrane edge and impairs its capacity to promote the formation of lamellipodia, suggesting that F-actin binding region is essential for the formation of the actin cytoskeleton and regulation of actin cytoskeleton at the leading edge of cells.

282
WH2 domain located at the C-terminal region of CAP1 plays an important role in ATP-G-actin binding. Our data demonstrates that mammalian CAP1 also interacts with profilin. We are currently mapping the actin and profilin binding sites of mammalian CAP1 and examining the biological roles of these interactions in cultured mammalian cells.

**Drebrin-A, a Spine Specific Actin-binding Protein in Neuron, Inhibits the ADF/cofilin-dependent Actin Dynamics and Actin-Mysyn- V Interaction**

R. Ishikawa, 1 A. Takahashi, 1 K. Oseki, 1 M. Watanabe, 2 M. Igarashi, 1 A. Nakamura, 1 K. Kohama 1 1Department of Molecular and Cellular Pharmacology, Gunma University School of Medicine, Maebashi, Japan, 2Division of Molecular and Cellular Biology, Graduate School of Medical and Dental Sciences, Niigata University, Niigata, Japan

Drebrin-A is an actin-binding protein localized in dendritic spine of mature neuron, and suggested to affect spine morphology. In last year’s ASCB meeting, we reported the purification of drebrin-A, and showed the inhibition by drebrin-A of the activities of caldesmon. In this report, we examined the effects of drebrin-A on the activities of other actin-binding proteins localizing in dendritic spines, and found that drebrin-A inhibited the activity of ADF/cofilin. Enhancement of actin polymerization by ADF/cofilin was canceled in the presence of drebrin-A, which were confirmed by the measurements of (i) the turbidity of the solutions and (ii) the fluorescence intensity of pyrene-lebelled G-actin. F-actin cosedimentation assay revealed that drebrin-A inhibited the actin-binding activity of drebrin-A. The ADF/cofilin-induced decrease in precipitated actin was also canceled in the presence of drebrin-A. We also found that drebrin-A inhibited the Mg-ATPase activity of myosin V. In viro motility assay revealed that the attachment of F-actin to glass surface coated with myosin-V was inhibited by drebrin-A, but once F-actin attached to the surface, sliding speed of F-actin was unaffected in the presence of drebrin A. These results suggest that drebrin-A may affect spine dynamics through regulating the activities of ADF/cofilin and myosin-V.

**UNC-87, a *C. elegans* Calponin-repeat Protein, Inhibits Actomyosin Contractility**

S. Yamashiro, K. Ono, S. Ono; Pathology, Emory University, Atlanta, GA

Calponin is an actin-binding protein that is distributed in smooth muscle and non-muscle cells and has been suggested as a regulator of actomyosin contractility. However, its precise in vivo function is still unclear. In the nematode *C. elegans*, UNC-87 has seven calponin repeats that are found in the C-terminal region of calponin, but does not have a calponin-homology (CH) domain, which is found in a variety of actin-binding proteins. Previous studies showed that UNC-87 binds and cross-links F-actin in vitro, is associated with thin filaments in body wall muscle, and is important for maintenance of the myoﬁbrils. We have shown that UNC-87 stabilizes actin ﬁlaments by inhibiting ADF/cofilin-dependent actin dynamics in vitro and in vivo. In this study, we report evidence that UNC-87 is a negative regulator of actomyosin contractility. We found that UNC-87 inhibited actin-activated Mg2+-ATPase activity of rabbit skeletal muscle heavy meromyosin. UNC-87 also inhibited slug formation of actin ﬁlaments on a glass surface coated with skeletal muscle heavy meromyosin. Immunostaining of UNC-87 showed that both striated body wall muscle and non-striated ovarian cells UNC-87 localized to a restricted region of the thin filaments near the dense bodies where actin ﬁlaments are anchored. On the other hand, tropomyosin localized to a region of the thin ﬁlament more distal to the dense bodies. These results suggest that UNC-87 has a distinct function from tropomyosin and acts as a negative regulator of actomyosin contractility.

**Biochemical Basis of Deafness-causing Actin Mutations**

K. E. Bryan, P. A. Rubenstein; Biochemistry, University of Iowa, Iowa City, IA

The actin cytoskeletal apparatus in the auditory hair cell plays a central role in sound detection. Recently it was discovered that six point mutations in non-muscle γ-actin cause early onset autosomal dominant nonsyndromic hearing loss. The molecular basis for the deafness is unknown. We have engineered each mutation into yeast actin to investigate the effects of these mutations on actin function in vivo and in vitro. Yeast expressing each of the mutant actins as its sole active actin is viable. Four strains exhibit significant growth deficiencies in complete media and an inability to grow on glycerol as a sole carbon source implying a mitochondrial defect. These four strains exhibit abnormal mitochondrial morphology. All of the mutations result in abnormal actin cytoskeletal patterns. Five of the six mutants display strain-specific vacuole morphology abnormalities. Two of the purified mutant actins exhibit decreased monomer thermal stability and increased rates of nucleotide exchange, suggestive of increased protein flexibility. Only the V370A actin displays abnormal polymerization kinetics. V370A filaments were one-third as long as WT filaments, and mixtures of WT and V370A actins display kinetic properties and filament lengths proportional to the mole fraction of each actin used in the mixture, indicating that the mutant actin had no dominant effect on filament stability. The lack of polymerization effects in most of the mutants implies that hearing loss arises because of inability of the mutant filaments to be properly regulated. Therefore, we have begun to assess the effects each mutation has on the interaction of actin with actin-binding proteins. Three mutants, T89I, K118M, and V370A exhibit allele-specific abnormalities in their interactions with yeast coﬁlin. These three mutants also show differential effects on their interaction with yeast Arp2/3. Our results implicate misregulation of actin filament behavior as the molecular basis of the hearing loss associated with these mutations.

**Conserved Residues of the ILWQE Module Mediate the F-actin Binding and Dimerization of Talin1**

S. J. Smith, R. O. McCann; Biochemistry, University of Kentucky, Lexington, KY

The ILWQE module is an ancient, conserved C-terminal actin-binding element found in animal talins, H1p/12, and fungal Sla2. The module has a consensus length of 186 amino acids arranged in four conserved blocks. Dysregulation of the expression of ILWQE module proteins has several negative consequences. Talin1 mutants lacking the ILWQE module do not form a linkage between the extracellular matrix and actin cytoskeleton. Overexpression of H1p/12 mutants without the ILWQE module displays a similar phenotype to H1p/12 mutants, while cation-coated vesicles accumulated due to delayed or blocked internalization. Yeast Sla2 lacking the ILWQE module results in abnormal endocytosis. These results indicate that the ILWQE module forms a link between the actin cytoskeleton and other cellular compartments, such as the plasma membrane and endocytic vesicles. We have previously shown that the ILWQE module contains a dimerization motif and that the C-terminal Block 4 is essential for both dimerization and F-actin binding. We have used site-directed mutagenesis of Block 4 of mouse Talin1 to determine whether dimerization and actin binding are coupled in the ILWQE module. The mutant ILWQE modules displayed a significant decrease in F-actin binding affinity. We used gel filtration chromatography, cross-linking, and analytical ultracentrifugation to correlate actin binding with dimerization. Our results show that the regulation of dimerization and actin binding of the ILWQE module are coupled. Future research will examine the mechanisms of F-actin binding and the role of the dimerization motif in ILWQE module-containing proteins.

**Prelude to Invasion: The Shigella Protein, IpaA, Targets Integrins and Rho Activity to Reorganize the Host Cell Cytoskeleton**

K. DeMali,2, A. Jue,2 K. Burridge2; 1Biochemistry, University of Iowa, Iowa City, IA, 2Lineberger Comprehensive Cancer Center, University of North Carolina, Chapel Hill, NC

Shigella, the causative agent of dysentery, invades epithelial cells by reorganizing the host cell actin cytoskeleton. This process requires the release of a set of Ipa proteins through a Shigella type-III secretion apparatus. IpaA is one of the proteins secreted by *Shigella*, and it has been shown to bind to vinculin. The idea that this interaction with vinculin mediates IpaA’s effects on the cytoskeleton has been rapidly accepted. Here we have examined how IpaA reorganizes the actin cytoskeleton. We show that IpaA does not require vinculin expression or an intact vinculin binding site to exert its effects. Rather, we find that IpaA acts via increasing Rho activity, resulting in the subsequent phosphorylation of the myosin light chain. IpaA also decreases integrin affinity for extracellular matrix ligands by interfering with talin recruitment to integrin cytoplasmic domains. The mechanism for IpaA’s effects will be addressed. The combination of these two effects, namely weakened adhesion and increased contractility, account for IpaA’s effect on the actin cytoskeleton. Based on these findings, we propose a new role for IpaA at the site of bacterial entry whereby IpaA regulates integrin affinity for ligands and stimulates contractility.

**How Do Cells Shape Actin-based Protrusions?**

S. A. Dilks, S. DiNardo; Cell and Molecular Biology, University of Pennsylvania, Philadelphia, PA

The ability of cells to organize actin filaments into stable structures is vital to many cellular functions such as nutrient absorption, hearing, and sensory input. Although the actin-based protrusions thatunderlie these processes have distinct, elaborate shapes, it is unknown how cells form shaped protrusions. To better understand this process, we are using a well studied and genetically manipulatable model system, the *Drosophila* embryo. In this tissue, certain cells of the ventral epidermis produce an actin-based protrusion (called a dendrite), which exhibits a characteristic, reproducible looking shape. This shape is coordinated along a cell row, and each cell row produces a distinctly shaped protrusion. Although it is unknown what proteins are
in involved in this process, certain properties of actin crosslinking proteins may provide insight into the mechanism of shaping protrusions. Drosophila have homologues of the vertebrate actin crosslinkers villin (quail), fascin (singed), and small espin (forked), and loss-of-function alleles of singed and forked cause defects in denticle shaping (Dickinson & Thatcher, 1997). We now show that singed and forked localize to denticles differentially, consistent with our hypothesis that different actin crosslinkers play distinct roles in shape determination. We further hypothesize that the coordination between crosslinkers and other cytoskeletal elements with cellular signaling cascades is required for shape production. In the Drosophila embryonic epidermis, development of the denticle result in embryonic, role of the different inhibitors of PI 3-kinase and MLCK. Although svb is both necessary and sufficient for denticle formation (Payre et al, 1999), we show that ectopic expression of svb alone does not result in properly shaped protrusions. Furthermore, we now show that singed is positively regulated by svb. In total, our data support the hypothesis that actin crosslinking proteins are crucial in creating the characteristic hooking shape of denticles.

Phagocytosis: Effects of Several Inhibitors of PI 3-kinase and Myosin Light Chain Kinase

D. V. Zuckroll1, L. Octavio1, L. A. Hufnagel1, School of Arts and Sciences, Massachusetts College of Pharmacy and Health Sciences, Boston, MA. 1Cell and Molecular Biology, University of Rhode Island, Kingston, RI

Phagocytosis in the ciliated protist, Tetrahymena thermophila, shares many properties in common with phagocytosis in mammalian cells. We previously reported that certain inhibitory effects of actin inhibitors latrunculin and cytochalasin on Tetrahymena thermophila on phagocytosis are mimicked by effects of an inhibitor of PI-3 kinase and myosin light chain kinase (MLCK), wortmannin. Like actin inhibitors, wortmannin blocked nascent phagosome closure, evidenced by the formation of oversized nascent phagosomes that failed to detach from the oral aperture. To determine which of wortmannin's enzyme inhibitory activities might be required for the inhibition of nascent phagosome release, we examined the effects of LY 294002 (a structurally unrelated inhibitor reported to inhibit PI 3-kinase, but not MLCK) and ML-7 (an inhibitor specific for MLCK), in comparison with wortmannin effects. Wortmannin inhibited the rate of phagosome formation by ~ten times lower than "natural" pregnancy rates (Goldstein et al., 2000). This study investigates how a single dose of 1.25mgCC given to ovariectomized rats before the implantation priming hormon, consisting of a single dose of progesterone for three days and a dose of estradiol-17β on day three (P-P-PE) (Psychylos, 1963), alters the expression and distribution of the actin binding proteins, α-actin, gelsolin and vinculin. Actin binding proteins show a specific distribution in uterine epithelium during implantation, linking the actin cytoskeleton to integrin expression on the uterine surface. Integrins may aid "adhesiveness" for apposition of blastocysts to the uterine epithelium, the first step of implantation. The results of the immunocytochemistry on frozen uterine sections using mouse monoclonal antibodies against α-actin, gelsolin and vinculin and peroxidase-conjugated secondary antibodies, indicate that CC, when administered before the P-P-PE regimen, down regulates the expression of vinculin, does not significantly alter the expression of gelsolin and up regulates α-actin, on the apical surface of the uterine luminal epithelium, when compared to P-P-PE treated animals. All three proteins are down regulated on the apical surface of the luminal epithelium and glands in all groups when compared to pregnant controls. Vinculin alone was localized in the basolateral compartment of the uterine epithelial cells in the CC treated groups. By down regulating these proteins on the uterine surface and up-regulating vinculin on the basolateral membrane of the epithelium, CC may therefore impede adhesion of blastocysts at implantation. An understanding of how CC affects the uterine epithelial cells during implantation will allow for the possibility of exogenously manipulating uterine receptivity to control fertility and improving assisted reproductive technique out-comes.

Cdc42 Interaction with Its Effector Proteins Observed by FRET and FCCS

S. Thanhka1, L. Ping1, W. Bu1, K. Lim1, T. Wehland2, S. Ahmed1, Regenerative Medicine, Centre for Molecular Medicine, Singapore. 2Department of Chemistry, National University of Singapore, Singapore

Rho GTPases (e.g. Rac1, Cdc42 and RhoA) are members of the Ras super family of GTP binding proteins. Rho GTPases play a crucial role in many biological functions including; cell polarity, movement, adhesion and cytoskeletal organization. We are investigating the role of Cdc42 pathways in filopodia and neurite formation and have identified IRS53, N-WASP and Toca-1 as important effector proteins in these pathways. IRS53 is an adaptor protein with a partial CRIB motif, an F-actin binding domain and a SH3 domain. N-WASP is an activator of the Arp2/3 complex, has a CRIB motif and acts as a scaffolding protein. Toca-1 can bind both N-WASP and Cdc42 and plays a role in regulating N-WASP. We are developing fluorescence microscopy techniques to follow Cdc42-effector complex formation and regulation of F-actin dynamics in vivo. Here, we present data using FRET ( Förster resonance energy transfer) and FCCS (Fluorescence Cross Correlation Spectroscopy) to monitor the spatial and temporal interaction of Cdc42 with IRS53, N-WASP and Toca-1. This study was carried out by using GFP and mRFP tagged proteins. FRET was observed by acceptor bleaching on single cells. FCCS was done by simultaneous excitation of GFP and mRFP by 514 laser on a customised Zeiss microscope. Our data show that FCCS is a sensitive methodology to measure protein-protein interaction that can be used to quantitate interactions in vivo. This work illustrates that the combination of FRET and FCCS represents a powerful approach to investigate cell signaling pathways in vivo.

The Role of Actin-related kinases in Tetrahymena Phagocytosis: Effects of Several Inhibitors of PI 3-kinase and Myosin Light Chain Kinase

B. V. Zackroll1, L. Octavio1, L. A. Hufnagel1, School of Arts and Sciences, Massachusetts College of Pharmacy and Health Sciences, Boston, MA. 1Cell and Molecular Biology, University of Rhode Island, Kingston, RI

Phagocytosis is the ciliated protist, Tetrahymena thermophila, shares many properties in common with phagocytosis in mammalian cells. We previously reported that certain inhibitory effects of actin inhibitors latrunculin and cytochalasin on Tetrahymena thermophila on phagocytosis are mimicked by effects of an inhibitor of PI-3 kinase and myosin light chain kinase (MLCK), wortmannin. Like actin inhibitors, wortmannin blocked nascent phagosome closure, evidenced by the formation of oversized nascent phagosomes that failed to detach from the oral aperture. To determine which of wortmannin’s enzyme inhibitory activities might be required for the inhibition of nascent phagosome release, we examined the effects of LY 294002 (a structurally unrelated inhibitor reported to inhibit PI 3-kinease, but not MLCK) and ML-7 (an inhibitor specific for MLCK), in comparison with wortmannin effects. Wortmannin inhibited the rate of phagosome formation by ~50% at a concentration of 0.1 μM, and induced oversized nascent phagosomes in most cells in the 0.2-2 μM concentration range. However, while LY 294002 significantly reduced the rate of phagosome formation over the 4-40 μM concentration range, it did not induce formation of oversized nascent phagosomes. Moreover, ML-7, up to 10 μM, did not significantly affect the rate of phagocytosis or induce giant phagosomes, even though at similar concentrations it inhibited another myosin-dependent process, cell division. These results demonstrate that while two different inhibitors of PI-3 kinase interfere with Tetrahymena phagocytosis, a specific MLCK inhibitor does not, and furthermore that the effect of wortmannin on phagosome closure cannot be explained by its activity in blocking either PI-3 kinase or MLCK. We conclude that PI-3 kinase, but not MLCK, is required for Tetrahymena phagocytosis, and hypothesize that the induction of giant phagosomes by wortmannin may be due to effects on still another enzyme, such as a polo-like kinase, recently reported to influence actin dynamics in other cells.

Palladin Interacts with SH3 Domains of Src and SPIN90 and Is Required for Src-induced Cytoskeletal Remodelling

M. Ronty1, A. Taivainen1, C. A. Otey2, E. Ehler3, W. K. Song4, O. Carpen5, 1Department of Pathology, University of Helsinki, Helsinki, Finland. 2Department of Cell and Molecular Physiology, University of North Carolina at Chapel Hill, Chapel Hill, NC. 3King's College London, The Randall Division of Cell and Molecular Biophysics, London, United Kingdom. 4Department of Life Science and Molecular Disease Research Center, Gwangju Institute of Science and Technology, Gwangju, Republic of Korea. 5Department of Pathology, University of Turku, Turku, Finland

Palladin and SPIN90 are widely expressed phosphoproteins, which play important roles in organization of actin cytoskeleton. Palladin is expressed as multiple isoforms that bind to several actin-associated proteins such as ezrin, VASP, alpha-actinin, profilin, ArgBP2 and LASP1. SPIN90 on the other hand binds to Nck, WASP, beta-pix and dynamin. Both proteins localize to cardiomyocyte Z-discs and probably play a role in the maintenance of sarcomere integrity. In this study we demonstrate an interaction between palladin and SPIN90 and characterize the role of these proteins in PDGF and Src-induced cytoskeletal remodelling. We show that SPIN90 SH3 domain directly binds palladin's amino-terminal poly-proline sequence. In non-muscle cells the proteins co-localize to PDGF-induced membrane ruffles and lamellipodia. The effect of PDGF on the cytoskeleton is at least partly mediated by the Src kinase, since PP2, a specific Src kinase family inhibitor, could block PDGF-induced changes. We therefore studied the behavior of palladin and SPIN90 in cells transfected with an active Src kinase construct. Again, the proteins co-localized in membrane protrusions implying that both proteins are involved in the cytoskeleton remodelling induced by Src. Knock-down of endogenous SPIN90 did not inhibit the cytoskeletal rearrangement. Instead, knock-down of palladin with a specific siRNA resulted in cytoskeletal disorganization and inhibition of Src-induced remodelling. Further studies indicated that palladin is tyrosine phosphorylated in cells expressing active Src. Since the SH3 domain of SPIN90 shows high homology to Src SH3, we also tested if palladin directly binds to Src and could show that this is indeed the case. Taken together we show that palladin's poly-proline motif binds to SPIN90 and Src SH3 domains, that palladin and SPIN90 are rearranged coordinately during PDGF-induced cytoskeletal remodelling, and that palladin directly links to Src mediated signaling.

ICAM1-mediated RhoG Activation Is Required for Leukocyte Transmigration Across the Endothelium

J. D. Van Buul,1,2 M. Allingham,1 T. Samson,1 R. Garcia-Mata,1 K. Burridge1; 1Cell & Developmental Biology, UNC, Chapel Hill, NC. 2Molecular Cell Biology, University of Amsterdam Sanquin, Amsterdam, The Netherlands.
During transendothelial migration (TEM), leukocytes induce endothelial cells to form transmigratory cups, dynamic membrane protrusions that partially surround adherent leukocytes. However, little is known about the signaling pathways that regulate these structures. Here we show that Rhôh is activated downstream from ICAM1 engagement and that this requires the intracellular tail of ICAM1. Moreover, ICAM1 co-localizes with the Rhô-specific guanine-nucleotide exchange factor SGEF and with RhôG, but not with Rac1. In addition, we show that SGEF interacts with the intracellular tail of ICAM1 through its SH3 domain. Depletion of Rhôh by siRNA decreased the formation of transmigratory cups and attenuated leukocyte TEM, but not initial adhesion. Silencing SGEF resulted in a partial reduction in cup formation and TEM. Together these results define a new signaling pathway involving the exchange factor SGEF and RhôG downstream from ICAM1 that is critical for leukocyte TEM.

Role of Dynin Light Chain 1 in the Movement and Dynamics of the Investment Cones of Drosophila melanogaster
B. S. Desai, A. Sarkar, R. Choudhary, D. Kar, A. Ghosh-Roy, K. Ray; Department of Biological Sciences, Tata Institute of Fundamental Research, Mumbai, India
During late stages of spermiogenesis, F-actin rich conical structures called Investment Cones (IC) form around the compacted sperm nuclei, which then move caudally to extrude cytoplasmic contents and tightly invest spermatids with plasma membrane. Although F-actin dynamics and the pro-apoptotic proteases are shown to regulate the movement, the exact mechanism remained unclear. Earlier, we have shown that the Dynin Light Chain 1 (Dlc1) is enriched in ICs and its partial loss in certain ddlc1 mutants proportionally reduces the F-actin levels at the cone (Ghosh-Roy et al., MBC, 2005, 16:3107). We have now found that levels of Dlc1 play a crucial role in regulating the IC movements as well. In dlcl1 hemizygous mutants, average rates of IC displacements were reduced causing an increased accumulation of the ICs at the basal ends of the testes and an overall reduction in the fraction progressed values. The IC distribution defect, however, was not altered by additional loss of Dsc64C, dalcl1(CI74), or Gld3 (P150) genes products. Furthermore, conditional loss of dynamin function significantly altered the progressed IC fractions within eleven hours. Surprisingly though, such defect was not observed in the WASp, eps15, syndapin and several other related mutants. Altogether, these suggested a novel mechanism of F-actin dependent propulsion of the ICs involving Dlc1 and dynamin.

Tyr53-phosphorylation of Dictyostelium Actin Inhibits Filament Nucleation, Elongation, and Stability
X. Liu, S. Shu,1 M. Hong,2 R. L. Levine,1 E. D. Korn2; 1Laboratory of Cell Biology, NHLBI, NIH, Bethesda, MD, 2Laboratory of Biochemistry, NHLBI, NIH, Bethesda, MD
Dictyostelium actin was previously shown to become phosphorylated, uniquely on Tyr53 adjacent to the DNase I-binding loop, when cells in the amoeboid stage are subjected to stress, including heat shock, inhibition of oxidative phosphorylation, and exposure to heavy metal salts, and also late in the developmental cycle. As much as 50% of the actin in spores or heat-shocked vegetative amoebae is phosphorylated on Tyr53. The properties of Tyr53-phosphorylated actin had not previously been studied. We have now purified Dictyostelium actin, separated phosphorylated and unphosphorylated actin by FPLC chromatography on a Mono P column, and compared the biochemical and biochemical properties of Tyr53-phosphorylated actin and unphosphorylated actin. Tyr53-phosphorylation substantially reduces actin's ability to inactivate pancreatic DNAse I activity, increases actin's critical concentration for polymerization from 0.5 to 1.25 μM, and greatly reduces the rate of actin polymerization; inhibits substantially, and possibly completely, the ability of elongation from the pointed-end of actin filaments; reduces the rate of elongation from the barbed-end by 75-80%; and delays the hydrolysis of ATP that accompanies polymerization. Tyr53-phosphorylation also destabilizes actin filaments. In contrast to the typical long (>2 μm) filaments of unphosphorylated actin, polymerized Tyr53-phosphorylated actin forms either short, 15-16-μm bars, or a variable mixture of short bars and filaments with obvious breaks. The mixture of small oligomers and broken filaments is converted to more typical, long filaments upon addition of myosin subfragment 1. Tyr53-phosphorylation does not affect the ability of filamentous actin to activate myosin ATPase. Tyr53-phosphorylated and unphosphorylated actin co-polymerize in vitro, and, as we have shown by immunofluorescence staining, co-localize in pseudopods and filopods of vegetative amoebae. The effects of Tyr53-phosphorylation on actin polymerization may explain, at least in part, why cells subjected to stress round up and lose their adherence to the substratum.

Analysis of Actin Organization and Dynamics in Migrating Epithelial Cells
J. I. Lim, L. Ji, C. M. Waterman-Storer, G. Danuser; Cell Biology, The Scripps Research Institute, La Jolla, CA
Cellular contraction is a crucial component of cell motility. The cell is thought protrude through actin polymerization at its leading edge, and utilizes its actin-myosin cytoskeletal network to generate contraction forces to "pull" itself forward against resistance to the extracellular matrix. How contraction and contraction events are coordinated is unclear. To analyze this process PtK1 cells were microinjected with fluorescently labeled actin and myosin regulatory light chain and imaged via multi-spectral spinning disk confocal microscopy. We have identified three dynamic organization states of actin-myosin based contractions in migrating epithelial cells (PtK1): 1. "Contraction-Depolymerization" in which the interface between converging actin networks is correlated with local actin disassembly; 2. "Shear" in which adjacent actin networks move anti-parallel to one another; 3. "Compression-Bundling" in which compression of the lamella network induces formation of transverse actin bundles. To further characterize these contraction states, the degree of local correlated motion between actin and myosin were investigated using correlational qFSM (quantitative Fluorescent Speckle Microscopy). Actin and myosin (speckles) were analyzed in contracting (converging) cytoskeletal networks. In all three contraction states, actin and myosin primarily displayed identical kinematics (direction and speed). However, some cells exhibiting the "Contraction-Depolymerization" phenotype showed differential speeds between actin and myosin motion, indicating motion of one system relative to the other. Often, cells exhibiting the contraction-depolymerization phenotype exhibited enhanced protrusive activity at their leading edge. We will confirm this observation with time correlation analysis to determine if differential speeds between actin and myosin (decoupling) are linked to cell protrusion events.

1545
Actin-mediated Rocketing of Phagosomes Induced by Mechanical Pressure
M. Clarke, A. Müller-Taubenberger, G. Gerisch; Molecular, Cell, and Developmental Biology, Oklahoma Medical Research Foundation, Oklahoma City, OK, 3Max-Planck-Institut für Biochemie, Martinsried, Germany
We have found that mechanical pressure from an agar overlay can trigger actin-mediated rocketing of phagosomes in Dictyostelium cells. Living cells expressing fluorescent fusion proteins that label actin filaments and other cytoskeletal components were fed S. cerevisiae, then covered with a thin layer of agar, which was blotted to remove excess moisture. Actin assembled wherever the plasma membrane pressed against a phagosome, and asymmetric deposition of actin led to phagosome rocketing. The class I myosin MyoII and the Arp2/3 complex became enriched at sites of phagosome-plasma membrane contact. GFP-ARP3 persisted briefly at the plasma membrane when the phagosome moved away, indicating that Arp2/3 was more concentrated at the plasma membrane than at the phagosome membrane. The actin filaments trailing the moving phagosome were labeled with two probes, mRF-LimE, which binds to newly formed actins, and coronin-GFP, which binds to slightly older filaments. These probes showed that new actin is always added close to the moving phagosome. Our data suggest that the force generated by a rocketing phagosome is sufficient to displace the nucleus and the entire microtubule apparatus. This mechanism may keep the cell cortex free of trafficking phagosomes until exocytosis commences, and may also prevent rigid particles from hindering a cell's movement through confined spaces.

In Vivo Dynamics of Type II Plasmid Segregation Systems
C. S. Campbell, J. S. van Zon, M. Zuccolotto, D. Mullins; 1University of California San Francisco, San Francisco, CA, 2Centre for Integrative Systems Biology, Imperial College London, London, United Kingdom, 3Umr144-CNRS, Institut Curie, Paris, France
The R1 Par operon is a self-contained plasmid partitioning system composed of three parts: parC, ParR and ParM. parC is a stretch of DNA consisting of 10 sequential repeats, each of which binds ParR. The ParR-parC complex in turn binds the actin homolog ParM. Previous studies have shown that ParM forms filaments nearly identical to those of eukaryotic actin filaments and that ParM filament bundles appear to position plasmids at each end of a rod-shaped cell. We recently demonstrated that ParM filaments are dynamically unstable and can elongate bidirectionally in vitro. These observations led to a model in which ParM filaments continually search the cytoplasm and eventually capture a ParR bound parC region on a plasmid. Insertional polymerization at the ParM-parR interface will then push the plasmids to opposite ends of the cell and hold them in place until cell division, ensuring that each daughter cell receives a copy. To test this model directly in live cells, we used GFP labeled lacI to visualize lacI sites present on a plasmid containing a functional R1 Par operon. We observe that the plasmids make both

285
2006 ASCB Annual Meeting Abstracts
diffusive and directed movements wherein two plasmids move away from each other very rapidly. These directed movements occur many times during a single cell division, indicating that segregation is a very dynamic process. In addition, we have visualized GFP labeled ParM filaments and observe very similar dynamics were filaments polymerize, undergo catastrophe, and rapidly depolymerize in less than a minute. We also observe the formation and dissolution of plasmid clusters. These clusters have reduced dynamics and are more frequently localized towards the center of the cell. Our results indicate that plasmid partitioning by ParM is a very dynamic process and suggest a new model for polymer-based plasmid segregation.

Does the Phosphorylation of Tropomodulin Control Actin Filament Dynamics?

R. A. Lewis, K. L. Weber, D. J. Moyer, V. M. Fowler; Cell Biology, The Scripps Research Institute, La Jolla, CA

Tropomodulins (Tmdos) are a family of actin-binding proteins that regulate actin dynamics by capping the slow-growing (pointed) ends of thin filaments. Tmdos interact with both tropomyosin and actin filaments to prevent depolymerization and elongation at the pointed end, thereby stabilizing the filament. Tmd1 caps stable actin structures such as sarcomeres in cardiacmyocytes and short membrane-bound filaments in erythrocytes but is also found in actin filaments undergoing turnover in lens fiber cells and neurons. It is currently unknown how actin pointed end capping is controlled; thus, understanding the regulation of Tmdos in both dynamic and static structures will provide insight into the regulation of cell shape changes during migration and development. Phosphorylation may provide a mechanism to regulate the function of Tmd1l by changing the sub-cellular localization of Tmd1 or by altering interactions with other proteins which could influence the dynamics of actin filaments. We demonstrate that Tmd1 is phosphorylated on serine2 (S2) in red blood cells. This serine residue is conserved in both Tmd1 and Tmd4 from several species suggesting that phosphorylation of this residue may play a role in regulating Tmd1 function. Phosphorylation of Tmd1l is enhanced by phorbol ester treatment of erythrocytes indicating that this event may occur by the protein kinase C pathway. To determine the role of phosphorylation in regulating Tmd1 function, we created FLAG-tagged versions of the wildtype protein, an S2A (unphosphorymorphic) mutant, and an S2E (phosphomimetic) mutant. Using these constructs we assay for altered localization using immunofluorescence staining. In addition, interaction studies by anti-FLAG immunoprecipitation will test how Tmd1 is regulated by phosphorylation on S2 and identify the kinase responsible for this regulation. The phosphorylation of Tmdos may function to modulate capping and actin pointed end dynamics, allowing for the formation of both stable and static actin structures throughout development.

Changes in Cytoskeletal Tension Rapidly Phosphorylate Vasodilator-stimulated Phosphoprotein (VASP) in Calcium and ROCK-dependent Manner

K. Yasuda, M. Sbia, J. Yost, M. Yoshigi; Pediatrics, Toyohashi Municipal Hospital, Aichi, Japan, 3Huntsman Cancer Institute, University of Utah, Salt Lake City, UT

BACKGROUND AND OBJECTIVE: Vasodilator-stimulated phosphoprotein (VASP) is highly expressed in smooth muscle-rich organs, where cells experience various mechanical stresses (stretch, shear, and compression). We previously identified VASP and its binding partner zyxin as mechano-sensitive focal adhesion constituents and regulators for mechanically induced actin cytoskeletal remodeling (J Cell Biol 171:209:2005). VASP regulates the actin cytoskeletal remodeling via its phosphorylation kinetics. However, how mechanical stress affects on VASP phosphorylation remains to be determined. METHODS: We applied uniaxial cyclic stretch or fluid shear stress on human aortic smooth muscle cells in vitro and determined VASP phosphorylation at serine 157 and serine 239 residues via immunoblots and densitometric quantification. We also developed a new device that allowed us to rapidly change basal length of scaffold and lyse cells while scaffold length is held (unphasic uniaxial stretch/relax stimulation). RESULTS: Within two minutes upon cyclic stretch (10%, 0.5Hz) or unphasic stretch/relax (10%), VASP was robustly (>80%) phosphorylated both at serine 157 and 239 residues. Fluid shear stress (15 dynes/cm2) weakly (<30%) phosphorylated VASP. Interestingly, VASP phosphorylation by cyclic stretch and shear stress had an initial robust peak at 5-15 minutes which decayed after one hour, and the second peak about 4-6 hours, which appeared to be transcriptionally regulated. Using pharmacological inhibitors for PKA and PKC, we demonstrated that fluid shear stress (15 dynes/cm2) weakly (<30%) phosphorylated VASP. These data suggest that mechano-induced VASP phosphorylation is regulated by unique signaling pathways distinct from commonly recognized pathways. Functional aspects regarding mechano-induced VASP phosphorylation and stress fiber formation remain to be determined in the future.

1549

Actin Assembly Processes Required for c-Met-mediated Membrane Ruffling and Listeria Invasion

T. Bosse, J. Ehinger, A. Czuchra, S. Benesch, A. Steffen, K. Schloen, H. H. Niemann, G. Scita, T. E. B. Stradal, C. Brakebusch, K. Rottner; 1Helmholtz Centre for Infection Research, Braunschweig, Germany, 3Max Planck Institute of Biochemistry, Martinsried, Germany, 5Institute of Molecular Biotechnology, Vienna, Austria, 3Institut Curie, Paris, France, 1IEO/FSM, Milan, Italy, 2University of Copenhagen, Copenhagen, Denmark

Reorganizations of the actin cytoskeleton drive various essential cellular processes such as protrusion of the front edge during migration, the engulfment of particles during phagocytosis as well as diverse types of specific host-pathogen interactions. These actin reorganizations are frequently initiated by binding of extracellular ligands to their receptors eliciting signal transduction pathways, which can be exploited by certain bacterial pathogens. A prominent example for such a pathway is the gram-positive bacterium Listeria monocytogenes, which by interaction of bacterial Internalin B (InlB) with the hepatocyte growth factor / scatter factor (HGF/SF) receptor, also called c-Met, induces its invasion into non-epithelial cells. In recent years, regulators of bacterial Internalin B (InlB) with the hepatocyte growth factor / scatter factor (HGF/SF) receptor, also called c-Met, induces its invasion into non-epithelial cells. In recent years, regulators of actin assembly processes required for c-Met-mediated membrane ruffling and Listeria Invasion have been identified. In this context, the Rho GTPases, which promote actin filament polymerization, play a central role. However, the precise mechanisms by which these Rho GTPases regulate actin dynamics during Listeria invasion and c-Met-mediated membrane ruffling remain to be determined. In this study, we addressed the question whether actin dynamics during Listeria Invasion and c-Met-mediated membrane ruffling are regulated by the Rho GTPases. To address this question, we performed Fluorescence Recovery After Photobleaching (FRAP) analyses. Full recovery of GFP-actin in individual microspikes occurred in 26 seconds. Increasing F-actin stability with cytochalas-D and jasplakinolide significantly slowed GFP-actin recovery, indicating that recovery was dependent on dynamic actin. In addition, the regulation of actin dynamics in different actin-rich regions was explored by examining GFP-actin recovery in dendrite spines and in microspikes. Recovery of GFP-actin in dendrite spines occurred at a slower rate than did GFP-actin in microspikes, suggesting different factors contribute to actin turnover in different actin-rich regions. Interestingly, the recovery kinetics of F-actin in microspikes was the same in mature and immature neurons. This result suggests that actin turnover in microspikes is independent of neuronal maturity. Taken together these data suggest that mechano-induced VASP phosphorylation and stress fiber formation remain to be determined in the future.

1550

Dynamics of Actin in Bundled Filaments in Cortical Neurons

Y. Lin, L. Redmond; Pharmacology & Toxicology, Medical College of Georgia, Augusta, GA

The actin cytoskeleton is essential for a multitude of cellular functions including determining cell shape, polarity, and motility. Actin performs these functions when it is assembled into branched networks or bundled into filaments yet remains dynamic and responsive to a variety of cellular signals. In an effort to understand mechanisms of neuronal differentiation, the actin cytoskeleton was examined in primary cortical neurons in vitro. Phalloidin staining revealed F-actin rich protrusions extending from the soma in some, but not all, neurons. We call these structures microspikes. Immunocytochemical and SEM analysis indicated these microspike cytoskeletal structures were composed of bundles of actin filaments. Further, confocal time-lapse imaging of GFP-actin containing microspikes indicated that the microspikes did not change in number or location over time. To begin to investigate actin dynamics in the microspikes, we expressed GFP-actin in neurons and performed Fluorescence Recovery After Photobleaching (FRAP) analyses. Full recovery of GFP-actin in individual microspikes occurred in 26 seconds. Increasing F-actin stability with cytochalasin-D and jasplakinolide significantly slowed GFP-actin recovery, indicating that recovery was dependent on dynamic actin. In addition, the regulation of actin dynamics in different actin-rich regions was explored by examining GFP-actin recovery in dendrite spines and in microspikes. Recovery of GFP-actin in dendrite spines occurred at a slower rate than did GFP-actin in microspikes, suggesting different factors contribute to actin turnover in different actin-rich regions. Interestingly, the recovery kinetics of F-actin in microspikes was the same in mature and immature neurons. This result suggests that actin turnover in microspikes is independent of neuronal maturity. Taken together these data suggest that microspikes are composed of dynamic actin, which forms stable F-actin rich cytoskeletal structures that persist during neuronal differentiation.

1551

Coordinated Control of Actin Assembly through IQGAPI and Rho GTPases

Y. Cai, H. Kan, G. S. Bloom; Department of Biology, University of Virginia, Charlottesville, VA

The assembly of branched actin networks provides the force for plasma membrane protrusion during cell motility and morphogenesis. The multi-subunit Arp2/3 complex is essential for network formation by simultaneously binding to the sides of pre-existing filaments, and nucleating new filaments from their minus ends. This property of Arp2/3 requires activation by other factors, for example N-WASP, which must in turn be activated by directly binding proteins, like IQGAPI (Benseker, et al. submitted) or activated (GTP-bound) Cdc42 (Rohatgi, et al. 2006 ASCB Annual Meeting Abstracts)
Consistent with a role of Rac1 in PIPKIα smooth to saltatory or erratic motility. These myriad interactions define a multi-scale state diagram of signaling. PIPKIα increases comet tail actin density, which results in decreased β-actin speed. Changing the rate of branch formation, and thus the degree of branching within the tail, affects the transition from dependence on ActA distribution (ultrapolar, unipolar, and bipolar). An unknown molecular detail we must specify is the nature of the mechanical interaction, which we call a tether, between an actin filament and the bacterium. Simulations tuned to satisfy our principal constraints produce realistic bond energies for this tether on the order of a few kT. Furthermore, these simulations produce actin densities within the comet tail within a 5-fold range of experimental estimates. For these tuned simulations we find, for example, that decreasing the F-actin depolymerization rate increases comet tail actin density, which results in decreased bacterial speed. Changing the rate of branch formation, and thus the degree of branching within the tail, affects the transition from smooth to salatory or erratic motility. These myriad interactions define a multi-scale state diagram of Listeria motility.

Differential Roles of Type I Phosphatidylinositol 4-Phosphate 5-Kinases in Cell Motility and Cell Spreading

W. T. Chao, A. C. Daquinag, J. Kunz; Molecular Physiology and Biophysics, Baylor College of Medicine, Houston, TX

Cell motility is dependent on the dynamic reorganization of the actin cytoskeleton at membrane protrusions and sites of cell-matrix contact. The lipid phosphatidylinositol-4,5-bisphosphate (PIP2) is a key second messenger that regulates actin cytoskeletal reorganization. PIP2 has been previously shown to modulate cell motility and cell-matrix adhesion and its synthesis at the plasma membrane appears upregulated during these processes. PIP2 is synthesized by Type I phosphatidylinositol-4-phosphate 5-kinases (PIPKis). There are three isoforms of PIPKI (Iα, Iβ, and Iγ) in mammals and all three can induce actin reorganization upon overexpression. However, it is not clear whether they normally have redundant roles in the regulation of actin dynamics and cell motility. Here we demonstrate that siRNA-mediated knock-down of either PIPKIα or PIPKIβ inhibits cell migration and cell spreading. In contrast, PIPKIγ knock-down enhances migration speed, and there was a proportional increase in cell spreading kinetics. Thus, silencing of each PIPKI isoform affects the migration machinery suggesting that these isoforms play non-redundant roles during cell motility. Here we report on further studies on the role of PIPKIγ. We demonstrate that PIPKIγ is required for actin assembly induced by local activation of integrin signaling. PIPKIγ, but not PIPKIβ or PIPKIα, is essential for membrane translocation of two key regulators of actin dynamics: the small GTPase Rac1 and the actin binding protein cortactin. Consistent with a role of Rac1 in PIPKIγ-mediated signaling, constitutive membrane targeting of Rac1 partially suppresses the motility defects of PIPKIγ knock-down cells. Together our data suggest that specific PIPKI isoforms are involved in different aspects of motility and control the recruitment of specific yet distinct signaling and scaffolding proteins to discrete membrane microdomains.

Stress Fibers Are Generated by Two Distinct Actin Assembly Mechanisms in Motile Cells

P. Hotulainen, P. Lappalainen; Institute of Biotechnology, Helsinki, Finland

Stress fibers play a central role in adhesion, motility, and morphogenesis of eukaryotic cells, but the mechanism of how these and other contractile actomyosin structures are generated is not known. By analyzing stress fiber assembly pathways using live cell microscopy, we revealed that these structures are generated by two distinct mechanisms. Dorsal stress fibers, which are connected to the substrate via a focal adhesion at one end, are assembled through formin (mDia1/DRF1)-driven actin polymerization at focal adhesions. In contrast, transverse arcs, which are not directly anchored to substrate, are generated by endwise annealing of myosin bundles and Arp2/3-nucleated actin bundles at the lamella. Remarkably, dorsal stress fibers and transverse arcs can be converted to ventral stress fibers anchored to focal adhesions at both ends. Fluorescence recovery after photobleaching analysis revealed that specific actin cross-linking in stress fibers is highly dynamic, suggesting that the rapid association-dissociation kinetics of cross-linkers may be essential for the formation and contractility of stress fibers. Based on these data, we propose a general model for assembly and maintenance of contractile actin structures in cells.
Regulation of Actin Dynamics-driven Processes during Drosophila Development
R. Stephan, R. Fricke, A. Mertens, C. Klämbt, S. Bogdan; Institute of Neurobiology, University of Muenster, Muenster, Germany
Actin polymerization is a key process for many cellular events during development. To a large extent, the formation of filamentous actin is controlled by the WASP and WAVE proteins that activate the Arp2/3 complex in different developmental processes. Wave function is regulated through a protein complex containing Scar, Kette and Abi. We have recently shown that the Abi protein also plays a central role in activating Wasp mediated processes. Abi directly binds to Wasp and is able to activate Wasp dependent F-actin formation in vitro and in vivo. Here, we report that the Drosophila Abi-Wasp function is generally required to promote sensory organ development by modulating EGFR signaling. Expression of a membrane-tethered activated Abi protein leads to tyrosine hyperphosphorylation and an increase in MAPK activity. Additionally, co-expression of activated Abi and EGFR dramatically enhances the induction of extra-sensory organs whereas inhibition of EGFR signaling leads to a suppression of the dominant phenotype. In agreement with this observation Abi is able to associate with the EGFR in a common complex at the membrane. Thus, in vivo different Abi complexes may set the balance between Wasp and Wave in different actin based developmental processes. In order to identify further proteins that regulate WASP and WAVE, we have conducted different genetic and biochemical approaches and selected different new candidates. A biochemical and functional analysis of one novel Abi interacting candidate will be presented.

Leiomodin: A Novel Actin Filament-nucleating Factor
D. Chereau,1 M. Bozcowska,1 I. Fujigawa,2 G. Rebowski,1 D. B. Hayes,1 P. Erhardt,1 T. D. Pollard,1 R. Dominguez2; 1Elan Pharmaceuticals, South San Francisco, CA, 2Physiology, University of Pennsylvania School of Medicine, Philadelphia, PA
The actin cytoskeleton undergoes constant remodeling during a variety of cellular processes, including cell morphogenesis and motility. The de novo assembly of actin filaments is highly regulated in vivo and requires the participation of actin filament-nucleating factors. To date, three types of filament nucleating factors have been identified: Arp2/3 complex, formin and spire. These nucleating factors appear to have specialized functions and work under the control of dedicated signaling pathways and activator proteins. Here we report the discovery of a novel nucleating factor of the actin cytoskeleton in muscle cells, leiomodin (Lmod). Like most cytoskeletal proteins, Lmod is a modular protein. The N-terminal portion of Lmod shares sequence similarity with tropomodulin, a filament pointed-end capping protein. Like tropomodulin, this portion of Lmod contains a flexible region involved in tropomyosin binding, followed by a globular domain that binds actin. However, compared to tropomodulin, Lmod presents a large C-terminal extension, which contains a poly-Pro region and additional actin-binding sites of the WASP-homology domain-2 (WH2) type. We show here that full-length Lmod increases dramatically the rate of actin filament nucleation. Functional domain mapping further demonstrates that this activity requires the presence of the tropomodulin-like globular domain as well as the C-terminal poly-Pro-WH2 extension, but not the flexible N-terminal tropomyosin-binding region. Yet, Lmod nucleates actin filaments efficiently in the presence of tropomyosin, suggesting that its function is to nucleate tropomyosin-decorated actin filaments in muscle cells.

The Susceptibility of Actin Filament Populations to Latrunculin A and Cytochalasin D Is Regulated by Tropomyosin Composition
S. J. Creed,1 N. Bryce,1 J. T. Stelm,1 P. Gunning2; 1Oncology Research Unit, The Children's Hospital Westmead, Westmead, NSW, Australia, 2Discipline of Paediatrics and Child Health, University of Sydney, Sydney, NSW, Australia
Actin altering drugs such as Latrunculin A and Cytochalasin D have been used to study the cytoskeleton for a number of years. While it is known that effects of these drugs are cell type dependent, it has been widely accepted that all actin filament populations are equally susceptible. However, the discovery that spatial and temporal regulation of tropomyosin isoforms results in dramatically different filament populations leads to the hypothesis that these drugs may not affect all filament populations in the same manner. Therefore, several conclusions on biological functions of actin filaments drawn from studies using these drugs may not always be accurate. The aim of this study was to determine if molecularly distinct filament populations have altered susceptibility to actin destabilizing drugs. The Tm5NM1 and Tm3 tropomyosin isoforms were over-expressed in neuro-epithelial cells. We examined the organization of microfilaments and susceptibility to Latrunculin A and Cytochalasin D using immunofluorescence and western blot analysis of detergent soluble and insoluble fractions. Over-expression of Tm5NM1 resulted in Tm5NM1-containing stress fibers with decreased detergent solubility. Tm3 over-expression caused an abundance of filopodia containing shorter Tm3-associated filaments with increased susceptibility. Filament populations containing Tm5NM1 demonstrated greater resistance to drug treatment, with filament organization maintained at higher concentrations than observed for control cells. Conversely, Tm3-containing filaments showed increased susceptibility. Supporting this, a Latrunculin A time course demonstrated faster filament breakdown in Tm3 cells. Combined the data suggest that filament populations containing Tm3 are shorter and more dynamic making them more susceptible to Latrunculin and Cytochalasin. Preliminary data examining ADF, an actin severing protein, suggests ADF is associated with Tm3 containing filaments at the filopodia, providing a possible mechanism for this phenomenon. We conclude that tropomyosins direct organization and dynamics of actin filaments, altering the sensitivity of the filaments to actin destabilizing drugs.

Actin Cross-linking with Cholera RTX Toxin
D. S. Kurdyanov,2 A. Durer,1 C. L. Cordero,1 S. A. Benchas,1 R. E. Reisler,2 K. J. Fullmer-Satchell1; 1Department of Chemistry and Biochemistry, UCLA, Los Angeles, CA, 2Department of Microbiology, University of Western Ontario, London, Canada
Vibrio cholerae RTX toxin causes rounding of mammalian epithelial cells in culture by dismantling actin filaments via a unique mechanism. The 47.8 kDa actin-crosslinking domain of RTX (ACD-RTX) covalently cross-links actin subunits in vitro and in vivo forming a ladder of oligomers similar to the ladder of longitudinal oligomers obtained by cross-linking of F-actin by azidonitrophenyl putreiscine (ANP). In contrast to ANP induced cross-linking, ACD-RTX cross-linking is blocked in F-actin; yet it requires high MgCl2 concentrations. CaCl2 and KCl (at concentrations high enough to polymerize actin) do not support the cross-linking in the absence of MgCl2. Actin polymerization and cross-linking reactions compete with each other when ACD and MgCl2 are added to G-actin simultaneously. The purified dimers of ACD-cross-linked actin do not accelerate the polymerization of intact actin, indicating that they do not nucleate new filaments growth. The toxin cross-linked oligomers, however, do not polymerize under physiological salt conditions, but the polymerization is rescued with either phalloidin or cofilin, as confirmed by light scattering, pelleting assays, and electron microscopy. We locate the cross-linking sites on actin, we used fluorescently labeled yeast actin mutant in limited enzymatic and chemical proteolysis experiments. Our preliminary data suggest that ACD-RTX covalently attaches SD2 of one actin protomer to the SD3 of another protomer in longitudinal manner. This type of interaction between the subunits is consistent with the Holmes model of actin filament. Yet, given the impaired polymerization of the cross-linked oligomers, their conformation must be different from that in F-actin. Additionally, a number of factors that destabilize F-actin - latrunculin, gelsolin S1, Kabiramide C, and Cys374 labeling with TMR - do not interfere with the ACD-RTX induced cross-linking. Thus, our data suggest that RTX toxin destabilizes actin filaments in an unusual way - by covalently capturing one of the unstable conformations of actin oligomers.

An APC2-Diaphanous Complex Organizes Actin in the Drosophila Syncytial Embryo
R. L. Webb,1 J. S. Weinberg, M. Zhou, S. E. Clark,2 B. M. McCartney1; 1Biological Sciences, Carnegie Mellon University, Pittsburgh, PA, 2Biological Sciences, Colby College, Waterville, ME
Organization and rearrangement of the cytoskeleton is essential for many cellular processes. Adenomatous polyposis coli (APC) family proteins associate with actin and microtubules and influence their behavior, however the precise molecular mechanisms involved are poorly understood. Drosophila syncytial embryos are an excellent in vivo model for understanding the role of APC proteins in organizing the cytoskeleton, as the coordination of actin and microtubules is necessary for cytoskeletal rearrangements involved in synchronous nuclear divisions. We examined embryos null for Drosophila APC2 and observed incomplete actin rings and lack of actin furrow extension during syncytial mitoses. To determine the mechanism by which APC2 functions to organize actin, we evaluated the role of the formin Diaphanous (Dia), which functions to organize actin during Drosophila cellularization and is in a complex with APC and EB1 in migrating mammalian cultured cells. Similar to APC2 mutant embryos, dia mutants have defects in actin rings and furrow extension. We found that APC2 and Dia form a complex in syncytial embryos, and that localization of APC2 to actin rings and furrows is dependent on Dia. Further, we found that reduction of dia in APC2 mutant embryos enhances the severity of APC2 actin defects. We asked whether an APC2-Dia complex is downstream of Rho1, as predicted from other studies, by examining RhoGEF2 and Rho1 mutant syncytial embryos. The actin defects in Rho1 and RhoGEF2 mutants are overlapping but distinct from those of APC2 and dia, suggesting that they are functioning in parallel pathways. Based on their functions in other systems, APC2 and Dia may influence actin directly, or indirectly through microtubules. To distinguish between these possibilities we are using Total Internal Reflection Fluorescence microscopy to assess cortical microtubules in live wild type and mutant embryos. Furthermore, we are probing the relationship between APC2, Dia and EB1 in this system.

The PH Domain Proteins Slm1 and Slm2 Are Novel Effectors of Sphingolipid Signaling Pathways during the Response to Heat Stress

A. Daquinag, M. M. Madri, J. Kunz; Molecular Physiology and Biophysics, Baylor College of Medicine, Houston, TX

The redundant and essential PH domain containing proteins Slm1 and Slm2 were previously identified as targets of the PI4,5P2 and TORC2 signaling pathways. Here, we demonstrate that Slm1 and Slm2 are also targets of sphingolipid signaling pathways during environmental stress conditions. We show that upon depletion of cellular sphingolipid levels Slm1 function becomes essential for survival under heat stress. We further demonstrate that in response to heat stress Slm proteins are regulated by a phosphorylation/dephosphorylation cycle involving the sphingolipid-activated protein kinases Ptk1/Pkh2 and the calcium/calmodulin-dependent protein phosphatase calcineurin. Mass spectrometry analysis identifies Ser659 in Slm1 as one of the residues phosphorylated during heat shock. Characterization of mutant Slm1 variants that mimic dephosphorylated and phosphorylated states, respectively, demonstrate that phosphorylation at Ser659 is vital for survival under heat stress and may play a role in the sphingolipid- and Pkh-dependent repolarization of the actin cytoskeleton. Finally, we present evidence that Slm proteins are also required for the trafficking of the raft-associated arginine permease Cari to the plasma membrane, a process that requires sphingolipid and phospholipid synthesis. Thus, Slm proteins are required for sphingolipid-dependent functions including actin polarization and aspects of vesicle trafficking in response to environmental stress conditions.

Myristoylated Alanine-rich Protein Kinase C Substrate PSD: Specific Functions and Possibilities for Regulation

E. G. Yarmola, J. Kress, T. V. Yarmola, M. R. Bubb; Medicine, University of Florida, Gainesville, FL

Myristoylated alanine-rich protein kinase C substrate (MARCKS) is a prominent phosphorylation substrate in the brain that binds calmodulin and acidic phospholipids, and has been implicated in cellular processes associated with cytoskeletal remodeling. The effect of the MARCKS active site, phosphorylation site domain (PSD) on actin polymerization is complex and requires detailed characterization. Our data characterize specific effects of PSD on actin filament dynamics, and suggest how these effects could incorporate into the overall PSD activity, depending on conditions. We demonstrate that MARCKS PSD nucleates actin filaments but does not change the effective nucleus size. PSD inhibits barbed end elongation at low ratios to actin consistent with capping effect, and promotes elongation at higher ratios, converging with the elongation rate for gelsolin-capped filaments. PSD crosslinks actin filaments and inhibits depolymerization in the cooperative manner consistent with crosslinking. PSD decreases actin critical concentration in presence and absence of gelsolin in a manner quantitatively consistent with its effect on the rates of elongation and depolymerization. Phospholipid PI(2) differentially modulates the effect of MARCKS PSD on actin polymerization. It eliminates inhibitory effect of PSD on elongation and depolymerization, and increases its nucleation effect. We suggest that the effect of phosphorylation on the PSD activity, we created several pseudophosphorylated peptides in which different serine residues in PSD were replaced with glutamic acid. These peptides crosslink actin filaments and inhibit actin depolymerization with lower activity depending on the specific site(s) of phosphorylation. Our data suggest that MARCKS PSD function is a combination of several effects that could be tightly regulated in cells. MARCKS could be used as a switch that determines whether quiescent actin bundles are stabilizing the membrane-cytoskeletal interface or whether a dynamic population of actin filaments is actively altering morphological plasticity by remodeling the cytoskeleton.

Mechanosensing and Mechanotransduction by the Na-H exchanger NHE1 for Actin Filament Assembly

J. R. Mackley,* C. Frantz,* L. LeClaire,* E. Almeida; Cell and Tissue Biology, University of California, San Francisco, San Francisco, CA; *NASA Ames Research Center, Moffett Field, CA

Mechanical forces regulate tissue organization and remodeling, and cell architecture and function. Our understanding of how cells sense and transduce mechanical force, however, is limited compared with what is known about sensing and transducing chemical cues. In specialized sensory cells mechanotransduction units include a plasma membrane ion transport protein anchored to the actin cytoskeleton. We previously reported that in fibroblasts the plasma membrane Na-H exchanger NHE1, which is anchored to actin filaments by binding ERM (ezrin, radixin, moesin) proteins, is mechanosensitive. Although integrins are also mechanosensitive and their activation stimulates NHE1 activity, we now report that mechanosensitivity of NHE1 is independent of integrin-matrix adhesion. Cells plated on a polystyrene strip mounted in a uniaxial loading system were mechanically stimulated by applying a 5 min 1% deformation and release. NHE1 activation in response to mechanical load was similar in fibroblasts plated for four hours on strips coated with either fibronectin or poly-L-lysine, and in 48 h cultures of wild-type or beta-1-null mouse embryonic tetarocarcinoma cells. We also found that mechanotransduction by NHE1 is necessary for dynamic actin filament assembly. Although the abundance of F-actin in quiescent, unstimulated fibroblasts is NHE1-independent, total F-actin increased 2-fold in fibroblasts expressing NHE1 but did not change in NHE1-deficient fibroblasts with mechanical load. Mechanical load also increased the number of new actin free barbed ends in cells expressing NHE1, but this was markedly attenuated in NHE1-deficient cells. The Arp2/3 complex is a primary nucleator of new actin filaments. Phosphorylation of the Arp2 subunit, which is necessary for Arp2/3 nucleating activity, increased with mechanical load and the increase was dependent on NHE1 activity. These data suggest that NHE1 functions within a mechanotransduction unit because it is activated by mechanical force independent of integrin-matrix adhesion and is necessary for mechanosensitive actin filament assembly. Supported by NASA grant NNA04CC53A.

Hydrogen/Deuterium Exchange Studies of Twinfilin-capping Protein Interactions and Dynamics

M. C. Merckel, M. R. Emmett, V. O. Paavilainen, P. Lappalainen, A. G. Marshall, R. Tuma; Institute of Biotechnology, Helsinki University, Helsinki, Finland, National High Magnetic Field Laboratory, University of Florida, Tallahassee, FL

Twinfilin (Twf) is an evolutionarily conserved actin-binding protein that regulates cytoskeletal dynamics by sequestering actin monomers and by binding to filament barbed ends [1]. Twf is composed of two actin-depolymerization factor homology (ADF-H) domains followed by a ~30 residue long C-terminal tail. CP binds to the barbed ends of the filaments and works as a 'cap' by preventing the addition and loss of actin monomers. Twf is composed of two actin-depolymerization factor homology (ADF-H) domains followed by a ~30 residue long C-terminal tail. vertebrate, the existence of two types of fibers is important since muscle should play a multiple of works depending on its location in the body. But the differentiation mechanism of these muscle fiber subtypes is unclear. We analyzed whether the differentiation of myoblasts into myofibers had variability between fast and slow types. Myoblasts from 7-day-old chick embryo were cultured for 7 days and formed into muscle fibers. When cells were stained immunohistochemically, more than 60% of fibers produced only MyHC, and remaining fibers produced both MyHC and MyHC in the control group. However, when the extract of slow muscle was supplemented to the culture medium, about 35% of muscle fibers expressed only MyHC and 65% of that expressed both MyHC and MyHC. The same result was obtained when the extract of slow muscle was added into the culture of cloned mouse myoblast, C2C12 cells. The factor, which induces the differentiation of slow muscle, is considered to be secreted protein, since it denatured by heating, but recovered by the dialysis after the urea denaturation. We performed DNA screening from adult chicken slow muscle cDNA library, and we discovered one gene, which induced the differentiation into slow muscle fiber when the product was supplemented into the culture medium. The results presented here show that an environment of myoblasts controls the subtype differentiation of muscle fibers.

1568 S100B Activates Quiescent Myoblasts and Satellite Cells
F. Riuszi, G. Sorci, R. Donato; Department of Experimental Medicine & Biochemical Sciences, University of Perugia, Perugia, Italy
We reported that low-density and high-density myoblasts, the effects of S100B on myoblasts, the effects of S100B on differentiation and the duration of exposure condition the sensitivity of myoblasts to S100B, suggesting that S100B might play a dual regulatory role during embryonic myogenesis and muscle regeneration.

1569 S100B in Myoblasts Interferes with MyoD Expression
R. Donato, C. Tubaro, C. Arcuri; Department of Experimental Medicine & Biochemical Sciences, University of Perugia, Perugia, Italy
The Ca2+-modulated protein of the EF-hand type, S100B, which participates in the regulation of several intracellular processes including cell cycle progression and differentiation, is expressed in related to the process of muscle development, the effects of S100B on myoblasts and inhibition of S100B expression by RNA interference. L6 myoblasts stably overexpressing S100B (clone L6C8) showed inability to express the muscle-specific transcription factor, myogenin, and the late differentiation marker, myosin heavy chain (MHC) and to fuse into myotubes, suggesting that S100B might interfere with myoblast differentiation. However, these effects were not consequent to increased proliferation of L6C8 myoblasts. Interestingly, no obvious decrease in the extent of activation of p38 MAPK, which is crucial for myoblast terminal differentiation, were detected in L6C8 myoblasts under differentiation conditions. Also, transfection with MKK4E, an active mutant of the p38 MAPK upstream kinase MKK3, while stimulating myogenin and MHC expression in mock-transfected myoblasts (clone L6C11) as expected, failed to counteract the inhibitory effect of S100B overexpression on myogenin and MHC expression in L6C8 myoblasts. Thus, S100B might interfere with myoblast differentiation and myotube formation by acting downstream of p38 MAPK. Inability of L6C8 myoblast to form myotubes was accompanied by reduced p21 induction and no MyoD expression while Myf-5 expression was unchanged, compared with L6C11 myoblasts. Also, transient transfection with the muscle-specific transcription factor, MyoD, but not Myf-5, restored L6C8 myoblast differentiation and fusion, while silencing S100B expression in wild-type myoblasts by RNA interference resulted in stimulation of MyoD, myogenin and MHC expression and myotube formation. Finally, the transcriptional activity of NF-kB, a negative regulator of MyoD expression, was greatly enhanced in L6C8 myoblasts. Thus, intracellular S100B might participate in the modulation of myoblast differentiation by interfering with MyoD expression in an NF-kB-dependent manner.

1570 Glucocorticoid Induces Accelerated MyoD Protein Degradation via Activation of the N-terminal Ubiquitination Pathway in Muscle Cells
L. Sun, J. S. Trausch-Azar, A. Ciechanover, A. L. Schwartz; 1Department of Pediatrics and Molecular Biology and Pharmacology, Washington University School of Medicine, St. Louis, MO, 2Vascular and Tumor Biology Research Center, Technion-Israel Institute for Technology, Haifa, Israel
MyoD is a tissue-specific transcriptional activator that acts as the master switch for skeletal muscle differentiation and development. Previous studies in surrogate, non-muscle cells have shown that MyoD protein degradation is mediated by the ubiquitin-proteasome system via two distinct pathways characterized by the site of ubiquitination of the protein, namely an N-terminal dependent pathway and a lysine-dependent pathway. However, the biological roles of the two ubiquitination pathways in MyoD protein degradation during muscle differentiation remain unclear. Therefore, we investigated the protein stabilities of two MyoD mutants, which are deficient either in N-terminal ubiquitination or internal lysine ubiquitination respectively, in muscle cells with or without glucocorticoid administration. Prolonged glucocorticoid administration at pharmacological doses is known to inhibit muscle differentiation and induce muscle wasting, a catabolic condition associated with stimulated proteolysis via the ubiquitin-proteasome system. In both C2C12 myoblasts and myotubes, we show that N-terminal blocked MyoD is rapidly degraded with a t1/2 ~ 1 hour, which is comparable to that of wild type MyoD, while lysine-less MyoD is more stable, with a t1/2 ~ 7 hours. Glucocorticoid administration induced accelerated protein degradation of both endogenous and exogenous wild type MyoD in C2C12 myotubes (t1/2 from ~1 hour to ~0.4 hour). However, the two ubiquitination pathways appear to be affected differently by glucocorticoid. In C2C12 myotubes, exposure to dexamethasone appears to stabilize N-terminal blocked MyoD (t1/2 ~ 3.4 hours), whereas lysine-less MyoD is destabilized (t1/2 ~ 1.2 hours). Taken together, our results suggest that glucocorticoid induces accelerated MyoD protein degradation, perhaps via activation of the N-terminal ubiquitination pathway. Thus, our findings support different roles for the two ubiquitination pathways in MyoD protein degradation in muscle cells, and suggest an important role for the novel N-terminal ubiquitination pathway in muscle cells under catabolic conditions.

1571 The Role of Phospholipase D and Phosphatidic Acid in the Mechanical Activation of mTOR Signaling in Skeletal Muscle
T. A. Hornberger, K. B. Sakihisa, S. A. Huang, S. Chien; Bioengineering, University of California San Diego, La Jolla, CA
Signaling by the mammalian target of rapamycin (mTOR) has been reported to be necessary for mechanical load-induced growth of skeletal muscle. The mechanisms involved in the mechanical activation of mTOR signaling are not known, but several studies indicate that a unique (PI3K- and nutrient-independent) mechanism is involved. In this study, we have demonstrated that a novel regulatory pathway for mTOR signaling, which involves phospholipase D (PLD) and the lipid second messenger phosphatidic acid (PA), plays a critical role in the mechanical activation of mTOR signaling. First, an elevation in PA concentration was sufficient for the activation of mTOR signaling. Second, the isomers of PLD (PLD1 and PLD2) are localized to the z-band in skeletal muscle (a critical site of mechanical force transmission). Third, mechanical stimulation of skeletal muscle with intermittent passive stretch or vivo-induced PLD activation, PA accumulation and mTOR signaling. Finally, pharmacological inhibition of PLD blocked the mechanically-induced increase in PA and the activation of mTOR signaling. Combined, these results indicate that mechanical stimuli activate mTOR signaling through a PLD-dependent increase in PA. Furthermore, we showed that mTOR signaling was partially resistant to rapamycin in muscles subjected to mechanical stimulation. Since rapamycin and PA compete for binding to the FRB domain on mTOR, these results suggest that mechanical stimuli activate mTOR signaling through an enhanced binding of PA to the FRB domain on mTOR.

1572 Functional Variation of Troponin between Smooth and Striated Muscles in Photicodrphates
T. Obinata, Y. Tandon, N. Sato, M. Ogawara, K. Kubokawa; 1Department of Biology, Chiba University, Chiba-shi, Japan, 2Ocean Research Institute, The University of Tokyo, Tokyo, Japan
Troponin is a protein characteristic of striated muscles in vertebrates. It is known to be an inhibitor for muscle contraction or actin-myosin interaction and Ca2+ removes the inhibition. We previously detected troponin in the smooth muscle of ascidian, one of protochordate animals, and found that its function is distinct from that of vertebrate striated muscle troponin, namely the ascidian troponin functioned as a Ca2+-dependent accelerator of muscle contraction (Endo & Obinata, 1981). This unique property of ascidian troponin was attributed to the characteristics of
troponin 1 (TnT) and T (TnT). In this study, we were interested in whether troponin in proteochondrate striated muscles functions as an inhibitor for muscle contraction or as a Ca++-dependent accelerator. We used amphioxus, Branchiostoma belcheri, as a model animal of proteochondrates to obtain striated muscle, because obtaining sufficient amount of striated muscle from ascidian is difficult. Troponin was extracted from frozen amphioxus tissue and partially purified. This troponin activated myosin in interaction in the absence of Ca++. To further clarify the properties of each troponin component, we prepared recombinant TnT and TnI of amphioxus and compared them with chicken troponin C. The complex markedly inhibited actomyosin ATPase in the presence of Ca++, the but the inhibition was eliminated by Ca++. Just as in the case of chicken or rabbit skeletal muscle troponin, Amphioxus TnI inhibited actomyosin ATPase strongly in a Ca++- independent manner. Amphioxus TnT shared common properties with chicken troponin. These results strongly suggest that troponin in proteochondrate striated muscles functionally resembles troponin in vertebrate striated muscle but is distinct from the smooth muscle troponin.

1573 Mutagenesis of Phosphorylation Sites in Drosophila Flightin Impair Flight Muscle Structure and Function

B. Barton,¹ G. Ayer,¹ D. W. Maughan,¹ J. O. Vigoreaux²,³; ¹Biology, University of Vermont, Burlington, VT, ²Molecular Physiology & Biophysics, University of Vermont, Burlington, VT

Flightin is a myosin rod binding protein that in Drosophila is expressed exclusively in the asynchronous, indirect flight muscles (IFM). Hyperphosphorylation of flightin precedes the emergence of flight competency in newly eclosed adults and plays an essential role in IFM structural stability and mechanics. Flightin null (fln) mutants display disorganization of muscle A-bands. Mutations that affect flightin expression or phosphorylation result in muscle hypercontraction, loss of power output, and flightlessness. Despite its essential role in IFM, flightin is not found in vertebrate striated muscle. The goal of this study is to reconstruct the evolutionary history of flightin to determine its origin as an IFM-specific protein. Flightin was identified in 32 insects (Orders Thysanura, Orthoptera, Hemiptera, Coleoptera, Hymenoptera, Lepidoptera, Diptera) and six crustaceans (Orders Crustacea, Isopoda, Decapoda). Analysis of flightin sequence revealed a highly variable (fast evolving) amino terminal region (first ~82 residues) and a ~52 amino acid central region within which residues that remain conserved or neutralized are abundant. The central region is shared by C. elegans and D. melanogaster (i.e., Pancrustacea) but absent in all other metazoans. Within the conserved region, 9 amino acids are invariant including an N-terminal tryptophan (W), 4 tyrosines (Y), and a C-terminal arginine (R). We refer to this conserved region as the WYR-W domain. The presence of flightin in the ancestrally wingless bristlefoot suggests this gene is present in all insects. The identification of flightin in C. elegans indicates the origin of more than 400 million years ago. Phylogenetic analysis of amino acid sequences suggests functional historical variation in selective forces have affected the evolution of flightin in higher insects, probably as a result of the newly evolved IFM-specific function. One possibility is that flightin is under dual evolutionary constraints (purifying and positive selection) to fulfill a conserved muscle physiological function and a rapidly evolving behavior-associated function. We propose that if WYR functions as a myosin rod binding domain.

1574 Evolutionary Analysis of Flightin Reveals a Putative Myosin Rod Binding Domain

F. Soto-Adames, J. Vigoreaux; Biology, University of Vermont, Burlington, VT

Flightin is a hyperphosphorylated, myosin rod binding protein that is necessary for the structural stability of thick filaments. In Drosophila melanogaster, flightin is expressed exclusively in the asynchronous indirect flight muscles (IFM), renowned for their enhanced stretch activation response. Mutations that affect flightin expression or phosphorylation result in muscle hypercontraction, loss of power output, and flightlessness. Despite its essential role in IFM, flightin is not found in vertebrate striated muscle. The goal of this study is to reconstruct the evolutionary history of flightin to determine its origin as an IFM-specific protein. Flightin was identified in 32 insects (Orders Thysanura, Orthoptera, Hemiptera, Coleoptera, Hymenoptera, Lepidoptera, Diptera) and six crustaceans (Orders Crustacea, Isopoda, Decapoda). Analysis of flightin sequence revealed a highly variable (fast evolving) amino terminal region (first ~82 residues) and a ~52 amino acid central region within which residues that remain conserved or neutralized are abundant. The central region is shared by C. elegans and D. melanogaster (i.e., Pancrustacea) but absent in all other metazoans. Within the conserved region, 9 amino acids are invariant including an N-terminal tryptophan (W), 4 tyrosines (Y), and a C-terminal arginine (R). We refer to this conserved region as the WYR-W domain.

1575 Characterization and Functional Analysis of the Drosophila UNC-45 Chaperone In Vitro and In Vivo

C. F. Lee, Biology, San Diego State University, San Diego, CA

UNC-45 is a chaperone important for muscle function. It may be responsible for folding the myosin head into the correct conformation, which is essential for muscle function. In addition, UNC-45 may also prevent myosin from denaturing at elevated temperatures, e.g., during exercise. Here, we explore UNC-45 localization using immunofluorescence confocal microscopy in Drosophila melanogaster and use electron microscopy to demonstrate that UNC-45 protects myosin heads from denaturing and fusing at elevated temperature. We find that UNC-45 is localized to the blastoderm in two-hour-old embryos and co-localizes with non-muscle myosin. In 14-hour-old embryos, UNC-45 is expressed strongly in the body-wall muscles, pterygophore muscle, and the heart tube. Lighter staining areas could indicate UNC-45 function in other tissues. In third instar larval body wall muscle, UNC-45 preliminarily shows an alternating staining pattern with phalloidin labeled actin in a subset of muscles, which implies its localization in the A-bands of sarcomeres. Further, UNC-45 expression is up-regulated by heat-shock in vivo, muscle, and the heart tube. Expression was observed in the same set of muscles (pharyngeal, vulval, body wall) in which UNC-45 is capable of maintaining the two-headed structure of myosin at elevated temperatures, as shown by electron microscopy of chicken skeletal muscle myosin at 25ºC and 42ºC. In contrast, chicken myosin at 42ºC in the absence of UNC-45 showed fused heads. Our studies indicate that phosphorylation of Thr158 and/or Ser162 is necessary for subsequent phosphorylation of other sites. All three transgenic strains express all nine phosphovariants. These results suggest that phosphorylation of Thr158 and/or Ser162 is necessary for subsequent phosphorylation of other sites. All three transgenic strains show normal, albeit long, IFM sarcomeres in newly eclosed adults. In contrast, sarcomeres in fully mature flies show extensive breakdown while those in fln0 are not as disordered. The fiber hypercontraction phenotype that characterizes fln is evident in fln0 and fln0 flies but partially rescued in fln0. Skinner fiber mechanics of newly eclosed flies show alterations in viscous and elastic moduli for fln0 and fln0 resulting in a significant reduction in oscillatory power output. Flightin sequence analysis revealed that Thr158 and Ser162, but not Ser139, Ser141, and Ser145, are conserved among 15 Drosophila species (~40-60 million years divergence time). Our studies indicate that phosphorylation of Thr158 and/or Ser162 fulfills an essential role in IFM structural stability and mechanics while phosphorylation in vivo may enhance secondary, species-specific functions.

1576 A Protein Phosphatase Is a Binding Partner for Protein Kinase 2 (PK2) of UNC-89 (obscurein) in C. elegans

H. Qadota, T. Ferrara, K. Mercer, G. Benian; Pathology, Emory University, Atlanta, GA

In C. elegans, unc-89 mutants display disorganization of muscle A-bands. unc-89 encodes 6 major polypeptides, as large as 800 kDa, composed of immunoglobulin (Ig), fibronectin type III (Fn3), SH3, DH, PH, and protein kinase domains (Benian et al., 1996; Small et al., 2004). Several UNC-89 isoforms contain two protein kinase domains, PK1 and PK2. Molecular modeling indicates that PK1 is inactive, whereas PK2 is catalytically active. Antibodies localize the UNC-89 proteins to the M-line. To gain further insight into the function of UNC-89, we screened a yeast 2-hybrid library, using portions of UNC-89 containing PK2, as baits. The screen resulted in 42 positive clones after re- transformation. These clones identified the same gene, B0379.4. Both isoforms, B0379.4a (38 kDa) and b (55 kDa), were represented. The only recognizable domain in B0379.4 is a serine protein phosphatase. When expressed in E. coli, B0379.4 has phosphatase activity towards p-nitrophenylphosphate in vitro. For the PK2 kinase domain, interaction with B0379.4 required both the autoinhibitory sequence lying C-terminal of the kinase domain, and the Ig and Fn3 domains lying N-terminal of the kinase domain. Moreover, when the analogous regions from the two other giant kinases of C. elegans, twitchin and TTN-1 (Ce titin), were tested, they failed to interact with B0379.4. Transgenic animals were generated carrying a plasmid in which 7.5 kb of sequence upstream of the 5'end of B0379.4 was fused to GFP. Expression was observed in the same set of muscles (pharyngeal, vulval, body wall) in which unc-89 is expressed. Rabbit antibodies were generated that recognize B0379.4 from worm extracts of wild type, and in truncated form from two knockout mutants. By immunofluorescence microscopy anti-B0379.4 localizes to the M-line and to a portion of the I-band. One hypothesis being tested is that PK2 phosphorylates B0379.4 to influence its phosphatase activity.

1577 unc-94 Encodes a Tropomodulin in C. elegans

T. Stevenson¹, K. Mercer,¹ C. Conley,¹ N. Szewczyk,² G. Benian;¹ Pathology, Emory University, Atlanta, GA, ²Aames Research Center, Moffett Field, CA

unc-94 is one of about 40 genes in C. elegans, that when mutant, show reduced motility and disorganization of myofilaments. The original allele, unc-94(x177) was recovered by Zengel and Epstein (1980) by a motility-requiring selection. We have recovered a new allele, n20, by an F1 non-complementation screen. Both alleles show reduced motility and brood size, and disorganization of muscle structure. By polarized light microscopy, there is alteration between normal and increased width of individual A-bands. The localization of a number of known sarcomeric proteins was examined in unc-94 mutants. Each of these proteins shows some degree of mis-localization, but the most dramatic effect is in the localization of F-actin, with some, abnormally many filaments appearing below the level of the cell cortex to a level between 500-600 nm below the cell surface. Among unc-94 mutants, include: (1) obtaining the Unc-94 polarized light phenotype using RNAi for C06A5.7, and (2) achieving transgenic
2006 ASCB Annual Meeting Abstracts

rescue of the Unc-94 mutant phenotype by using cosmid C06A5. After creating transgenic animals that carry putative promoter sequences for tmd-1.a and mid-1.b fused to GFP, we determined that isoform-a is primarily expressed in body wall muscle, while isoform-b is found mostly in the pharyngeal and anal depressor muscles, and the spermatheca.

Proper Localization of Paramyosin Within Thick Filaments Depends upon UNC-98 and UNC-96, Two C. elegans M-line Proteins
R. Miller, K. Mercer, H. Qudota, T. Stark, G. Benian; Pathology, Emory University, Atlanta, GA

Mutations in unc-96 or unc-98 cause reduced motility and a characteristic defect in muscle structure: M-lines and dense bodies are disrupted, and by polarized light microscopy birefringent needles are present. UNC-96 is a 48 kD protein with little similarity to known proteins (Mercer et al. 2006). UNC-98 is a 37 kD protein consisting of four C2H2 Zn finger domains (Mercer et al. 2003). Antibodies localize both UNC-96 and UNC-98 to M-lines in wild-type animals. Non-null mutations in unc-15, the structural gene for paramyosin, also show similar needle-like birefringent needles in mutant animals. Additionally, triple null unc-15+/+ unc-96+/+ and unc-15+/+ unc-98+/+ transheterozygotes, with only one wild-type copy of each gene, have more severe polarized light phenotypes than unc-96, unc-98, or unc-15 heterozygotes alone. ELISAs demonstrate that UNC-98 and UNC-96 interact with paramyosin in vitro. By yeast 2-hybrid, the N-terminus of UNC-96 and C-terminus of UNC-98 interact with a similar region of the coiled-coil rod of paramyosin. Additionally, genetic, cellular, and biochemical data indicate that UNC-98 and UNC-96 interact (Mercer et al. 2006). Our working hypothesis is that UNC-96 and UNC-98 work together to promote thick filament maintenance, either by promoting incorporation of paramyosin into thick filaments or by promoting degradation of paramyosin that has dissociated from thick filaments.

New UNC-97 / PINCH Interactors Localized at Muscle Focal Adhesions in C. elegans
H. Qudota, K. Mercer, K. Kaibuchi, G. Benian; Pathology, Emory University, Atlanta, GA; Cell Pharmacology, Nagoya University, Nagoya, Japan

Myofilaments within C. elegans body wall muscle cells are organized and anchored to the muscle cell membrane by dense bodies and M-lines. These structures are both analogous and homologous to vertebrate focal adhesion plaques. To clarify the molecular mechanisms regulating these intergins-associated attachment structures, we are investigating protein-protein interactions between integrin-associated proteins using a systematic two hybrid approach. Previously, we found a protein cluster associated with integrin including PAT-4 (ILK), PAT-6 (actopaxin), UNC-97 (PINCH), UNC-112 (Mig-2). From a collection of yeast two hybrid constructs consisting of candidate proteins localized at dense bodies and M-lines, we found novel UNC-97/PINCH interactors: UNC-95, LIM-8 and LIM-9. All three proteins contain a LIM domain, which is essential for interaction with UNC-97/PINCH. UNC-97/PINCH is composed of 5 LIM domains and we found that the first LIM domain of UNC-97 is responsible for binding to UNC-95, LIM-8, and LIM-9. LIM-8 and LIM-9 can bind to UNC-96, a novel M-line protein (Mercer et al. 2006). These interactions were confirmed with in vitro binding assays using purified fusion proteins expressed in bacterial cells. UNC-97 and UNC-95 have been reported to be localized at M-lines by using GFP fusions. We investigated expression profiles of two novel gene products, LIM-8 and LIM-9, by promoter-GFP fusions and found that these two genes are expressed in body wall muscle cells. We also prepared antibodies against UNC-97, UNC-95, UNC-96, and UNC-98. We confirmed the localization of UNC-97 and UNC-95 at dense bodies and M-lines, but not in nuclei. With immunostaining of worm adult muscle, LIM-8 and LIM-9 are localized both at dense bodies and M-lines. Taking together the biochemical and cell biological data, we propose a model that the UNC-97/PINCH protein functions for the maintenance of cell-substratum adhesion through the cooperation of three LIM domain proteins.

MAPping the Eukaryotic Tree of Life: The Evolution of the MAP215/Dis1 Family of Microtubule-associated Proteins
D. L. Gard; Biology, University of Utah, Salt Lake City, UT

The MAP215/Dis1 family of proteins is an evolutionarily ancient family of microtubule-associated proteins, with characterized members in all major kingdoms of eukaryotes. An extensive BLAST search of public databases (including both EST and genome sequences) identified partial or complete sequences predicted to encode more than 160 of the MAP215/Dis1 family members from diverse eukaryotic species, including 11 Protists, 3 Stemnophelidae, 32 algae and plants, 44 fungi (39 Ascomyces, 5 Basidiomycetes, and 1 Zygomyces), and more than 70 species in 7 phyla of animals. MAP215/Dis1 proteins in all plants, most animals (except nematodes), and fungi (except ascomyces) are characterized by the presence of four TGT domains, each ~240 amino acids in length and consisting of 1-5 HEAT repeats, suggesting that the gene duplication events from which they are derived occurred prior to the divergence of the major kingdoms of eukaryotes. The two TGT proteins of nematodes and ascomycete fungi are postulated to be derived from ancestral four TGT proteins through deletions and gene rearrangement. MAP215/Dis1 proteins in plants, most animals (except nematodes), at least one fungal (U. maydis), and several protists, also contain a single copy of a moderately conserved ~18 amino acid sequence similar (~45% identical) to the Tau repeat of vertebrate brains. The widespread occurrence of this Tau repeat in vertebrates suggests that it arose early in the evolution of the MAP215/Dis1 family.

Evolution of Alternative Splicing in the MAP215/Dis1 Proteins of Vertebrates
S. K. Evans, E. D. Sanzenbacher, D. L. Gard; Biology, University of Utah, Salt Lake City, UT; Jordan Applied Technology Ctr, West Jordan, UT

We previously identified developmentally-regulated transcripts encoding two isoforms of MAP215 (MAP215M and MAP215S), a member of the MAP215/Dis1 family of microtubule-associated proteins. These isoforms differ in the presence (XMAP215M) or absence (XMAP215S) of a 36 amino acid insert (ins2) encoded by a single exon. XMAP215M transcripts are expressed during oogenesis and present in gastrula embryos and adults. BLAST searches revealed that genes encoding MAP215/Dis1 proteins of teleost fish and mammals lack sequences encoding ins2. However, a related sequence (55% identical; 77% similar) is encoded by the MAP215/Dis1 gene of chickens. We used nested primer pairs and sequential RT-PCR and PCR to clone and sequence cDNAs spanning the ins2 exon of MAP215/Dis1 transcripts from a variety of vertebrates. Transcripts encoding ins2 were identified in oocytes or eggs from several species of amphibians and reptiles, but were absent from somatic transcripts in those species. Nine phosphorylatable amino acids (S/T), including a predicted target for the cell cycle kinase CDK1, are conserved in ins2 sequences from four amphibian species obtained to date (X. laevis, X. tropicalis, R. pipiens, and Bufo sp.), suggesting that phosphorylation of ins2 plays an important role in regulating MAP215M activity during amphibian development. Six of the conserved S/T, including the CDK1 target, have been lost to deletion or mutation in ins2 of the garter snake (Thamnophis sp.). These results support the hypothesis that (1) the ins2 exon arose in a common ancestor of terrestrial vertebrates subsequent to their divergence from fish; (2) ins2 may play an important role in XM215 function in amphibians; and (3) that ins2 function has been lost, through divergence or deletion of ins2 sequences, from other terrestrial lineages. Supported by grant #MCB-0212000 from the N.S.F. and the University of Utah.
To identify putative targets and other components of the Aurora complex in plants, we have performed yeast two-hybrid screening using AtAurora1. Candidate Aurora interactors localize in a centrosome-dependent and centrosome-independent processes during microtubule spindle assembly in Xenopus. In sperm asters with fewer microtubules, Interestingly, targeting of the microtubule nucleator, γ-tubulin, to sperm centrosomes is not affected in these samples. Consistent with a centrosome-independent role for AtXEN1 in aster assembly, XEN1 depleted extracts assemble unoriented microtubules in response to RanGTP, suggesting a role for XEN1 in microtubule organization. Addition of recombinant XEN1-C-terminus to XEN1 egg extracts, or to microtubules assembled in vitro, causes the microtubules to become highly bundled. Recombinant XEN1-C-terminus can recruit γ-tubulin from egg extracts and is able to interact with microtubules directly in vitro. Based on these observations, we hypothesize that XEN1 functions in both centrosome-dependent and centrosome-independent processes during microtubule spindle assembly in Xenopus.

Transcripts Encoding Multiple TACC Proteins Are Expressed During Development of the African Frog Xenopus laevis
J. F. Plant, D. L. Gard, Biology, University of Utah, Salt Lake City, UT

Transforming acidic-coiled-coil (TACC) proteins are a conserved family of proteins that have been implicated in the localization and anchoring of the MAP215/Dis1 proteins to the centrosome. Characterized by a highly conserved TACC domain predicted to form an acidic coiled-coil, TACC proteins have been identified in a diverse range of animals, including both invertebrate and vertebrate species. The invertebrates D. melanogaster and C. elegans each express a single TACC protein. In contrast, mammals, including humans and mice, express three TACC proteins characterized by divergent TACC domains. Previous studies identified a single member of the TACC family (Maskin) in the African frog, Xenopus laevis. Sequence comparison suggests that Maskin is most closely related to TACC3 of mammals. A BLAST search of the incomplete genome of the related frog, X. tropicalis, identified three independent sequences encoding putative TACC proteins, one of which corresponds to the Maskin gene. A BLAST search of Xenopus laevis cDNAs identified partial sequences related to TACC1 and TACC2. Using primers designed from these sequences, we used RT-PCR and PCR-RACE to clone transcripts encoding two putative TACC1 and TACC2 proteins from X. laevis. RT-PCR and in-situ hybridization demonstrated distinct temporal and spatial patterns of expression of TACCs 1-3 during Xenopus development. Supported by grant #MCB-0212900 from the National Science Foundation and by the University of Utah.

Identification of Arctica, a Novel Kinetochore-binding Protein That Interacts with Aurora Kinase in Plants
S. Couture,1 D. Van Damme,1 D. Inze,2 D. Geeler3
1Department of Plant Systems Biology, Flanders Interuniversity Institute for Biotechnology (VIB), Ghent University, Ghent, Belgium
2Faculty of Bioscience Engineering, Department of Plant Production, Ghent University, Ghent, Belgium

Introduction: From budding yeast to human, Aurora serine/threonine kinases are essential for the successful execution of cell division. Aurora kinases form chromosomal passenger complexes (CPCs) that are responsible for the establishment of a bipolar mitotic spindle, accurate segregation of chromosomes and the completion of cytokinesis. Although Aurora has been well-studied in animal and yeast, plant Aurora kinases have only recently been identified (Demidov et al, 2005). The Aurora kinase family in Arabidopsis has 3 Aurora homologues. Structure and expression of AtAurora1 and AtAurora2 suggest that these genes arose by a recent gene duplication, whereas the diversification of plant alpha and beta Aurora kinases predates the origin of land plants. Intracellular localization of GFP-tagged AtAurora1 and AtAurora2 shows labelling of microtubule spindle and the growing cell plate of dividing tobacco BY-2 cells while GFP-AtAurora3 localizes to the kinetochores.

Objective and methods: To identify putative target partners and other components of the Aurora complex in plants, we have performed yeast two-hybrid screening using AtAurora1 as a bait. To validate the interaction data, 37 Aurora interactors were GFP-tagged and localized in dividing tobacco BY-2 cells. Results and conclusions: 7 putative interactors localize in a dynamic cell-cycle-specific manner. The candidate Arctica shows the classical double-dot kinetochore pattern and translocates to the growing cell plate during cytokinesis. This unknown Aurora-interactor has no homology with yeast or animal Aurora kinases, suggesting that plants have developed divergent Aurora kinase signalling pathways involved in chromosome segregation and cytokinesis. The interaction between Arctica and AtAurora1 is investigated using co-localization experiments with GFP and RFP and radioactive kinase assays. Knock-out, knock-down and overexpression studies will be performed to analyze the role of the new Aurora interactor in plant growth and development. This approach will enable us to provide insights into the role of the Arctica-Aurora complex in plants.

Cytoskeletal Components of an Invasion Machine: The Apical Complex and Conoid of Toxoplasma gondii
E. Nagayasu,1 F. Zhang,2 K. Hu,3 J. M. Murray1; 1Cell & Developmental Biology, University of Pennsylvania, Philadelphia, PA, 2Biology, Indiana University, Bloomington, IN

Toxoplasma gondii is an obligate intracellular human parasite in the phylum Apicomplexa, which includes many important human and veterinary pathogens. Central to both invasion and proliferation of Toxoplasma is the apical complex, a group of cytoskeletal and membrane-bound organelles. The complex includes the "conoid", an extraordinary array of 14 spirally arranged tubulin-containing fibers (not microtubules) that is actively motile during invasion (Hu et al., 2002). We are studying the structure and formation of the conoid, particularly the basis for assembly of the non-microtubular tubulin polymer. The primary sequence of the T. gondii tubulins seems unlikely to account for the novel polypeptide form, as these same tubulins assemble into canonical 13-pf microtubules elsewhere in the cell. Furthermore, human tubulin expressed in T. gondii is readily incorporated into the conoid. Candidate accessory proteins that might account for the unusual polymer structure were identified in a proteomics screen (Hu et al. 2005), and we have now characterized several. TgDCXP (55.08188) is one such protein. Its C-terminal region contains a DCX domain, which was originally found in human doublecortin, a neuronal microtubule-associated protein, which has been shown to interact with microtubules. In spindle positioning, the Kar9p and dynein pathways are required to accurately position the mitotic spindle. We are currently testing the hypothesis that dimerization of Bik1p is important for its binding to microtubules. In spindle positioning, the Kar9p and dynein pathways are required to accurately position the mitotic spindle. We are currently testing the hypothesis that dimerization of Bik1p is important for its binding to microtubules. The conoid is a highly dynamic structure that is comprised of a CAP-Gly head domain believed to bind microtubules, a serine rich region, a central coiled-coil, and a C-terminal cargo-binding domain. A structure-function analysis using both purified full length Bik1p and truncated proteins showed that in contrast to full length Bik1p, the CAP-Gly domain together with the serine rich region is not sufficient to bind microtubules. We are currently testing the hypothesis that dimerization of Bik1p is important for its binding to microtubules. In spindle positioning, the Kar9p and dynein pathways are required to accurately position the mitotic spindle. Bik1p has recently been shown to physically interact with proteins of both pathways. To begin to dissect its role in each of these pathways, a screen was carried out to obtain bik1 mutants lacking subsets of these interactions. One mutant was identified that interacted poorly with both Kar9p and Kip2p. Sequencing identified a mutation in bik1 that results in a premature termination at position 61 (Y61H). Phenotypic characterization of Y61H revealed that its cytoplasmic microtubules are short. Bik1p-Y61H tagged with GFP is localized as discrete punctae throughout the cell. Biochemical analyzes showed that the Bik1-Y61H protein was about 8 kD smaller than wild-type, suggesting that this mutation affects the stability of Bik1p. Further analyses revealed that the bipartite Y61H is intact, suggesting that it is clipped at its N-terminus, the region believed to bind microtubules. A possible candidate to carry out this clipping is Lap4p, a leucine aminopeptidase found in the cytoplasm and vacuole. Lap4p has been previously reported to interact with Bik1p by affinity capture methods. We are currently testing the novel hypothesis that limited proteolysis of wild-type Bik1p may regulate its function.

Mutational Analysis of Bik1p the Yeast Ortholog of CLIP-170
S. D’Souza,1 H. Hoops,2 H. V. Goodson,3 R. K. Miller2; 1Dept. of Chemistry and Biochemistry, University of Notre Dame, Notre Dame, IN, 2Dept. of Biology, University of Rochester, Rochester, NY, 3Dept. of Biology, State University of New York-Geneseo, Geneseo, NY

Bik1p, the yeast homolog of the mammalian microtubule binding protein CLIP-170, plays an important role in spindle positioning by stabilizing cytoplasmic microtubules. Like CLIP-170, the structure of Bik1p is comprised of a CAP-Gly head domain believed to bind microtubules, a serine rich region, a central coiled-coil, and a C-terminal cargo-binding domain. A structure-function analysis using both purified full length Bik1p and truncated proteins showed that in contrast to full length Bik1p, the CAP-Gly domain together with the serine rich region is not sufficient to bind microtubules. We are currently testing the hypothesis that dimerization of Bik1p is important for its binding to microtubules. In spindle positioning, the Kar9p and dynein pathways are required to accurately position the mitotic spindle. Bik1p has recently been shown to physically interact with proteins of both pathways. To begin to dissect its role in each of these pathways, a screen was carried out to obtain bik1 mutants lacking subsets of these interactions. One mutant was identified that interacted poorly with both Kar9p and Kip2p. Sequencing identified a mutation in bik1 that results in a premature termination at position 61 (Y61H). Phenotypic characterization of Y61H revealed that its cytoplasmic microtubules are short. Bik1p-Y61H tagged with GFP is localized as discrete punctae throughout the cell. Biochemical analyzes showed that the Bik1-Y61H protein was about 8 kD smaller than wild-type, suggesting that this mutation affects the stability of Bik1p. Further analyses revealed that the bipartite Y61H is intact, suggesting that it is clipped at its N-terminus, the region believed to bind microtubules. A possible candidate to carry out this clipping is Lap4p, a leucine aminopeptidase found in the cytoplasm and vacuole. Lap4p has been previously reported to interact with Bik1p by affinity capture methods. We are currently testing the novel hypothesis that limited proteolysis of wild-type Bik1p may regulate its function.

Plakins are a family of cytoskeletal proteins that interact with cytoskeletal microfilaments to each other and to cell junctional complexes. In epithelia, plakins form junctions between intermediate filaments and desmosomes, as well as hemidesmosomes. The epithelial plakins are generally composed of a so-called plakin domain that interacts with cell junctional complexes, a coiled-coil rod that allows for protein dimerization and a plakin repeat region that interacts with intermediate filaments. Bullous pemphigoid antigen 1 (BPAG1) and microtubule-actin crosslinking factor 1 (MACF1) are members of the plakin family that exhibit tissue-specific alternative splicing. Like the epithelial isoform, BPAG1 and MACF1 isoforms expressed predominantly in the brain and muscle also contain the plakin domain. However, they do not contain the coiled-coil rod domain and plakin repeat region, rather these isoforms are composed of N-terminal calponin-homology domains that can bind to actin filaments, an internal plakin repeat region (BPAG1 muscle isoform), 23 spectrin repeats, and a C-terminal microtubule binding domain (MTBD). Recent reports reveal that the MTBD of human BPAG1 interacts with the microtubule plus-end binding protein, EB1 (Slep et al., 2005). We report the alternative splicing of the MTBD of BPAG1 and MACF1. This alternative splicing uses different 3′ exons to yield four additional variants of the neural and muscle isoforms of BPAG1 and MACF1. We have examined the expression profile and microtubule binding properties of each newly identified isoform. We also determine if the alternative splicing alters BPAG1 and MACF1 interaction with the EB1 family members.

Bim1p also interact with proteins involved in the sumoylation pathway—

sumoylation regulates spindle positioning in yeast. Here, we show that Kar9p and Bim1p are likely to be modified by SUMO/Smt3p. Both interact with SMT3 by two-hybrid analysis. However, neither interact with a mutant form of SMT3 in which the terminal glycine required for conjugation has been mutated to alanine. Both Kar9p and Bim1p also interact with proteins involved in the sumoylation pathway—UBC9 an E2 enzyme required for SUMO conjugation; NIP1 an E3 enzyme conferring specificity for SUMO targets; and PSS1 a weak suppressor of SUMO. Because Kar9p and Bim1p physically interact with each other, the two simplest bridging models were tested by deleting either KAR9 or BIM1 from the two-hybrid reporter strain and testing for the reciprocal interaction. In both cases, Kar9p and Bim1p retained their interactions with the sumoylation machinery. The Kar9p-Ube9p interaction was confirmed in vivo by affinity chromatography. Experiments to characterize the cellular and molecular requirements for this interaction of Kar9p with the sumoylation system are in progress. Our data support the hypothesis that sumoylation regulates spindle positioning in yeast.

A central question in cell biology is how cells determine and maintain the size of their organelles. Mitotic chromosome segregation is orchestrated by dynamic interaction between spindle microtubules and the kinetochores. In a proteomics discovery of previously uncharacterized microtubule-associated proteins, we identified a unique human microtubule-associated protein named CAP140. CAP140 localizes to microtubules in interphase, associates with the mitotic spindle during mitosis, and redistributes to the central body during cytokinesis. Our biochemical characterization reveals that CAP140 binds to microtubules via its central coiled-coil domain. While endogenous CAP140 is located along cytoplasmic microtubules in interphase and on the spindle in mitosis, overexpression of CAP140 resulted in exclusive interphase microtubule bundles without affecting early mitotic spindle organization. However, overexpression of CAP140 central domain induces profound bundling of cytoplasmic microtubules in interphase cells and aberrant spindles in mitosis suggesting the integrity of CAP140 is essential for spindle stability. Indeed, depletion of CAP140 by RNA interference results in severe mitotic delays and defective cytokinesis. The mitotic abnormalities seen in CAP140-depleted cells include multiple spindle poles and stimulated spindle assembly. Truncation mutants demonstrate that the central region of CAP140 is important for localization to the mitotic spindle, and to the center of the midbody, whereas the C-terminal tails, with the high sequence homology to tau, bearing microtubule depolymerase activity. These results suggest a crucial role CAP140 in the organization of the bipolar mitotic spindle, and mitotic progression, and define CAP140 as a novel key factor for proper spindle assembly. Currently, we are studying the real-time chromosome movements in living cells depleted CAP140 and elucidating the phospho-regulation of CAP140 in mitosis.

One role of Kar9p in spindle positioning is to link the actin and microtubule cytoskeletons. The microtubule binding protein and EB1 homologue Bim1p links Kar9p to the microtubule. The type V myosin links Kar9p to the actin cytoskeleton. However, little is known about the molecular mechanisms that regulate Kar9p function. SUMO/Smt3p is a conserved small ubiquitin-related modifier that is covalently attached to other proteins as a post-translational modification. SUMO is analogous to ubiquitin in several ways, but functionally different. Unlike ubiquitin, sumoylation does not target proteins for degradation. Although targets of sumoylation are associated with a diverse set of biological processes, it was not previously known whether sumoylation regulates the microtubule-dependent process of spindle positioning in yeast. Here, we show that Kar9p and Bim1p are likely to be modified by SUMO/Smt3p. Both interact with SMT3 by two-hybrid analysis. However, neither interact with a mutant form of SMT3 in which the terminal glycine required for conjugation has been mutated to alanine. Both Kar9p and Bim1p also interact with proteins involved in the sumoylation pathway—UBC9 an E2 enzyme required for SUMO conjugation; NIP1 an E3 enzyme conferring specificity for SUMO targets; and PSS1 a weak suppressor of SUMO. Because Kar9p and Bim1p physically interact with each other, the two simplest bridging models were tested by deleting either KAR9 or BIM1 from the two-hybrid reporter strain and testing for the reciprocal interaction. In both cases, Kar9p and Bim1p retained their interactions with the sumoylation machinery. The Kar9p-Ube9p interaction was confirmed in vivo by affinity chromatography. Experiments to characterize the cellular and molecular requirements for this interaction of Kar9p with the sumoylation system are in progress. Our data support the hypothesis that sumoylation regulates spindle positioning in yeast.

E. S. Kannegaard, W. F. Marshall; Biochemistry, University of California San Francisco, San Francisco, CA

Cilia are known to be crucial for many developmental and physiological processes, yet cilia biogenesis and maintenance are not well understood. In particular, apart from intraflagellar transport proteins, molecular players in the process of ciliogenesis are largely unknown. Two recent studies utilizing the unicellular green alga Chlamydomonas reinhardtii, which has two flagella that are homologous to human cilia, have determined the proteome of the flagellum and identified genes that are upregulated upon deflagellation. By analyzing these datasets we have identified a set of genes that are upregulated during flagellar regeneration for which the gene products are not components of the flagellum itself, suggesting that there is a class of proteins related to those in the Chlamydomonas flagellum that are homologous to human cilia, have determined the proteome of the flagellum and identified genes that are upregulated upon deflagellation. By analyzing these datasets we have identified a transcriptional circuit that may help increase system stability during flagellar regeneration.

Dynamics, Feedback, and Bifurcations in an Organelle Size Control System

W. Marshall, W. Ludington, I. Zamora; Biochemistry, UCSF, San Francisco, CA

A fundamental question in cell biology is how cells determine the size of organelles. Flagella are a convenient system to address the question of organelle abundance since their size can be described by a single number—length. An interesting feature of flagellar length control is length equalization—when one flagellum is severed from a cell with two flagella, it will grow back, but as it does so, the other unperturbed flagellum will shorten until the two flagella reach the same length. This has been taken as evidence that the cell "knows" how long its flagella are, and "instructs" the long one to shorten. Based on studies of flagellar microtubules, we have proposed a simple model in which length is determined by the balance of turnover and intraflagellar transport. We will show that simulations based on this model can predict the length equalization of flagella. Numerical explorations with the model predict that as the level of intraflagellar transport machinery is increased, the system should undergo a supercritical Hopf bifurcation, leading to sustained limit cycle oscillations. To test this prediction, we searched a panel of mutants and identified one with increased intraflagellar transport, and as predicted the flagella no longer can attain a stable steady-state length but instead undergo continual oscillations. Our model can be viewed as an integral-only control system, and such systems are prone to instability due to the phenomenon of "integrator wind-up". Model control systems are never integral-only, and always employ additional control loops of a derivative or proportional nature to counteract the instability caused by the integrator. We have searched for such additional loops within the flagellar length control system and have identified a transcriptional circuit that may help increase system stability during flagellar regeneration.

K. A. Wenner, J. L. Feldman, W. F. Marshall; Biochemistry, UC San Francisco, San Francisco, CA

A central question in cell biology is how cells determine and maintain the size of their organelles. Chlamydomonas reinhardtii flagella provide an excellent model system for studying this problem, as Chlamydomonas is tightly and precisely controlled. It is known that the distal tips of flagella are unstable and undergoing continuous turnover, therefore the precise flagellar length must be maintained by balancing assembly and disassembly at the tip of each flagellum. Several models have been proposed to explain the mechanism responsible for this balance. We would like to investigate these models by examining flagellar length mutants using a combination of genetics and microscopy to test predictions derived from these models of length control.
1595 Regulation of the Flagellar Length Control Kinase LF4 by Phosphorylation

M. M. McLaren, B. Raber, N. F. Wilson; Anatomy & Cell Biology, Oklahoma State University Center for Health Sciences, Tulsa, OK

Regulation of flagellar length in Chlamydomonas oda7 (L1, L2, LF3, and LF4) have been identified that when mutated generate cells with abnormally long flagella. LF4 was recently shown to encode a MAP kinase. Immunoblot analysis revealed that in cell bodies, LF4p migrates as a doublet at 73/72 kDa whereas in flagella, LF4p migrates as a single band at 65 kDa. Both isoforms in cell bodies are recognized by an anti-phosphoTEY antibody that recognizes the activated form of MAP kinases. Interestingly, the flagellar form of LF4p was not recognized by the anti-active MAP kinase antibody. Consistent with the observation that the cell body isoforms of LF4p are enzymatically active, LF4p from cell bodies but not flagella was able to phosphorylate myelin basic protein in an in-gel kinase assay. These observations suggest that LF4p exists as an active kinase in cell bodies while the flagellar form is maintained in a largely inactive state. In vitro mixing experiments suggest that the flagellar form of LF4p is inactivated by the activity of one or more flagellar phosphatase(s). We have utilized the genome sequence of Chlamydomonas to identify phosphatases(s) that regulate the kinase activity of LF4p in flagella. We have identified 8 putative MAP Kinase Phosphatases (MKPs) in the genome of Chlamydomonas that could potentially regulate LF4p. We are using Northern analysis to determine which of these 8 MKPs are upregulated during flagellar regeneration. To date, 1 (MKP1) of the 4 phosphatases screened in such a manner is upregulated during flagellar regeneration. Currently, we are completing our screening of the remaining phosphatases by Northern analysis. In addition, we are generating RNAi constructs for knock-down of gene expression for MKP1, as well as substrate-trapping mutants for this phosphatase.

1596 Importance of Golgi for the Regulation of Flagellar Length in Chlamydomonas

W. Dettler; Molecular Biosciences, University of Kansas, Lawrence, KS

The importance of IFT for flagellar microtubule assembly and maintenance is established but the role of the membrane for flagellar growth or maintenance is not understood. Haller & Fabraz (1998, BBRC 24:597) reported that brefeldin A (BFA), which disrupts Golgi, arrested flagellar growth in Gonium, suggesting that membranes may partly regulate flagellar growth. To study the role of membranes in flagellar maintenance, Chlamydomonas fla10 and pf18 cells were treated with BFA to answer the following questions: (a) Does BFA block flagellar growth or induce flagellar shortening? Cells were delflagellated by pH shock and measured during regeneration. On cells treated with 0-4.0 µg/ml BFA, flagella grew to 70-80% the length of control flagella but then shortened to 51% of control lengths within 120 min; greater inhibition was observed with 10-15 µg/ml BFA. After BFA removal, flagella rapidly grew to control lengths. On nonflagellated cells, BFA induced flagella to shorten to 50% of control length within 3 hrs and to 10% of control length with longer treatment. This occurred on fla10 cells and on pf3B23 cells, which shorten during the day. (b) Are new processes (delivered from Golgi) required to maintain flagellar length? Flagella slightly shortened on cells treated with 30 µg/ml cycloheximide for up to 6 hrs, but shortening was significantly less than that produced by BFA. (c) Does BFA affect IFT? Examination of pf18 flagella with DIC (Dettler, 2005; ICB 170:649) revealed normal IFT. (d) Does BFA affect Chlamydomonas Golgi? By TEM, Golgi were present in control cells but absent in cells treated with 10µg/ml BFA. IFT particles were present in both control and BFA-treated flagella. Taken together, these data indicate that flagellar length depends, in part, on the regulated delivery of membrane to flagella via the Golgi that may be independent of the IFT-mediated delivery of newly synthesized flagellar proteins.

1597 The Ciliary Transcriptome

W. Marshall; L. Zamora; Biochemistry, UCSF, San Francisco, CA

The assembly of a cilium requires production of hundreds of proteins. We have analyzed the transcriptional program of ciliogenesis, both as a way to identify genes involved in ciliary assembly or function, and also in order to explore the role of transcriptional regulatory circuits in coordinating the assembly process. The system we employ is flagellar regeneration in Chlamydomonas - upon flagellar severing induced by pH shock, hundreds of genes become transcriptionally upregulated, including virtually all known flagellar proteins. How does the nucleus know to turn these genes on? We have investigated the cues that drive activation of the ciliogenesis program, and will present evidence that transcriptional activation is NOT triggered by the pH shock itself, nor by the loss of the flagellum, but rather by the active process of flagellar assembly. This suggests a feedback system for the assembly machinery into the nucleus. By analyzing flagellar gene transcription in a collection of pre-existing flagellar assembly mutants, we have found a mutant that regenerates flagella but no longer activates flagellar genes during regeneration. This gene, which encodes a component of the intraflagellar transport machinery, may therefore act to couple the two processes of assembly and transcription. In terms of ciliary gene-discovery, a major drawback of the transcriptional profiling approach has been the possibility that some of the genes identified may simply represent a stress response to the pH shock or severing. By using mutants which block transcription of known flagellar genes following delflagellation, we have developed a strategy to classify transcriptome elements as bona fide ciliogenesis genes versus generalized stress response genes.

1598 Ca2+-dependent Interaction of the Heavy Chain-associated LC4 Light Chain and Intermediate Chain 1 within Chlamydomonas Outer Arm Dynein

M. Sakato, S. M. King; MMSB, University of Kansas Health Center, Lawrence, KS

Chlamydomonas flagella exhibit waveform conversion upon an increase in intraflagellar [Ca2+] from pCa 6 to 4. Mutational studies suggest that the outer row of axonemal dynein arms is involved in this Ca2+-mediated regulatory pathway. Outer arm dynein consists of three heavy chains (α, β, and γ), two intermediate chains, multiple light chains and the docking complex. We have previously shown that α- LC4 directly activates ATP-sensitive microtubule binding by a dynein subparticle containing the β and γ heavy chains. The γ heavy chain-associated LC4 light chain is a member of the calmodulin family and binds 1-2 Ca2+ with Kd ~ 3 x 10^{-5} M in vitro, suggesting it may act as a Ca2+-sensor for outer arm dynein. We further investigated interactions between L4C and the γ heavy chain in vivo. Two I2Q consensus motifs for binding calmodulin-like protein are located within the stem domain of the γ heavy chain. In vitro experiments indicate that LC4 is permanently tethered C-terminal of this region, and that it undergoes a Ca2+-dependent interaction with the I2Q motifs. In addition, chemical crosslinking revealed that LC4 moves into close proximity of the intermediate chain IC1 in the presence of Ca2+. Interestingly, the sedimentation profiles of the γ heavy chain subunit changes subtly following Ca2+ addition suggesting that the entire complex alters conformation in response to Ca2+. We propose that a Ca2+-dependent conformational change within LC4 has a direct effect on the stem domain of the γ heavy chain and eventually leads to alterations in mechanical interactions between microtubules and the motor domain(s) of the outer arm dynein.

1599 The Chlamydomonas Oda7 Protein Links Outer Row and Inner Row Dyneins

J. Freshour, R. Yokoyama, D. R. Mitchell; Cell and Developmental Biology, SUNY Upstate Medical University, Syracuse, NY

Most Chlamydomonas mutations that disrupt the assembly of outer row dyneins encode either dynein motor complex subunits, or subunits of doublet microtubule attachment sites for dynein motors. We identified the gene products of two outer row dynein assembly loci on LG1, ODA47 and ODA48, through positional cloning and characterization of mutations that disrupt each gene. Both loci were cloned by walking from near-by molecular markers; their identities were confirmed by phenotypic rescue with genomic clones and by comparing wild type and mutant copies of each gene. The oda7 strain contains a deletion of exon 1 of gene C_410113 (GI Chlamydomonas genome database V2.0); the oda6 strain contains a frame shift in the first coding exon of gene C_1330506. Both genes encode leucine-rich repeat (LRR) proteins in the SDS22 superfamily, which includes outer row dynein light chain 1. ClustalW analysis suggests that most flagellated organisms contain single homologs of LC1, Oda7 and Oda6. Among flagellates, four genes a 60 kD protein on western blots of both whole cells and flagella. Oda7 is present in flagella of all single mutants examined except oda7, thus we could not genetically identify an axonemal structure essential for its assembly. After extracted by 0.6 M NaCl from axonemes of wild type or oda7 mutants such as p28, Oda7 preferentially co-sediments on sucrose gradients with Inner row dynein. In extracts from 11 mutants it co-sediments with outer row dynein. Sedimentation rate shifts to the top of the gradient in extracts of mutants that lack both outer row and Inner row dynein. We hypothesize that Oda7 resides in a doublet-associated complex that interacts with both outer row and Inner row dyneins. Supported by a grant from the National Institutes of Health to DRM.

1600 Regulation of Flagellar Inner Arm Dynein 11: The β Heavy Chain Motor Domain Is Necessary for Control of Microtubule Sliding by Phosphorylation

L. A. Fox, D. Tritschler, M. E. Porter, W. S. Sale; Cell Biology, Emory University School of Medicine, Atlanta, GA, Genetics, Cell and Development, University of Minnesota, Minneapolis, MN
The inner arm dynein I1, also known as the f-dynein, is a two-headed axonemal dynein required for regulation of microtubule sliding and control of flagellar bending. The mechanism of regulation involves the radial spokes, axonemal kinetics (PKA; CK1) and control of phosphorylation of the intermediate chain IC138 (Hendrickson et al., 2004). To test the role of the two different dynein heavy chain (DHC) motor domains in regulation, we measured microtubule sliding in axonemes from pf17 mutant cells that also lack either the 1α or 1β motor domains of I1 (Myster et al., 1999; Perrone et al., 2000 and see Toba et al., these Proceedings). The motor domain mutants were generated by crossing pf17 to transformants expressing the N-terminal region of the appropriate DHC in a null mutant background. These N-terminal DHC constructs selectively delete the motor domains but permit the assembly of the remainder of the I1 dynein complex. Genotypes of paralyzed “triple” mutants were confirmed by PCR and Western blotting. In 1 mM MgATP, microtubule sliding velocity was greatly reduced in axonemes from both triple mutants (~90 µm/sec - similar to microtubule sliding in pf17) compared to wild type (~18.0 µm/sec). Addition of the kinase inhibitors PKI or DRB rescued microtubule sliding in pf17 axonemes. Similarly, the kinase inhibitors rescued sliding in pf17 axonemes lacking the 1α DHC motor domain. However, the kinase inhibitors had no effect on microtubule sliding in pf17 axonemes lacking the 1β DHC motor domain. Based on these, and other data indicating I1 and IC138 assembly is required for regulation (e.g. Yang and Sale, 2006; Bower et al., these Proceedings), we conclude that the I1 DHC, but possibly not the 1α DHC, motor domain is necessary for regulation of microtubule sliding by the IC138 phosphorylation pathway.

1602 The Role of the IC97 in I1-Dynein Assembly and Axonemal Anchoring
Cell Biology, Emory University School of Medicine, Atlanta, GA; Genetics, Cell Biology & Development, University of Minnesota, Minneapolis, MN; Molecular, Cellular, and Developmental Biology, University of Colorado, Boulder, CO; Cell Biology, Emory University, Atlanta, GA

Our goal is to understand how the BOP5 gene product, the IC138 phosphophotoprotein, regulates the activity of the I1 inner arm dynein (Hendrickson et al., 2004). Here we focus on an unusual motility mutant, 6F5, obtained by insertional mutagenesis. We previously found that ~90% of the IC138 gene is deleted in 6F5, and that the motility defect co-segregates with the loss of IC138 (Bower et al., ASCB 2005). Contrary to expectation, we also found that most I1 subunits are present in 6F5 axonemes, but both IC138 and IC97 are missing (see also Wirschel et al., these proceedings). Fractionation of dynein extracts by sucrose density gradient centrifugation revealed that the remaining I1 subunits dissociate into two distinct peaks. Thus IC138 and IC97 appear to stabilize the I1 dynein, but they are not required for its assembly in the axoneme. Analysis of 6F5 axonemes by electron microscopy and computer image averaging revealed a defect at the base of the I1 dynein, in close proximity to radial spoke I1. Microtubule sliding velocities are also reduced. Transformation with wild-type IC138 restores assembly of both IC138 and IC97 and increases sliding velocities to wild-type levels. These observations suggest that the IC138 is required for activation of the I1 dynein motor domains by the radial spokes. To test this hypothesis, we have now analyzed sliding velocities in a double mutant lacking both the radial spoke head and IC138. As expected, treatment with protein kinase inhibitors increased sliding velocities in pf17 axonemes, but not in pf17 6F5 double mutants. Together with similar observations on I1 motor domain mutants (Fox et al., these proceedings), our results indicate that IC138 (and IC97) play a key role in mediating signals between the radial spokes and the I1 dynein motor domains (supported by NIH).

1603 Characterization of the Protein Kinase CK1 That Regulates Dynein-driven Microtubule Sliding and Is Anchored in Chlamydomonas Flagellar Axonemes
A. Gokhale, M. Wirschel, W. S. Sale; Cell Biology, Emory University, Atlanta, GA

Biochemical, functional and pharmacological evidence reveal that caspase kinase 1 (CK1), is anchored in the flagellar axoneme and regulates microtubule sliding. The mechanism of regulation appears to require inner arm dynein I1 and involves control of phosphorylation of IC138 (Yang and Sale, 2000, Hendrickson et al., 2004). To test the hypothesis that CK1 is anchored to the outer doublet, near I1 dynein, we have cloned and characterized CK1 identified in the flagellar proteome (Pazour et al., 2005). MS/MS analysis of axonemal fractions revealed multiple unique peptide corresponding to one gene located on scaffold 20 (GI version 3). The same gene model was identified in a eyespot proteome, indicating that CK1 is targeted to multiple cell functions (Schmidt et.al, 2006). Analysis of mapped BAC clones containing the CK1 gene indicates that it maps to linkage group XII/XIII. The predicted 38 kDa protein is highly conserved in the N terminal and catalytic domains. Polyclonal antibodies were made to a unique 34 amino acid sequence at the C-terminus. Western blots show a single band in axonemes that migrates at about 36 kDa. The protein is protease resistant and associated with axonemal structure. In summary, we have characterized a putative CK1 in axonemes that is conserved in both cell and tissue specific functions. Our current objective is to test the hypothesis that the axoneme contains a CK1 specific binding protein. EDC treatment of axonemes results in a robust CK1 cross-linked product of ~90 kDa. We are in process of identifying this protein ~60 kDa axonemal protein.

1604 IDA6 Encodes a Conserved Coiled Coil Polypeptide Associated with the Dynein Regulatory Complex
D. Tritschler, E. O'Toole, C. Perrone, M. E. Porter; Genetics, Cell Biology & Development, University of Minnesota, Minneapolis, MN; Molecular, Cellular, and Developmental Biology, University of Colorado, Boulder, CO

The dynein regulatory complex (DRC) is a group of tightly bound axonemal polypeptides thought to mediate signals between the radial spokes, nexin linkages, and dynein motor domains (Mastronarde et al., 1992; Gardner et al., 1994; Piperno et al., 1994; Nicastro et al., 2006). Several motor mutants lacking DRC components are also associated with defects in the assembly of a crescent shaped structure in the DRC and an associated dynein head domain. To identify the IDA6 gene product, we screened the flagellar and basal body proteomes (Li et al., 2004, Pazour et al., 2005) for candidate genes that are linked to the dynein regulatory complex. Genotypes of paralyzed “triple” mutants were confirmed by PCR and Western blotting. In 1 mM MgATP, microtubule sliding velocity was greatly reduced in axonemes from both triple mutants (~90 µm/sec - similar to microtubule sliding in pf17) compared to wild type (~18.0 µm/sec). Addition of the kinase inhibitors PKI or DRB rescued microtubule sliding in pf17 axonemes. Similarly, the kinase inhibitors rescued sliding in pf17 axonemes lacking the 1α DHC motor domain. However, the kinase inhibitors had no effect on microtubule sliding in pf17 axonemes lacking the 1β DHC motor domain. Based on these, and other data indicating I1 and IC138 assembly is required for regulation (e.g. Yang and Sale, 2006; Bower et al., these Proceedings), we conclude that the I1 DHC, but possibly not the 1α DHC, motor domain is necessary for regulation of microtubule sliding by the IC138 phosphorylation pathway.

1605 Identification of a DF2/P22/GASS Required for Assembly of the Dynein Regulatory Complex
R. Bower, D. Tritschler, J. Mueller, K. Vander Waal, C. Perrone, M. E. Porter; Genetics, Cell Biology & Development, University of Minnesota, Minneapolis, MN

The Chlamydomonas pf2 gene encodes a highly conserved coiled coil protein that is the orthologue of the growth arrest specific gene GAS8 (Rupp and Porter, 2003). Closely related sequences are found in other organisms that assemble motile cilia, consistent with the hypothesis that PF2 is a conserved component of the dynein regulatory complex (DRC). The DRC is a group of tightly bound axonemal polypeptides thought to mediate signals between the radial spokes, nexin linkages, and dynein arms (Mastronarde et al., 1992; Gardner et al., 1994; Piperno et al., 1994; Nicastro et al., 2006). To further characterize the DRC in Chlamydomonas, we generated a series of antibodies against PF2/GASS. Western blot analysis of DRC mutant axonemes

296

2006 ASCB Annual Meeting Abstracts
confirmed that the antibodies are specific for PF2, but also showed that PF2 is modified in sup-pf-3 axonesmes. Cloning and sequence analysis subsequently showed that the sup-pf-3 mutation was the result of transposon insertion into the PF2 locus. RT-PCR revealed the presence of cryptic splice sites, and the resulting transcripts contain in-frame deletions within the PF2 coding sequence. The truncated PF2 subunits still assemble into the axoneme, but other DRC subunits are missing (see Huang et al., 1982). Transformation of pf2 and sup-pf-3 with epitope-tagged PF2 rescues the motility defects. High salt extraction and sucrose gradient centrifugation demonstrated that PF2 is part of a large complex in wild-type and rescued strains, but sediments as a smaller complex in sup-pf-3 extracts. These results suggest that the missing PF2 domains in sup-pf-3 are critical for the assembly of the DRC. Dikarya rescue experiments with a PF2-GFP strain also indicated that the time course of DRC assembly is much slower than might be predicted simply on the basis of intrflagellar transport. (Supported by NIH).

1606 Microtubule Binding and Assembly of a Calmodulin and Radial Spoke Associated Complex (CRC) E. E. Dynek, F. Smith; Biological Sciences, Dartmouth College, Hanover, NH
As a first step towards defining the role of calmodulin in modulating ciliary motility, we used an immunoprecipitation approach to identify calmodulin interactors in the axoneme. In an accompanying abstract (authors Dynek and Smith) we present data supporting the discovery of a calmodulin associated complex that includes three polypeptides, one of which (CaM-IP2) is an AKAP binding protein. This complex is associated with the radial spoke protein RSP3 (an AKAP) locus. The band at the AKAP localization in the CRC complex, which lacks RSP3, is confirmed that the antibodies are specific for PF2, but also showed that PF2 is modified in sup-pf-3 axonesmes. Cloning and sequence analysis subsequently showed that the sup-pf-3 mutation was the result of transposon insertion into the PF2 locus. RT-PCR revealed the presence of cryptic splice sites, and the resulting transcripts contain in-frame deletions within the PF2 coding sequence. The truncated PF2 subunits still assemble into the axoneme, but other DRC subunits are missing (see Huang et al., 1982). Transformation of pf2 and sup-pf-3 with epitope-tagged PF2 rescues the motility defects. High salt extraction and sucrose gradient centrifugation demonstrated that PF2 is part of a large complex in wild-type and rescued strains, but sediments as a smaller complex in sup-pf-3 extracts. These results suggest that the missing PF2 domains in sup-pf-3 are critical for the assembly of the DRC. Dikarya rescue experiments with a PF2-GFP strain also indicated that the time course of DRC assembly is much slower than might be predicted simply on the basis of intrflagellar transport. (Supported by NIH).

1607 Reduced Inter-doublet Sliding and the Response to Calcium in Mouse Sperm Lacking the Central Apparatus Protein, SPA16L K. A. Leech, Z. Zhang, J. F. Strauss, C. B. Lindemann; Biological Sciences, Oakland University, Rochester, MI. "Obstetrics and Gynecology, Virginia Commonwealth University, Richmond, VA
A targeted disruption of the PF20 gene in mice affected spermatogenesis and resulted in sperm cells with reduced flagellar motility (Zhang et al., 2002, Mol.Cell.Biol. 22: 7993-8004). The same study determined that the defective protein associated with this mutation, spermatogenic-antigen 16 (SPA16L), is localized to the central apparatus of the flagellar axosome. To test the potential role of the SPA16L protein in sperm motility we compared the primary motor function of sperm from mice carrying this defect to sperm from age and strain-matched controls. Axonemal sliding disintegration was assayed by a method that utilized a 0.5% Triton X-100 / 2 mM DTT extraction buffer (pH 9.4) to remove the mitochondrial sheath. Sliding disintegration was initiated with 1mM ATP and the number of disintegrating cells vs. non-responders was counted and the pattern of disintegration recorded. Fewer SPA16L sperm cells showed disintegration than control cells (27% vs. 52%, p<0.01), and of the responding cells significantly fewer cells from the SPA16L strain extruded doublets from both sides of the axoneme (6% vs. 14%, p<0.05). We evaluated the ability of demembranated sperm to respond to Ca^2+ which is evident by a change in direction of flagellar curvature following exposure. Significantly less of the sperm from the mutant mice responded to Ca^2+ (37%) compared to the control sperm (74%), p=0.006. Furthermore, control sperm responded to 1mM Ca^2+ by acquiring a curlicue configuration (1.9 x 10^9 radians/meter) while the SPA16L sperm cells showed a significantly reduced curvature development in the midpiece region (2.5 x 10^9 radians/m; p<0.001). This suggests a reduced ability of sperm cells from SPA16L mice to develop bending torque. Taken together, our results implicate a central role for the SPA16L protein in primary motor function of sperm flagella. Supported by N.S.F. grant #MCB-0516181 and N.I.H. grant # HD37416.

1608 Lack of Cilia Is Permissive for Knock-down of the Microtubule-severing Protein Katanin M. Q. Rasi, L. M. Quarmby; Molecular Biology and Biochemistry, Simon Fraser University, Burnaby, BC, Canada
Katanin is a member of the AAA family of proteins. We have previously cloned and implicated Chlamydomonas katanin (ep60) in calcium-activated microtubule severing, a process which leads to the excision of flagella from the cell body (Lohret et al., 1999, Cell Mol. Cytoskeleton, 45: 221). Evidence from other model systems indicates that katanin plays a role in cell cycle regulation, but the precise role has been difficult to define. In this study we investigate the cell cycle status of katanin in Chlamydomonas reinhardtii. Repeated failure to isolate katanin mutants lead us to speculate an essential role for this protein. Consequently, we used RNA interference to knock down katanin. We screened over ~1500 stable katanin RNAi transformants for independent lineage-specific expansions of Nek family members. In order to identify subfamilies with potential ciliary functions, we are expressing representative eGFP-tagged cDNAs in ancestral Neks in both of the major eukaryotic lineages (unikonts and heterokonts), as well as in the last common ancestor of all eukaryotes. We find that various organisms have undergone phylogenetic analysis of this gene family. Neks are divergent enough to have resisted evolutionary analysis by traditional methods. We have used Bayesian inference to construct the gene family trees. The number of NIMA kinase genes in organisms is correlated with the presence of cilia on cells that divide (Quarmby & Mahjoub 2005. J. Cell Sci. 15:5161). Based on this correlation, and our

1609 Defining the Ciliary Targeting Domain of Chlamydomonas NIMA-related Kinase 2 (Cnk2p) B. Bradley, M. White, L. Quarmby; Simon Fraser University, Burnaby, BC, Canada
Cnk2p is an ankyrin repeat protein that plays a role in regulating flagellar length and cell cycle progression in Chlamydomonas (Bradley and Quarmby 2005. J. Cell Sci. 118:3317). In mouse IMCD-3 (inner medulla collecting duct) cells, transiently transfected eGFP-Cnk2p localizes to primary cilium and centrosomes suggesting that a mammalian Nek may perform similar functions. Because the ciliary localization of Cnk2p is conserved we were able to use mammalian cells to express truncation mutants of Cnk2p. We have determined that the ciliary targeting domain of Cnk2p contains a motif (LLQ/NTIK/RXP LPXXY) conserved in a ciliary subfamily of Tetrahymena NRK members but not in mammalian Neks (Wicigo et al. 2006. Mol. Biol. Cell 17:2799). The localization of eGFP-K40A-Cnk2p, carrying a mutation in the invariant lysine of the kinase domain, is the same as eGFP-Cnk2p indicating that kinase-activity is not required for localization. Like Cnk2p, eGFP-Cnk2p appears to be regulated via phosphorylation. Cnk2p migrates as a doublet on Western blots of sucrose density gradient fractions of KCl extracts from wildtype Chlamydomonas axonesmes. We propose that the second band represents a phosphorylated Cnk2p because we also observe differences in the electrophoretic mobility of 6xHis-tagged Cnk2p compared with kinase-dead Cnk2p expressed in E. coli. This observation also suggests that Cnk2p is capable of autophosphorylation. This work is supported by an NSERC operating grant to LMJ. BAB is supported by graduate fellowships from MSHFR and NSERC.

1610 Evolutionary Analysis of the NIMA-related Kinase Family B. Bradley, J. Parker, L. Quarmby; Simon Fraser University, Burnaby, BC, Canada
The number of NIMA kinase genes in organisms is correlated with the presence of cilia on cells that divide (Quarmby & Mahjoub 2005. J. Cell Sci. 15:5161). Based on this correlation, and our studies in Chlamydomonas which revealed that at least two different Neks in this organism serve both ciliary and cell cycle functions (Parker & Quarmby, 2005. J. Cell Biol. 169:707) we have hypothesized that the ancestral roles of this kinase family relate to the alternating use of centrioles as spindle poles and as basal bodies. In order to test this idea, we have undertaken a phylogenetic analysis of this gene family. Neks are divergent enough to have resisted evolutionary analysis by traditional methods. We have used Bayesian inference to construct the gene family tree of Nek kinase domains, using sequences from the genome projects of diverse eukaryotic organisms. We infer the number of ancestral Neks in both of the major eukaryotic lineages (unikonts and heterokonts), as well as in the last common ancestor of all eukaryotes. We find that various organisms have undergone independent lineage-specific expansions of Nek family members. In order to identify subfamilies with potential ciliary functions, we are expressing representative eGFP-tagged cDNAs in ciliated mouse kidney cells. We have identified several proteins with ciliary or centrosomal association. We anticipate that this work will contribute to our understanding of ciliopathies such as...
the cystic kidney diseases. For example, mutations in two mammalian Neks (Nek1 and Nek8) have been shown to be causal in the murine models of proliferative cystic kidney diseases and jck, respectively. The cellular roles of these Nek remain enigmatic. This project is funded by an NSERC Discovery Grant to LMQ. BAB is supported by graduate fellowships from MSFHR and NSERC.

1611 Architectural Analysis of the Chlamydomonas Intraflagellar Transport Complex B

B. F. Luckner,1 M. S. Miller,2 H. Qin,2 P. Blackman,3 M. Ferrell,1 J. Rosenbaum,2 D. G. Cole,1 1Microbiology, Molecular Biology and Biochemistry, University of Idaho, Moscow, ID, 2Biology, Texas A&M University, College Station, TX, 3Cellular, Developmental, and Behavioral Biology, Yale University, New Haven, CT

Intraflagellar transport (IFT) is a strongly conserved process required for the assembly and function of eukaryotic cilia and flagella. During IFT, large protein particles carry axonemal precursors to the distal tip of the organelle while axonomal turnover products are ferried back to the cell body. Excluding the IFT motors, IFT particles consist of multiple copies of two separate complexes, A and B. Here we report on our ongoing characterization of complex B architecture. Previously, we have found that several B subunits dissociate from the Chlamydomonas complex in moderate ionic strength (300 mM NaCl) revealing a salt-stable core containing IFT88, IFT81, IFT74, IFT72, IFT52 and IFT27. Using a combination of biochemical and yeast-two- and three-hybrid analyses we have found IFT81, IFT74, and IFT72 appear to form a higher order oligomer within the complex B core at a ratio of 2:1:1, respectively (Luckner et al., J. Biol. Chem. 280:27688). Here we report that yeast two-hybrid analysis indicates that IFT46 and IFT52 are able to interact, while chemical cross-linking reveals that IFT52 and IFT88 are neighboring subunits. Bacterial co-expression studies further support this finding by revealing that IFT46 can interact separately with either IFT52 or IFT88 and that all three subunits are capable of forming a ternary complex. Deletion analysis reveals that the C-termini of both IFT46 and IFT72 are important in mediating the IFT46-52 interaction. Lastly, in an effort to verify that the reconstituted IFT46 retains biologic activity, we electrofugally fluorescently labeled IFT46 into an ikt64 mutant. Within 8 h, the flagellar assembly phenotype was rescued in more than 50% of the cells. Furthermore, the labeled IFT46 was imaged in live cells and, as expected for IFT proteins, was found to localize near the basal bodies and within the flagella. Supported by GM16920 (DGC), P20RR016454 (DGC) and GM14642 (JL).
shifting to the restrictive temperature, the amount of PKD2 in flagella increased, suggesting that IPT is involved in the turnover of flagellar PKD2. Flagellar PKD2--GFP fusion protein was concentrated in puncta that may represent clustered channels. When visualized by time-lapse imaging, most of the puncta did not move along the flagellum; however, smaller PKD2--GFP particles did move bidirectionally along the flagellum. Several PKD2 RNA interference strains show defects in mating, suggesting that this cation channel is involved in coupling flagellar adhesion to the increase in flagellar calcium concentration required for gamete activation. Supported by NIH grants GM14642 to JLR and GM30626 to GBW.

1616 Guanine Nucleotide Exchange Factor Vav2 Couples VEGF Signaling to Rac1 in Human Endothelial Cells

T. A. Garrett, J. D. van Baal, K. Burridge; Cell and Developmental Biology, University of North Carolina at Chapel Hill, Chapel Hill, NC

Vascular endothelial growth factor (VEGF) signaling is critical for both normal and disease-associated vascular development. Dysregulated VEGF signaling has been implicated in ischemic stroke, tumor angiogenesis, and a host of other vascular diseases. VEGF signals through several intracellular effectors, including the Rac family of small GTPases. Rac1, a member of this family, promotes endothelial cell migration by stimulating lamellipodia and membrane ruffles. To form these membrane protrusions, Rac1 is activated by guanine nucleotide exchange factors (GEFs) that catalyze the exchange of GDP for GTP. Although VEGF has been shown to activate Rac1, the GEFs that promote activation have not been identified. Using a Rac1-nucleotide-free mutant (G15A Rac1), a mutant that has a high affinity for binding activated GEFs, we show that G15A Rac1 associates with Rac1 GEF Vav2 after VEGF stimulation. Conversely, G15A Rac1 fails to stably associate with Vav2 when VEGF receptor-2 (VEGFR-2) signaling is inhibited. We also show that depleting endothelial cells of endogenous Vav2 using siRNA prevents VEGF-induced Rac1 activation, suggesting Vav2 couples VEGF signaling to Rac1. Additionally, Vav2 is tyrosine phosphorylated upon VEGF stimulation. Tyrosine phosphorylation of Vav2 temporally correlates with Rac1 activation and requires VEGF-2 signaling and Src kinase activity. Finally, we illustrate that expression of Vav2 siRNA impairs endothelial cell chemotaxis towards VEGF and wound healing. Taken together, our results provide evidence that Vav2 acts downstream of VEGF to activate Rac1 and is important for endothelial cell migration that precedes blood vessel formation. Supported by an American Heart Association Predoctoral Fellowship (TAG) and NIH grant HL45100 (KB)

1617 Transition State for Actin Filament Elongation by Ena/VASP

F. Ferron,1 Y. Li,1 G. Rebowski,1 D. Chereau,1,2 R. Dominguez1; 1Department of Physiology, University of Pennsylvania, School of Medicine, Philadelphia, PA, 2Elan Pharmaceuticals, Inc, San Francisco, CA

The dynamics of the actin cytoskeleton and its regulation by a myriad of actin-binding proteins play a critical role in eukaryotic cell motility. The Ena/VASP family of actin-binding proteins has been implicated in actin-based motility during fibroblast migration, axon guidance, and T cell polarization. Members of this family share a common architecture, consisting of an N-terminal EVH1 domain, a central Pro-rich region and a C-terminal EVH2 domain. The EVH2 contains G- and F-actin-binding sites, known respectively as the GAB and FAB domains, and a tetramerization coiled-coil region. Ena/VASP is enriched at the tips of filopodia, where it is a critical component of the so-called elongation complex. VASP associates with the barbed ends of growing filaments, competing with capping proteins. VASP binds profilin via the central Pro-rich region, and this interaction plays a role in filament elongation. Despite intensive investigation, the molecular bases of actin-filament elongation by members of the Ena/VASP family remain a mystery. Based on a number of crystal structures and a throughout biochemical characterization of the many protein-protein interactions involved in this process, we propose a model for actin filament elongation by Ena/VASP. This model explains how the poly-pro-GAB module of Ena/VASP contributes to filament elongation by "processing" profilin-actin complexes for their incorporation onto the barbed end of growing actin filaments.

1618 The Involvement of Shp-2 in Rho/ROCK-mediated Cell Detachment

H. Lee, Z. Chang; Institute of Biochemistry and Molecular Biology, College of Medicine, National Taiwan University, Taipei, Taiwan

Rho protein-mediated cell interplay between cell adhesion and de-adhesion plays an important role in normal hematopoiesis. Dysregulation of cell migration behavior has been shown to be closely associated with hematopoietic disease. In this study we focused on unraveling the mechanism by which myeloid leukemia cells detach from the fibronectin (FN) matrix is regulated. We showed that RhoA activity was down-regulated in cells when adhering to FN matrix. Treatment of cell with dominant active form of TAT-RhoAV14 protein induced cell de-adhesion from FN matrix, accompanying by myosin light chain (MLC) phosphorylation in a ROCK-dependent manner. Interestingly, the RhoAV14-induced cell detachment was abrogated by the pretreatment of tyrosine phosphatase inhibitor or expression of catalytically inactive mutant of tyrosine phosphatase Shp-2(C/S). By in vitro kinase analysis, we demonstrated that ROCK kinase activity was decreased in cells expressing Shp-2(C/S). Further analysis showed that ROCK was tyrosine phosphorylated in the pervanadate-treated cells and the expression of Shp-2(C/S) enhanced the ROCK kinase activity. By in vitro kinase assay, we found that tyrosine phosphorylation decreased the binding affinity of ROCK to RhoA. Accordingly, we proposed that Shp-2-regulated dephosphorylation of ROCK modulates Rho/ROCK activating signal to control cell migration.

1619 Endogenous Arf6 Interacts with Rac1 upon Angiostatin II Stimulation to Regulate Membrane Ruffling and Cell Migration

M. Cotton,1 P. Boulay,1 T. Houndolo,1 J. A. Pitcher,1 A. Claing1; 1Pharmacologie, Université de Montréal, Montréal, PQ, Canada, 2MRC Laboratory for Molecular and Cellular Biology and Department of Pharmacology, University College London, London, United Kingdom

ARF6 and Rac1 regulate remodelling of the actin cytoskeleton. Here, we demonstrate that these GTPases are sequentially activated when HIEK 293 cells expressing the angiostatin type 1 receptor are stimulated with angiostatin II (Ang II). Following receptor activation the two small G proteins transiently form a complex. ARF6/Rac1 complex formation is, at least in part, direct and dependent upon the nature of the nucleotide bound to both small G proteins. ARF6-GTP preferentially interacts with Rac1-GDP. AT1R expressing HIEK293 cells ruffle, form membrane protrusions and migrate in response to agonist treatment and ARF6 and Rac1 localize to the actin rich protrusions. ARF6, but not ARF1, depletion using small interfering RNAs recapitulates the ruffling and migratory phenotype observed following Ang II treatment. These results suggest that ARF6 depletion or Ang II treatment are functionally equivalent and point to a role for endogenous ARF6 as an inhibitor of Rac1 signaling. Taken together, our findings reveal a novel function of endogenously expressed ARF6 and demonstrate that by interacting with Rac1, this small GTPase is a central regulator of the signaling pathways leading to actin remodelling.

1620 A Rho Family GEF GEFL Promotes Prosurvove Activity at the Leading Edge of Migrating Cells

J. M. Bristow, D. Webb; Dept of Biological Sciences, Vanderbilt University, Nashville, TN

The Rho family of small GT Pases, which includes Rho, Rac and Cdc42, are involved in many cellular processes, including cell migration. Because individual Rho GT Pases can have various effects on cells, the level of regulation for specific cellular functions, such as migration, is almost certainly controlled by upstream activators. Activation of the small GT Pases is tightly controlled by guanine nucleotide exchange factors (GEFs), which promote the exchange of GDP for GTP. When we identified a novel Rho family GEF in a proteomics screen for molecules that regulate cell migration, we saw this as an opportunity to gain insight into the function of these molecules. Our results indicate that this GEF is a strong activator of Cdc42, but only weakly activates Rac1. Further analysis showed that Cdc42-GTP is more effective than Rac1-GTP in regulating cell migration activity. Taken together, these results provide evidence that Cdc42 acts downstream of VEGF to activate Rac1 and is important for endothelial cell migration that precedes blood vessel formation. Supported by an American Heart Association Predoctoral Fellowship (TAG) and NIH grant HL45100 (KB)

1621 The IFN-γ-induced Murine Guanylate-binding Protein-2 Does Not Require GT Pase Activity but Must Be Inoprenylated to Inhibit Cell Spreading

A. F. Messmer, S. Balasubramanian, D. J. Vestal; Biological Sciences, University of Toledo, Toledo, OH

Interferon-γ (IFN-γ) can alter cell adhesion/spreading and migration in a variety of cell types. The Guanylate-Binding Proteins (GBPs) are a family of large GT Pases that are robustly induced by IFN-γ. The two most closely related murine GBP family members mGBP-2 and mGBP-1, are 80% identical and share complete identity through the first 160 amino acids. mGBP-2 inhibits

299
cells spreading on fibronectin through inhibition of the small GTPase Rac1. This inhibition by mGBP-2 does not require GTPase activity. In absence of the N-terminal GTP binding domain, the C-terminal α-helices are sufficient to inhibit spreading. However, inoposyn is necessary for this inhibition. The type of inoposyn is not important, as shown by the ability of the normally geranylated geranylgeranyl mGBP-2 to inhibit cell spreading as efficiently when farnesylated. In contrast, mGBP-1 fails to inhibit cell spreading and is poorly inoposynylated, despite having an identical CaaX sequence. Together these results suggest that 1) there is a second signal within the C-terminus of mGBP-2 that directs efficient geranylgeranylation and 2) mGBP-2 inhibits cells spreading through interactions at the C-terminus rather than GTase activity. Using chimeric GTase proteins generated by exchanging regions of the C-terminus of mGBP-2 with the same regions of mGBP-1, we predict that the second signal for inoposynylase resides within the α-helices 10 and 11. Work is currently underway to further define the region proposed as the putative second signal.

1622 Modeling Membrane Diffusion with Virtual Cell: Application to Quantitative Analysis of FL
I. L. Novak, F. Gao, Y. Chu, D. Resasco, J. C. Schaff, B. M. Slepchenko; 2Cell Biology, University of Connecticut Health Center, Farmington, CT, 1Mathematics, University of Connecticut, Farmington, CT, 3Computer Science, Yale University, New Haven, CT

A new Virtual Cell capability, that allows one to model diffusion in cell membranes coupled to processes in the cytosol, is applied to a quantitative analysis of experiments with fluorescence loss in photobleaching (FLIP). The experiments involve G-protein Rac, which cycles between the cytosol and cell membrane (Moissoglu et al., Mol Biol Cell, 17, 2770 (2006)). Simulations, which are run on realistic 3D geometry based on experimental images, help validate, and determine the accuracy of, a simple method of obtaining parameters of the in vivo Rac-membrane interactions from FLIP data. The project is supported by NIH through grants P41 RR13186 and U54 GM64546.

1623 RLIP76 (RalBP1) Is an R-Ras Effector That Mediates Adhesion-dependent Rac Activation and Cell Migration
L. E. Goldfinger, C. Patak, E. D. Jeffery, J. Shahanawatz, D. F. Hunt, M. H. Ginsberg; 1Medicine, University of California, San Diego, La Jolla, CA, 2Advan Biosciences, Inc., Ithaca, NY, 3Chemistry, University of Virginia, Charlottesville, VA, 4Chemistry and Pathology, University of Virginia, Charlottesville, VA

The Ras family of small GTases regulates cell proliferation, spreading, migration and apoptosis, and malignant transformation by binding to several protein effectors. One such GTase, R-Ras, plays distinct roles in each of these processes, but to date identified R-Ras effectors were shared with other Ras family members (e.g. H-Ras). We utilized a new database of Ras-interacting proteins to identify RLIP76 (RalBP1) as a novel R-Ras effector. RLIP76 binds directly to R-Ras in a GTP-dependent manner, but does not physically associate with closely related paralogues, H-Ras and Rap1A. RLIP76 is required for adhesion-induced Rac activation and resulting cell spreading and migration, and for the ability of R-Ras to enhance these functions. RLIP76 regulates Rac activity through the adhesion-induced activation of Arf6 GTase and activation of Arf6 bypasses the requirement for RLIP76 in Rac activation and cell spreading. Thus, we identify a novel R-Ras effector, RLIP76, which links R-Ras to adhesion-induced Rac activation through a GTase cascade that mediates cell spreading and migration.

1624 Rac and Rho Regulation of Focal Adhesion Kinetics
M. K. Knowles, E. Rericha, C. M. Waterman-Storer; Physiology, Marine Biologicacl Laboratory, Woods Hole, MA

Rac and Rho are small GTases critical in regulating focal adhesion (FA) formation and maturation in cell migration. FA maturation is characterized by mechanically and/or biochemically induced growth of small focal complexes into FA. We hypothesize that growth/maturation is mediated by altering the balance of on and off rates of key structural proteins that bind to and dissociate from FA. To test this hypothesis, we analyzed the dynamics of GTP-fusion proteins in mouse embryo fibroblasts (MEF) cells using TIRF and FRAP. The size and FA turnover rates were assessed by TIRF microscopy and the turnover times of individual proteins within FA were measured with FRAP. We focused on paxillin, thought to be a key regulator of adhesion maturation. Rac and Rho activity were modulated by transfection with constitutively active (CA) and dominant negative mutants. As is established, CA Rac produced small focal complexes and the CA Rho induced an elongated mature FA. Rac and Rho affected the recovery rates of paxillin-GFP fluorescence after photobleaching in FA. The recovery curves are well fit by the sum of two exponentials, indicating two characteristic times for paxillin interaction with FA. The long time recovery (t∞ ~ 50 s) was independent of Rac and Rho conditions, however, the initial recovery was affected by Rho activation. In control cells, the short time paxillin recovery occurred with a t1/2 ~ 1.5 s, while for CA Rho conditions, paxillin recovered faster (t1/2 ~ 2 s). Thus, Rho promotes rapid dissociation of a portion of adhesion-associated paxillin. In addition, constitutive Rho activity caused anisotropy in the fluorescence recovery - the intensity filled in centripetally within the bleached zone. The complex kinetics of paxillin within FA are consistent with the established complexity of binding interactions and phosphoregulation for paxillin. These results suggest that Rho may be key in FA maturation.

1625 Rac1 Modulation of Ca2+ Mobilization in Neuronal Growth Cone: Novel Role for Rac1 in Promoting MT Dynamics and Sensitizing Ca2+ Release
X. Zhang, P. Forscher; MCDB, Yale University, New Haven, CT

Rac1, a member of the small Rho GTase family, promotes neuronal growth cone extension. Ca2+ exerts myriad effects on growth cone motility. Here we report that Rac1 activity modulates Ca2+ mobilization evoked by 5-HT or LPA in growth cones of Aplysia bag cell neurons. In CA Rac1 backgrounds, 5-HT/LPA evoked a sustained Ca2+ rise in greater than 78% of growth cones tested. In contrast, only 5-6% of growth cones responded to 5-HT/LPA with transient Ca2+ increases in DN Rac1 backgrounds. In controls, 13-17% of the growth cones manifested Ca2+ mobilization after 5-HT/LPA exposure. Inhibitors of PLC or IP3 receptors blocked 5-HT/LPA induced Ca2+ rise in CA Rac1 backgrounds, but ryanodine receptor inhibition had no effect on Ca2+ elevation triggered by 5-HT/LPA. Rac1 activation by 5-HT/LPA, suggesting that Rac1 enables a 5-HT/LPA-PLC/IP3-Ca2+ signaling cascade in growth cones. Analysis of MT and ER dynamics revealed that Rac1 promotes concomitant MT and ER extension into the growth cone periphery. Inhibition of MT dynamics selectively suppressed peripheral Ca2+ responses. On the other hand, assessment of reactive oxygen species (ROS) indicated that Rac1 enhanced ROS levels in growth cones. Inhibition of NADPH oxidase activity or addition of ROS scavengers abolished 5-HT/LPA evoked Ca2+ elevations in CA Rac1 backgrounds, whereas HO2 restored this Ca2+ response in DN Rac1 backgrounds. Taken together, these results suggest Rac1 regulates 5-HT/LPA evoked Ca2+ mobilization by: 1) regulating MT dynamics with subsequent effects on ER distribution and 2) ROS dependent sensitization of Ca2+ release from ER stores.

1626 Filamin A Is Required for R-Ras to Inhibit Breast Epithelial Cell Migration
R. K. Schmocker, L. Kwong, P. J. Keely, S. Gehler; Pharmacology, University of California, Madison, WI

R-Ras, a small GTase, is important for breast epithelial cell migration, which is necessary for cancer cell metastasis. It has been shown that constitutively active of R-Ras (38V) inhibits random cell migration and disrupts cells polarity on a collagen substratum (Wozniak et al., 2005). Furthermore, R-Ras mediates its migratory and adhesive effects through the n2β1 integrin (Keely et al., 1999). Filamin A, an actin binding protein, has been shown to associate with β1 integrin and plays an important role in melanoma cell migration, but it is unclear which signaling molecules regulate filamin A (Stossel et al., 2001; Cunningham et al., 1992; Calderwood et al., 2001). Since expression of R-Ras (38V) increases the association of filamin A with the n2β1 integrin, and filamin A and R-Ras both regulate cell migration, we hypothesize that filamin A is necessary for the inhibitory effects of R-Ras on the migration of breast epithelial cells. Migration was assessed by inducing a wound through a confluent cell monolayer and measuring the rate of wound closure at 24 and 48 hours. We have demonstrated that control cells expressing pZip vectors alone migrate twice as fast as cells expressing R-Ras (38V). Co-transfection of control cells with filamin A shRNA induced a slight increase in cell migration after 24 hours and a 35% increase after 48 hours. Interestingly, filamin A shRNA rescues the migratory phenotype of R-Ras (38V)-expressing cells by increasing migration 58% and 66% after 24 and 48 hours, respectively. These results suggest filamin A is required for the regulation of cell migration by R-Ras.

1627 A RasGEF Complex Coordinates Regulation of Activation of Distinct Ras Proteins during Chemotaxis in Dictyostelium
P. G. Charest, A. T. Sasaki, Z. Shen, S. Briggs, R. A. Firel; 1Division of Biological Sciences, University of California, San Diego, La Jolla, CA, 2Dep’t of Systems Biology, HMS, Div. of Signal Transduction, BDIMC, Boston, MA

Ras activation is one of the earliest polarized responses to directional chemotactant stimulation in Dictyostelium, which occurs at the leading edge of chemotactic cells. Dictyostelium cells lacking the Ras guanine exchange factor (GEF) Aimless (alet) were reported to display defects in gradient sensing and cAMP production. To further study the role and regulation of Ras

300
signaling in chemotaxis, we identified Aimless interacting proteins using sequential affinity purification coupled to mass spectrometry. In addition to Aimless, the complex contained another RasGEF, RasGEFH, and a 150 kDa protein, DG1105. Developmental analysis of null mutants of these genes revealed that while DG1105 cells fail to aggregate, rasgefh cells exhibit delayed development but ultimately produce small fruiting bodies. The two null strains, as well as aleA, grow normally but display defects in both chemotaxis and random cell movement. Also, aleA, rasgefh and DG1105 present reduced basal tyrosine and cAMP-stimulated Akt activation and show impaired chemotaxis. The second peak of chemotactic-stimulated actin polymerization that is linked to pseudopod elongation, disruption of Aimless or RasGEFH produces strong effects on cAMP-induced Ras activation (using a pan-Ras antibody): total Ras activity is reduced in aleA whereas it is increased in rasgefh cells. Moreover, preliminary biochemical data indicate that Aimless and RasGEFH have different substrate specificities, regulating the activity of distinct, or distinct sets, of Ras proteins. Altogether, these results suggest that Aimless and RasGEFH have both distinct and shared functions. We hypothesize that a complex containing Aimless and RasGEFH, two RasGEFs with individual specificities, allows for the coordinated regulation of different Ras signaling pathways that control directed cell movement.

1629 Elevation of Plasma Membrane Cholesterol Content Impairs Macrophage Migration through Inactivation of RhoA
T. Nagao1, C. Qin1, I. Groshova1, R. F. Maxfield2, L. M. Pierini1; 1Biochemistry, Weill Medical College of Cornell University, New York, NY, 2Surgery, Weill Medical College of Cornell University, New York, NY
Atherogenesis generally begins as small accumulations of lipid-laden macrophages, known as foam cells, in the space just beneath the endothelial cells that make up arterial walls. Foam cells develop through unregulated uptake of subendothelial modified and aggregated LDL. The reason why foam cells remain in the atherosclerotic plaque rather than migrating out of the area is unclear. We tested the hypothesis that elevated membrane cholesterol content, which may result from interactions with aggregated LDL, affect macrophage migration. To investigate the effects of elevated membrane cholesterol content on macrophage migration, cholesterol-cholchit-substituted methyl-β-cyclodextrin was used to acutely increase membrane cholesterol levels. Functional responses to complement 5a (C5a) were examined for control and cholesterol-loaded J774 cells. Cholesterol loading decreased macrophage migration in transwell migration assays, even though cholesterol-loaded macrophages responded to a bath application of C5a with modified changes similar to control cells. In a microperitope polarization assay, cholesterol-loaded cells were able to polarize toward a C5a gradient, indicating that cholesterol-loaded cells maintained abilities to sense and respond to chemotactic gradients. Further analysis of J774 cells migrating through pores of a transwell filter revealed that cholesterol-loaded cells could extend lamellae through the pores but were unable to translocate their cell bodies. Since translocation of the cell body is thought to be dependent on contractile forces and regulated by the RhoA/Rho kinase pathway, we measured the activation status of RhoA in these two cell types. We found that cholesterol loading decreased GTP-bound active RhoA and phosphorylation of myosin light chain. These results suggest that increases in plasma membrane cholesterol content interfere with RhoA activation, resulting in inhibition of cell migration due to reduced contractile force generation. These findings provide one possible explanation for the retention of foam cells in atherosclerotic lesions.

1630 A Dictyostelium Rabgap Protein Regulates Chemotaxis by Mediating F-actin Polymerization and Cell Adhesion
F. Du, K. Edwards, Z. Shen, B. Sun, S. Lee, B. Briggs, R. A. Firtel; 1UCSD, La Jolla, CA, 2La Jolla Institute for Allergy and Immunology, La Jolla, CA
Several studies have demonstrated expression of B class Ephs and ephrins in a variety of tumors and suggested a functional relationship between their expression and tumor progression. Here we show that EphB receptors, and especially EphB4, regulate the migration of murine melanoma cells. Highly malignant melanoma cells express the higher levels of EphB4 receptor and migrate faster than less malignant melanoma cells. We further demonstrate that EphB4 receptor tyrosine kinase is actively engaged in signaling in the fast migrating SW1 melanoma cells and its inhibition by overexpression of a B class Ephb lacking the cytoplasmic portion or by treatment with competitively acting soluble Ephb2-Fc result in slower cell migration. In contrast, overexpression of full length Ephb4 or its activation with ephrinB2-Fc enhances cell migration. The effects of Ephb4 receptor on cell migration and cell morphology require its kinase activity because the inhibition of Ephb4 kinase activity by overexpression of kinase dead Ephb4 inhibits cell migration and affects the organization of actin cytoskeleton. Activation of Ephb4 receptor with its ligand ephrin-B2-Fc affects the morphology of melanoma cells and increases RhoA activity, while inhibiting Ephb receptor forward signaling decreases RhoA activity. Moreover, expression of dominant negative RhoA blocks the effects of active Ephb4 on cell migration and actin organization. These data suggest that Ephb4 forward signaling contributes to the high migratory ability of invasive melanoma cells by influencing RhoA-mediated actin cytoskeleton reorganization.

1632 hMena Works as a Negative Regulator of Rac1 GTPase at the Tip of Lamellipodia
C. Ishikawa, M. Higashi, K. Azuhata, H. Kawana, M. Kitagawa, K. Harigaya; Molecular and Tumor Pathology, Chiba University Graduate School of Medicine, Chiba, Japan
hMena, a member of Ena/VASP proteins, has been implicated in cell motility through regulation of the actin cytoskeleton, including lamellipodial protrusion. However the molecular mechanism and the signaling mechanism of hMena are not well understood. hMena (hMena) by siRNA causes cells to be highly spread with enormous lamellipodia, and to be highly motile. Increased motility of the cells with the siRNA can be reversed by introducing dominant negative form of Rac1, but not with LY294002, an inhibitor of phosphatidylinositol 3-Kinase (PI3-Kinase). With a Rac activation assay, hMena knockdown cells show increased Rac activation. hMena colocalizes with Rac1 at the tip of lamellipodia. These results indicate that hMena negatively regulates the activity of Rac1 at the leading edge.
SSX, New Molecular Target to Regulate Sarcoma Invasion
K. Isho, K. Yoshokawa; Biology, Osaka Medical Center for Cancer, Osaka, Japan

The SSX / SYT fusion genes were initially identified as fusion partners to the SYT gene in human synovial sarcomas carrying a recurrent t (X;18)(p11.2; q11.2) chromosomal translocation. Besides adult human testis, SSX genes were expressed at varying frequencies in a number of malignancies thereby categorized as cancer/testis antigens. Using Nucleic Acid Sequence-Based Amplification, we have reported that the expression level in the malignant tumors (3.8±plasmn.1.4 copies/µg of total RNA in log10 order) was significantly higher than that in the benign tumors (2.4±plasmn.0.5, p<0.0001). In order to examine the biological function of SSX, we made stable transfectants with wild type SSX using human osteosarcoma cell line, Saos-2, which moderately expressed SSX. The expression of SSX was mainly localized in the nucleus with patched pattern. The SSX transfectants promoted colony formation in soft agar and tumor formation in nude mice, but showed little change in growth rate in 2D culture. The transfectants also increased motility, chemotaxis and invasiveness using scratch wound assay and Boyden chamber assay. Enhanced Rho activity and stress fibers were observed in these SSX overexpressed Saos-2 cells. By contrast, the lowering of the endogenous expression of SSX1 in fibrosarcoma HT1080 cells by the treatment with specific siRNA markedly decreased membrane ruffling, chemotaxis and invasiveness using Boyden chamber assay, but did not affect cell proliferation in 2D culture. Moreover, SSX1 deficient R1c-activation and myosin light chain phosphorylation. We also prepared wrapped liposome containing siRNA and introduced into nude mice bearing HT1080 cells. Preliminary results showed in vivo inhibitory effects of siRNA against SSX in tumor progression. Collectively, these data suggested that SSX protein regulated Rho-family small GTPases to the tumor invasion and progression, and thus could be a novel molecular target under clinical setting.

Integrin Signaling through Arg Activates p190RhoGAP by Promoting Its Binding to p120RasGAP and Recruitment to the Membrane
W. D. Bradley,1 S. E. Hernandez,1 J. Settleman,2 A. J. Koleske1,2,3; 1Department of Molecular Biophysics and Biochemistry, Yale University, New Haven, CT, 2MGH Cancer Center, Massachusetts General Hospital, Harvard Medical School, Charlestown, MA, 3Interdepartmental Neuroscience Program, Yale University, New Haven, CT

The Rho family GT-Pases RhoA (Rho), Rac1, and Cdc42 are essential effectors of integrin-mediated cell attachment and spreading. Rho activity, which promotes formation of focal adhesions and actin stress fibers, is inhibited upon initial cell attachment to allow sampling of the new adhesive environment. The Abl-related gene (Arg) tyrosine kinase mediates adhesion-dependent inhibition of Rho through phosphorylation and activation of the Rho inhibitor p190RhoGAP-A (p190). p190 phosphorylation promotes its binding to p120RasGAP (p120). Here, we elucidate the mechanism by which p120 binding regulates p190 activation following adhesion. We show that p120 binding inhibits p190 activity in vitro. However, p120 binding is not sufficient to activate p190RhoGAP activity in vivo. Instead, activation of p190 requires its recruitment to the cell periphery. Integrin-mediated adhesion promotes relocalization of p190 and p120 to the cell periphery in wild type fibroblasts, but not in arg/−/− fibroblasts. A dominant-negative p120 fragment blocks p190 complex formation, prevents activation of p190 by adhesion, and disrupts the adhesion-dependent recruitment of p190 to the cell periphery. Our results suggest that integrin signaling through Arg activates p190 by promoting its association with p120, resulting in recruitment of p190 to the cell periphery where it inhibits Rho.

Regulation of Lipoma Preferred Partner in Cell Motility by c-Src-mediated Phosphorylation at Multiple Sites
C. Chen, Y. Lai, F. Lin; Cell Biology, UAB, Birmingham, AL

Lipoma Preferred Partner (LPP) is an actin-associated focal adhesion molecule that belongs to the LIM domain-containing zyxin family. Suppression of endogenous LPP expression reduces Lysophosphatic acid (LPA)-induced Rho GTPase activation and cell migration, suggesting an important role for LPP in cell motility. Previously we have shown that c-Src-mediated phosphorylation of TRIP6, another zyxin family member, regulates its function in the binding to Crk and LPA-induced cell migration. In this report, we further demonstrate that LPP, but not zyxin, is a substrate for c-Src in vitro and in cells. LPA induces tyrosine phosphorylation of LPP, which is virtually eliminated in Src-null fibroblasts. In contrast to TRIP6 that is specifically phosphorylated by c-Src at Tyr-55 residue, LPP is phosphorylated at multiple sites in the internal sequences. This phosphorylation does not affect the function of LPP in focal adhesion targeting or association with actin. However, mutation of these phosphorylation sites abolishes the association of LPP with Rac1 and reduces LPA-induced Rho GTPase activation. Consequently, the function of LPP in promoting LPA-induced cell migration is impaired. Taken together, c-Src phosphorylates LPP and TRIP6 at different sites, and regulates their functions in cell motility through distinct mechanisms.

Caspase Regulated Cytoskeletal Rearrangement in Macrophages for Chemotaxis and Fusion
T. Nihan,1 R. W. Liles,2 S. Schwartz; 1Pathology, University of Washington, Seattle, WA, 2Molecular Medicine, University of Toronto, Toronto, ON, Canada

Active caspases are the hallmark of a dying cell undergoing apoptosis. We observed that thioglycollate-elicited mouse peritoneal macrophage (MPM) adherence in vitro activate caspases in a Fas-dependent (CD95) manner without leading to cell death. Active caspases within living macrophages selectively cleaved a subset of caspase substrates, such as Rho kinase (ROCK-1). Functional assays of living macrophages with active caspases showed that caspases can regulate macrophage chemotaxis and fusion. Cell permeable inhibitors of caspases (zVAD) and ROCK-1 (Y27632) attenuated macrophage chemotactic response to monocyte chemotactic protein-1 (MCP-1). Caspases from MCF-7, T47D, BT20, MDA-MB-231 cells. By confocal laser-scanning microscopy, we examined localization of hamartin and tuberin in MCF-7 cells migrating in response to insulin-like growth factor 1 (IGF-1). Hamartin, but not tuberin, accumulated in activated-enriched lamellipodia of IGF-1-stimulated cells. Hamartin and tuberin co-precipitated; however, the phosphorylated hamartin (140 kDa) was absent from the complex. In MCF-7 cells, IGF-1 causes rapid but transient activation of a small GTPase Rap1, an essential regulator of adhesion receptors and actin dynamics. Based on in vitro findings of tumorIP activity towards Rap1, we hypothesized that tumorIP may act as Rap1GAP in cells. To test this hypothesis, we used 3 approaches: over-expression of tumorIP, siRNA inhibition of hamartin, and over-expression of tumorIP mutants that have potential to be dominant-negative towards endogenous tumorIP. We found that the N-terminus truncated mutant of tumorIP inhibited IGF-1-induced Rap1 activation. Together, these data implicated the phosphorylated hamartin in the regulation of lamellipodia and tuberin in modulation of Rap1 in moving breast cancer cells. These results suggest a new role for hamartin, tuberin and migration of breast cancer cells. (Sponsored by the University of Pennsylvania Research Foundation and the American Cancer Society IRG1/78-002026 to M.A.G.)

Dynamic Imaging of Human Tumor Invasion and Angiogenesis in an Novel Zebrasfish Xenograft Model
K. Stolcovo, O. Pertz, M. Holcomb, T. Ronai, R. Klemke; Pathology, UCSD, La Jolla, CA

We developed a novel human tumor xenograft model that takes advantage of transgenic Zebrasfish. When injected in immunosuppressed Tg(B1:EGFP) Zebrasfish fluorescently labeled human tumor cells home to the fish blood vessels where they form tumor-like aggregates and induce rapid angiogenic response. Transparency of Zebrasfish tissue allows us to perform high resolution multi-color in vivo imaging of dynamic interplay between the tumor invasion and angiogenesis for periods ranging from several hours to days. Using this model, we examined the role of the small GTPase Rac in tumor invasion. Rac is overexpressed in a highly metastatic form of breast cancer, however the mechanism by which it promotes tumor cell invasion is not known.
Simultaneous imaging of differentially labeled parental and RhoC overexpressing tumor cells revealed that while parental cells form tightly packed aggregates, RhoC overexpressing cells scatter within the tissue. Time lapse analysis revealed that while parental cells utilize mixed amoeboid and mesenchymal types of 3D cell migration RhoC switches cell migration to completely amoeboid. RhoC overexpression also increased tumor cell membrane dynamics leading to continuous shedding of small cellular fragments. RhoA overexpression had significantly less potent effect than RhoC with tumor cells being of intermediate morphology. Chemical inhibition of RhoC downstream effector ROCK reversed these processes. We also performed quantitative imaging of effects of two anti-cancer compounds: a VEGFR inhibitor, SU5416, and a Src inhibitor, PP1 on tumor progression. Analysis of 3D high resolution images of compound and mock treated animals revealed that SU5416 leads to shrinkage of tumor cells and tumor-induced vasculature while PP1 mainly affects tumor cell survival. Taken together, we designed a novel 3D in vivo tumor invasion and angiogenesis model that allows for high resolution quantitative imaging of these processes as well as for quantitative in vivo testing of pharmacological compounds.

Integrin α4β1-stimulated Neuroblastoma Cell Motility Requires Src and p130Cas but Not FAK

L. Wu,1 J. A. Bernard-Trifilo,1 Y. Lim,1 S. Lim,1 D. G. Stupack,2 D. D. Schlaepfer2; 1Immunology, The Scripps Research Institute, La Jolla, CA, 2Pathology, University of California San Diego, La Jolla, CA

The fibronectin binding integrins α5β1 and α6β1 generate signals pivotal for cell migration through distinct yet undefined mechanisms. Neuroblastoma (NB) cells are highly invasive and derive from α6β1-expressing neural crest cells. Here, we analyzed the role of α4-associated integrin signaling involved in NB cell motility using two representative human-derived α4 integrin-expressing NB cell lines, NB8 and SK-N-AS. We found that NB cells expressed high levels of fibronectin-binding integrins and that their migration on cellular fibronectin was mediated by both α4β1 and α5β1 integrins. It was further revealed that α4β1 integrin-mediated NB cell migration required both Src-family kinase and focal adhesion kinase (FAK) activities whereas α5β1 integrin-mediated NB cell migration involved Src but not FAK activity. By employing haptotaxis motility assay and time-lapse imaging analyses, we found that inhibition of p130Cas and c-Src expression with short-hairpin RNA (shRNA)-mediated interference decreased α4β1 integrin-mediated NB cell motility. Inhibition of FAK or paxillin expression was without effect on α4β1-stimulated NB cell motility whereas inhibition of c-Src expression selectively reduced α4β1-stimulated p130Cas tyrosine phosphorylation. In addition, α4β1 integrin-mediated cell spreading and motility of α130Cas-/- fibroblasts was enhanced by p130Cas re-expression. Abolishing α4 integrin expression in NB cells blocked α4β1 but not α5β1-stimulated cell migration. Further, α4β1 integrin-mediated NB cell motility and α4-stimulated Src activation was rescued by re-expression of wild type α4 but not by an α4 integrin mutant with a cytoplasmic domain deletion. These results show that α4 integrin plays an important role in promoting NB cell motility and that the α4 cytoplasmic domain is an important determinant for α4β1 integrin-stimulated Src activation, p130Cas tyrosine phosphorylation, and NB cell migration.

Visualization of Axonal Transport of α-synuclein in Slow Component-b (SCb)

S. Roy,1 M. J. Winton,1 M. M. Black,2 J. Q. Trojanowski,1 V. M. Y. Lee1; 1Center for Neurodegenerative Research, University of Pennsylvania, Philadelphia, PA, 2Anatomy and Cell Biology, Temple University Hospital, Philadelphia, PA

Overall rates of slow and fast axonal transport differ by several orders of magnitude. Slow axonal transport moves cytoskeletal and cytosolic proteins along the axon in fairly discrete compartments called slow component-a and -b (SCa and SCb) respectively. Mechanisms generating this slow overall movement are intriguing, as velocities of known molecular motors are much lower than the velocity of the slow component. Previously, we had shown that individual neurofilaments moving in SCa are transported rapidly at rates comparable to known motors, but the movement was infrequent and intermittent, making the overall population slow (Roy et al., J Neuroscience 2000, 20:6484-61). In this study, we visualized the axonal transport of an SCb protein α-synuclein (α-SYN) and directly compared it to synaptophysin (SYP), a transmembrane fast component protein. Using live cell imaging of fluorescent-tagged α-SYN and SYP we show that individual particles of both proteins are transported at similar average velocities (~1μm/s), α-SYN particles often pause during transit and their overall transport frequency is ~10 times lower than SYP. Simultaneous visualization of both proteins in the same axon by dual-cam video microscopy using red/green chimeras revealed that despite moving with vastly different frequencies, individual α-SYN and SYP particles can transiently merge during transit. By directly comparing a slow and fast component protein, these data show that α-SYN, an SCb protein is transported rapidly like fast component proteins, but the movement is infrequent with pauses, and suggest that all slow component proteins may use this “stop and go” mechanism for transport.

Effects of Crowding on Intracellular Diffusion

P. Kraikivski, I. L. Novak, B. M. Slepchenko; Center for Cell Analysis and Modeling, Department of Cell Biology, University of Connecticut Health Center, Farmington, CT

The interior of the cell is filled with polymer meshwork and intracellular membranes with intricate geometry. Recently, there have been a number of reports of anomalous subdiffusion in both in vitro and in vivo experiments. Here we use various modeling approaches to analyze how the intracellular structures affect diffusion of macromolecules in the cytoplasm. Three-dimensional simulations of a Brownian motion in the entangled filament networks reveal the anomalous time dependence of a particle mean square displacement on the time and spatial scales determined by the ratio of a particle radius and the network mesh size. This is consistent with experiments with tracer particles and earlier modeling studies of diffusion on lattices. Using these results, an accurate continuous approximation for the diffusive transport in crowded media is derived and tested numerically. The project is supported by NIH through the grant 1U54 RR022232.

In Vivo Motor Protein Interaction Revealed in Spatial and Temporal Dynamics of Vesicle Transport in Drosophila Segmental Nerve Axons

G. F. Reis,1 G. Yang,1 S. Shah,2 L. Szpankowski,3 G. Danuser,1 L. S. Goldstein; 1Neuroscience, UCSD, La Jolla, CA, 2The Scripps Research Institute, La Jolla, CA, 3Bioengineering, University of Maryland, College Park, MD, 4Bioinformatics, UCSD, La Jolla, CA, 5Cellular and Molecular Medicine, UCSD, La Jolla, CA

Proper functioning of microtubule-based bidirectional axonal transport is crucial for neuronal function and survival. We studied molecular mechanisms of neuronal transport by imaging and measuring high-resolution trajectories of axonal cargo motion in vivo. By altering the expression of specific motor proteins, we probed the regulation and coordination of the molecular transport machinery. Until recently, a major hurdle in obtaining an accurate quantitative analysis of single axon cargo trafficking hinged on development of reliable and efficient computational tools to track vesicle motion and generate complete spatial and temporal readouts for large datasets. The computational challenge lies in the physiology of vesicle transport, which is often comprised of dense anti-parallel motion with apparent particle crossing, merging, and splitting. We have developed reliable and efficient computational tools to recover complete trajectories of large numbers of cargos as well as characterize the spatial and temporal dynamics of vesicle transport. These tools include a novel multiple-hypothesis-testing (MHT) algorithm for resolving particle superposition. Human-machine interaction is used to complement automation, ensuring complete and accurate trajectory readouts. We are able to recover complete tracks of large numbers of cargos by validating an approach suitable for high-throughput processing. Experimentally, we imaged the bidirectional movement of motor-associated cargoes containing Yellow Fluorescent Protein (YFP) fused to the C-terminal of human amyloid precursor protein (APP-YFP) in a subpopulation of Drosophila segmental nerve axons. We imaged transport in wild type and mutants expressing a 50% genetic reduction in components of kinesin and dynein motor complexes, enabling comparative analyses of several transport parameters across 7 genotypes and over 560 movies. Our results reveal mutant-dependent changes in cargo populations and motility parameters, suggesting distinct modes of coordination and regulation for kinesin and dynein. Among other intriguing findings, we report a possible novel role for kinesin as a processivity factor for the retrograde motor dynein.

Regulated Bidirectional Transport of Drosophila Lipid Droplets Involves Functional Cooperation and Physical Interactions between Klar, LSD2, and the Novel Protein Sfo

D. Kim,1 M. Zapata,2 J. G. Ghimbar3, M. A. Wehe1; 1Rosenstiel Center, Brandeis University, Waltham, MA, 2Department of Biology, University of Richmond, Richmond, VA

How motor proteins are regulated in vivo is poorly understood. We study this issue using lipid droplets in Drosophila embryos; these organelles display developmentally controlled bidirectional transport along microtubules. Therefore this model system provides the opportunity to understand how plus- and minus-end directed motors are coordinately controlled in vivo. Klar to lipid droplets. Yet the complexes containing Klar, Sfo and/or LSD2 must have additional roles since double mutants of Klar and LSD2 or Sfo display stronger defects in embryonic development than single mutants. Using yeast two-hybrid screens, we identified the novel protein Sfo as a Klar binding partner. Indeed, the distribution of an Sfo-RFP fusion in embryos resembles that of Klar, and LSD2 interact physically in embryos. These interactions are apparently functionally important as embryos lacking Sfo show defective droplet transport; net plus-end motion is abolished. Sfo, Klar to lipid droplets and of Klar. In yeast, Sfo also binds to LSD2, and a central 98 aa region is sufficient for interaction with both LSD2 and Klar. By immunoprecipitation, we confirmed that Sfo, a central 98 aa region is sufficient for interaction with both LSD2 and Klar. By immunoprecipitation, we confirmed that Sfo, Klar, and LSD2 interact physically in embryos. These interactions are apparently functionally important as embryos lacking Sfo show defective droplet transport; net minus-end motion is impaired. In embryos doubly mutant for LSD2 and Sfo, but not in the single mutants, Klar fails to localize to lipid droplets; thus LSD2 and Sfo act in a partially redundant manner to recruit Klar to lipid droplets. Yet the complexes containing Klar, Sfo and/or LSD2 must have additional roles since double mutants of Klar and LSD2 or Sfo display stronger defects in embryonic axonal transport.
Zebrafish Melanophilin Implements Pigment Granule Dispersion by Suppressing the Frequency and Run Lengths of Dynein-driven Motility Events

L. Sheetz,1 D. G. Ransom,1 E. M. Mellgren,2 S. L. Johnson,3 B. J. Schnapp;4 Department of Cell and Developmental Biology, Oregon Health and Science University, Portland, OR, 2Washington University School of Medicine, St. Louis, MO

The coordination of different motors on the same organelle is crucial for many cell processes. An ideal system for investigating this is the fish melanocyte, which rapidly aggregates and disperses its pigment granules in response to cAMP. How cAMP actually regulates the melanin, dynein and myosin motors that direct granule transport is not understood. To elucidate these mechanisms we are using zebrafish because we can study pigment mutations. Here we report on the mutant normal, whose melanocytes disperse their granules only part way. We tracked single granules in wild-type and normal melanocytes during dispersion, and computed the kinetic parameters of granule transport along microtubules. Whereas the frequency and run lengths of minus-end motility events are suppressed in wild type cells, which causes net plus-end travel, these parameters remain high in normal, and the average travel distances in the plus- and minus-end directions remain, thereby, precisely balanced. Thus, the normal mutation unmasks a regulatory feature, which we term the “balancer”. The balancer appears to equalize the oppositely directed travel distances by adjusting the frequency and run lengths of only the minus-end, dynein-driven motility events. We propose that the product of the normal gene normally inhibits the dynein-based balancing of travel distances, and thereby triggers cAMP-induced dispersion by biasing granule movement toward the microtubule plus-end. Positional cloning of the normal gene reveals it is zebrafish melanophilin, a novel finding, as melanophilin and its homologues in mammals link myosins to organelles to facilitate their “hand-off” from microtubules to the cortical actin network. A microtubule-related function for melanophilin proteins has not been suspected or investigated. We propose that melanophilin proteins coordinate both actin and microtubule-based transport to determine an organelle’s position in the cell.

Adaptor Protein-2 Interaction with Arrestin Regulates N-formyl Peptide Receptor Post-endocytic Trafficking

B. M. Wagener, C. M. Revankan, N. A. Marjon, E. R. Prossnitz; Cell Biology and Physiology, University of New Mexico School of Medicine, Albuquerque, NM

G protein-coupled receptors (GPCRs) are integral to cellular function in nearly all physiologic and numerous pathologic processes. GPCR signaling is an intricate balance between receptor activation, inactivation (desensitization and internalization) and resensitization (recycling and reassembly). While much is known regarding the first two processes, the latter has not been as thoroughly studied. To better understand the process of GPCR post-endocytic trafficking, we focused on the N-formyl peptide receptor (FPR), a chemoattractant receptor found primarily on neutrophils and macrophages. Previous studies have demonstrated that, although FPR internalization occurs in the absence of arrestins, FPR recycling is blocked. Furthermore, FPR stimulation in the absence of arrestins leads to receptor accumulation in recycling endosomes and apoptotic signaling. In this study, we determined that the carboxy terminals of arrestin-2 is critical for intracellular receptor trafficking and performed scanning mutagenesis of this region to ascertain the mechanisms involved. Our results reveal that two arrestin-2 mutants (F391A and K397A/M399A/K400A), at sites known to be involved in AP-2 binding, fail to rescue the trafficking and signaling defects observed in the absence of arrestins. Further results demonstrate that AP-2 associates with the receptor-arrestin complex in recycling endosomes and is required for proper post-endocytic trafficking of the FPR. Finally, we observe that AP-1 is associated with the receptor-arrestin complex under recycling-competent conditions, suggesting a transfer of receptors from AP-2- to AP-1-associated vesicles. This is the first study to demonstrate a requirement for AP-2 in the post-endocytic trafficking of a GPCR and serves as a model for future studies in GPCR trafficking and resensitization.

Actin Filament-based Motility of Ntcp-containing Hepatocyte Vesicles

S. Sarkar, A. W. Volling, J. D. Murray; Anatomy and Structural Biology and Liver Research Center, Albert Einstein College of Medicine, Bronx, NY

The bile salt transporter moves between an intracellular vesicular pool and the hepatocyte plasma membrane. Vesicles must move on both actin microfilaments and microtubules. In previous studies, we reconstituted and characterized the microtubule-based motility in vitro. We now report reconstitution of the actin-based motility. A glass microcoated chamber was washed with rhodamine-labeled actin to which vesicles prepared from rat liver were bound. Ntcp was observed by staining with primary and fluorescently-labeled secondary antibodies. Nearly 20% of the actin-bound ntcp-containing vesicles (n=692) moved following addition of 1mM ATP but not buffer or ADP. Motility events were of two types: (1) 11.8% vesicles moved >2pixels (~420 nm) before detaching and (2) 8.2% immediately detached (“pop-off”). Addition of the myosin ATPase inhibitor, butane-dione monooxime (10mM) significantly decreased movement of >2pixels but not pop-off events whereas at 30mM it decreased both events by >50%. Immunoblot showed the presence of the actin-based motors, myosins Ila/b and Va/b but not myosin VI. Immunofluorescence analysis revealed that 50% and 87% of actin-containing vesicles co-localized with myosins Ila/la and Ila/la respectively while only 12% and 18% colocalized with myosin Ila/Ia respectively. While myosin Va/Va/Vb antibodies did not inhibit motility, myosin Ila/Ia antibody decreased motility by 30%. Interestingly, we have shown previously that >50% of the ntcp-containing vesicles are associated with microtubule-based motors kinesin-1 and dynein, suggesting that a single vesicle can be associated with microtubule and actin-based motors. This may facilitate transfer of vesicles between the two cytoskeletal systems. Other previous studies also showed the presence of PKCδ on these vesicles and inhibition of its activity by a highly specific pseudosubstrate inhibitor eliminated microtubule-based motility. This inhibitor decreased actin-based movements of >2pixels by 60%, suggesting that phosphorylation plays an essential role in the actin-based motility of these vesicles as well.

The Roles of Cytoskeletal and Membrane Proteins in Tip Growth in Aspergillus nidulans

N. Taheri-Talesh, T. Horio, X. Dou; S. A. Osmani, B. R. Oakley; Molecular Genetics, Ohio State University, Columbus, OH, 2Institute of Health Biosciences, University of Tokushima Graduate School, Tokushima, Japan

To clarify mechanisms of tip growth in Aspergillus, we have created fluorescent-protein-tagged cytoskeletal and membrane proteins and observed them in growing hyphae. Actin is in patches at the cell cortex. Many are clustered in a ring slightly behind the hyphal tip and there is an actin spot at the extreme apex. Actin Binding Protein 1 (ABP1) shows the same localization except that the apical spot is not apparent. A vesicular snare (SNC1 homolog) is in vesicles within the hypha and at the plasma membrane in a hemisphere extending from the extreme hyphal apex to the ring of actin-ABP1 patches. A target snare (SSO1 homolog) is located in the plasma membrane with a small region of higher concentration at the apex. These data suggest that vesicles with SNC1 fuse to the plasma membrane in a small zone at the extreme hyphal tip. Actin-ABP1 patches are likely sites of endocytosis that remove SNC1 from the plasma membrane, allowing it to be reused. When microtubules are depolymerized with benomyl, actin-ABP1 patches remain but lose their localization. Hyphal tip growth continues at a reduced rate, and is often abnormally curved. Additional sites of growth may form, creating branched hyphae. Actin-ABP1 patches cluster at the sites of new growth. These data indicate that microtubules play a role in maintaining the directionality of growth and preventing branching in the tip cell presumably by helping to maintain the localization of the polarisome at the apex of the hypha. Although microtubules are important for the localization of actin-ABP1 patches, a second microtubule-independent positioning mechanism also must exist. Cytocelalasin A causes all actin-containing structures to disappear and hyphal growth to stop completely. Supported by the National Institute of General Medical Science, the Deutsche Forschungsgemeinschaft and the Japan Society for the Promotion of Science.

Differential Association of Cas with Crk or BCA23 in a Cell-dependent Manner upon Insulin-stimulation

M. J. Oh, K. H. Kim, B. H. Juann; Nanomedical Engineering, Pusan National University, Miryang, Republic of Korea

Cas is known to associate with Crk and BCA23, a novel adaptor protein containing SH2-domain, but it is not investigated in the insulin-sensitive adiocytes and muscle cells. In the present study, we studied a functional role of Cas in insulin signaling and its association with Crk and BCA23. Microinjection of anti-Cas antibody inhibited the insulin-induced DNA synthesis and the membrane ruffling, suggesting that Cas is important in the insulin signaling. In HIRcB cells, Cas was associated with both Crk and BCA23, and dephosphorylated upon insulin stimulation resulting in the decreased association with Crk. But, the association of Cas protein with BCA23 was not changed. EGF and IGF-1 stimulation did not change the phosphorylation and association of Cas with BCA23. In 3T3-L1 adipocytes, Cas did not change the tyrosine phosphorylation of Cas. Crk association with Cas was increased in the 3T3-L1 adipocytes and L6 muscle cells. BCA23 association with Cas upon insulin stimulation was decreased in L6 muscle cells, but not changed in 3T3-L1 adipocytes. Our result show that p300 is involved in the insulin signaling and differentially associates with Crk or BCA23 in a cell-dependent manner upon insulin-stimulation.
Presenilin (PS), Amyloid Precursor Protein (APP) and Molecular Motors: Two Alzheimer’s Disease (AD) Proteins in the Kinesin Mediated Transport Pathway

S. Gunawardana, L. S. B. Goldstein; Cellular and Molecular Medicine, UCSD/HHMI, La Jolla, CA

Previously we suggested that APP and APP-like function as kinesin receptors in axonal transport. Recently, secretases (BACE and PS) responsible for the generation of pathogenic Ab were suggested to be present within APP vesicles transported by kinesin. Biochemical analysis indicates that APP cleavage occurs in Drosophila. Strikingly, PS influences both kinesin and APP-mediated transport pathways. Reduction of PS with excess APP causes the suppression of APP-mediated axonal blockages. Surprisingly, reducing the dose of nicastrin, APH-1 or PEN-2 with APP did not suppress blockages, suggesting that the PS-dependent suppression phenotype may not solely be due to PS’s gamma secretase activity. In vivo analysis of APP transport in RS cells revealed axon show increased anterograde transport of APP vesicles, and the velocities of APP vesicles traveling anterogradely and retrogradely increase compared to the transport of synaptogamin vesicles, suggesting that reduction of PS directly affects APP transport. One possibility is that PS mediates the transport of APP by aberrant cleavage of APP. Alternatively, PS may independently influence the transport of APP by directly affecting the transport machinery. To test this we increased the dose of PS with excess APP. Surprisingly, increasing PS also lead to the suppression of APP-mediated axonal blockages. Although excess PS alone had no effect, reducing the dose of kinesin (not dynexen) with excess PS caused blockages, suggesting that PS also affects kinesin-mediated transport. In vivo analysis of APP transport in PS increased axon also shows increased anterograde transport of APP vesicles, but a broad distribution of velocities for APP vesicles traveling anterograde or retrograde is observed. Perhaps excess PS may cleave APP to generate C-terminal fragments, which may be moving at different speeds. Thus we propose that while PS may also function in kinesin-mediated transport, APP cleavage may play a vital role in regulating APP vesicle movement within axons.

Shiga Toxin: A Model for Studying the Regulation of Dyneme-based Motility

H. A. Hetchly, M. Sambres; Physiology & Biophysics, University of Iowa, Iowa City, IA

The organization of cellular organelles and transport of intracellular vesicles require the cytoskeleton. We found that a bacterial exotoxin, Shiga toxin, requires microtubules for its retrograde traffic through the secretory system. Shiga toxin also increases the rate of microtubule and dynein dependent Golgi stack repositioning following nocodazole treatment. We have developed a permeabilized-cell system to study motor protein requirements during transport. Using permeabilized cells we found that Shiga toxin transport can be reconstituted in a cytosol- and ATP-dependent manner. Dynein inhibitors revealed that Shiga toxin utilizes dynein for transport to a juxtanuclear region. We have now tested whether other dynexin-dependent motility events can be studied in a permeabilized cell system. Following dispersal using nocodazole treatment, Golgi membranes can reassemble in permeabilized cells in the presence of cytosol and an ATP regenerating system. We are currently exploiting this reconstitution system to examine the role of Rho-family GTP-binding proteins, such as Cdc42, in regulating the motor-based intracellular motility of Shiga-toxin-containing transport intermediates and Golgi-derived vesicles. We hypothesize that some features of regulated dynein function in the secretory pathway will be shared among different trafficking steps.

Sequence-specificity of Plasmid Cytoplasmic Trafficking

E. E. Vaughan, D. A. Dean; Medicine, Northwestern University, Chicago, IL

Relatively little is known about how naked DNA moves through the cytoplasm to the nucleus during transfections and other forms of gene delivery. We have shown that in adherent cells, plasmid DNA requires intact microtubules to reach the nucleus (Vaughan and Dean, 2006, Molecular Therapy 13:422). Further, we have demonstrated that inhibition of dynein impedes this trafficking. However, it remains to be determined how plasmids interact with dynein and microtubules. In these studies, we used plasmids containing a promoter, a reporter gene, and a downstream DNA nuclear Targeting Sequence (DTS) that acts as a scaffold for transcription factors involved in DNA nuclear import. We envision two possible mechanisms for plasmid cytoplasmic trafficking. Either specific DNA sequences are required to bind to specific proteins that then interact with the dynein/microtuble complex, or no DNA sequence specificity exists and rather non-specific DNA-binding proteins (s) can act to bridge the DNA to the microtubules. To address this, we used a microtubule spin-down assay and quantitative PCR to determine if plasmas with or without various eukaryotic sequences were able to bind to microtubules in the presence of cell extract. We found that pBR322, a plasmid with no eukaryotic sequences did not interact with microtubules. By contrast, plasmids with a eukaryotic promoter were found to interact with the microtubules, suggesting that DNA-microtuble interactions are sequence dependent. These results are important in elucidating how naked DNA reaches the nucleus and an understanding of this process is imperative to improving the efficiency of gene transfer.

RhoB and the Mammalian Diaphanous-related Formin mDia2 Govern Actin Dynamics on Endosomes Necessary for Trafficking and Vesicle Fusion

A. D. DeWard, B. J. Waller, A. S. Alberts; Cell Structure and Signal Integration, Van Andel Research Institute, Grand Rapids, MI

Rho GTPases and the dynamic assembly and disassembly of actin filaments have been shown to have critical roles in both the internalization and trafficking of growth factor receptors. While all three mammalian Diaphanous-related (mDia1/2/3) formin GTPase effectors have been localized on endosomes, a role for their actin nucleation, filament elongation, and/or bundling remains poorly understood in the context of intracellular trafficking. In a study of a functional relationship between RhoB, a GTPase known to associate with both early- and late-endosomes, and formin mDia2, we show that 1) RhoB and mDia2 interact on endosomes; 2) inhibition of RhoB or mDia2 has no effect on internalization of growth factors; 3) GTPase - the ability to hydrolyze GDP - is required for the ability of RhoB to govern endosome dynamics; and 4) the actin dynamics controlled by RhoB and mDia2 is necessary for vesicle trafficking as well as maintaining their morphology. These studies further suggest that Rho GTPases significantly influence the activity of mDia family formins in driving cellular membrane remodeling through the regulation of actin dynamics.

Actin Filament Polarity in Retinal Pigment Epithelial Cells of Green Sunfish, Lepomis cyanellus

R. Vagnozzi, C. King-Smith; Department of Biology, Saint Joseph's University, Philadelphia, PA

The retinal pigment epithelium (RPE) lies between the retina and the choroid of the vertebrate eye. RPE cells from fish contain numerous pigment granules, or melanosomes, which undergo massive migrations in vivo to protect photoreceptors from bleaching. In the light, melanosome disperses from the RPE cell body out into long, thin apical projections. In the dark, melanosomes aggregate out of the projections back into the cell body. Melanosomes aggregation and dispersion are both actin-dependent. Previous research using in vitro motility assays has shown that melanosomes move towards the barbed end of actin filaments, presumably by myosin motors [McNeil et al., 2004 Cell Motil. Cytoskel. 58:71]. The purpose of the current research was to determine the polarity and organization of actin filaments in RPE cells using myosin S1 labeling. Dissociated RPE cells isolated from green sunfish were permeabilized in 10% saponin and incubated in 0.5 mg/ml myosin S1. Cells were then fixed in glutaraldehyde, embedded, sectioned, and examined using transmission electron microscopy. Both individual decorated actin filaments and actin filament bundles were observed in the cell bodies of RPE. Of the bundles analyzed, 69% had uniform polarity, 71% had completely random polarity, 21.4% showed 2/3 uniformity, and 7.1% showed ¾ uniformity. The presence of highly isotropic actin bundles in the RPE cell body suggests that melanosomes may independently influence the transport of APP by directly affecting the transport machinery. Thus we propose that while PS may also function in kinesin-mediated transport, APP cleavage may play a vital role in regulating APP vesicle movement within axons.
midbody. In addition, in mouse primary Schwann cells the two proteins also colocalize at the cell membrane. Our data indicates that the lack of merlin in the mouse primary Schwann cells drastically alters their microtubule cytoskeleton. Furthermore, merlin enhances tubulin polymerization both in vitro and in vivo in primary Schwann cells. This study describes a role for merlin as a microtubule organizing protein. It also suggests that merlin plays a key role in the regulation of Schwann cell microtubule cytoskeleton, possibly contributing to cytoskeletal defects observed in human schwannomas.

1655 Spindophilin Facilitates PPI-mediated Dephosphorylation of Pser297 Doublecortin in Microtubule Bundling at the Axonal "Wrist"
S. L. Bielas, F. Serno, M. Chechlas, T. Deerrink, P. Allen, M. Ellisman, J. Gleeson; 1Neurobiology, UCSD, La Jolla, CA, 2Neuroscience, UCSD, La Jolla, CA, 3National Center for Microscopy and Imaging Research, UCSD, La Jolla, CA, 4Psychiatry, Yale, New Haven, CT

The axon shafts of neurons contain bundled microtubules, extending through the transition zone may bundle microtubules during axon outgrowth. Among the candidates for mediating microtubule condensation is Doublecortin (Dcx), a microtubule-associated protein with a role in microtubule stabilization and bundling that when mutated in humans disrupts normal cortical development. Phosphorylation has been shown to regulate Dcx microtubule associated functions. We find that that Dcx is associated with Spindophilin (Spn), a protein- phosphatase 1 (PP1) targeting protein, selectively at the base of growth cones. Deletion of Spn results in mislocalization of inactive phosphorylated Dcx, and deletion of either Spn or Dcx results in defective microtubule bundling in axon shafts. Spn/PPI promotes Dcx dephosphorylation specifically at CdK5-phosphorylated S297, which restores the MT bundling effects of Dcx. We propose that the Spn/PPI/Dcx association is important for proper microtubule condensation at the base of the growth cone, leading to constriction of the growth cone and organized microtubule bundling in the axon shaft.

1656 Regulation of Microtubule Formation in Activated Mast Cells by Complexes of γ-Tubulin with Fyn and Syk Kinases
P. Draber, V. Sulimenko, E. Draberová, L. Macík, V. Richterová, P. Draber; 1Biology of Cytoskeleton, Institute of Molecular Genetics, Academy of Sciences of the Czech Republic, Prague, Czech Republic, 2Signal Transduction, Institute of Molecular Genetics, Academy of Sciences of the Czech Republic, Prague, Czech Republic

Aggregation of the high affinity IgE receptors (FceRI) on the cell surface initiates a chain of signaling events culminating in the release of allergy mediators. Although microtubules are involved in mast cell degranulation, the molecular mechanism that controls microtubule rearrangement after FceRI triggering is poorly understood. Here we show that the activation of bone marrow-derived mast cells (BMMCs) induced by FceRI aggregation or treatment with pervanadate leads to a rapid polymerization of microtubules. This polymerization was not dependent on the presence of Lyn kinase as determined by experiments with BMMCs isolated from Lyn-negative mice. One of the key regulators of microtubule polymerization is γ-tubulin. Immunoprecipitation experiments revealed that γ-tubulin from activated cells formed complexes with Fyn and Syk protein tyrosine kinases and several tyrosine phosphorylated proteins from both wild-type and Lyn− BMMCs. Pre-treatment of the cells with Src-family or Syk-family selective tyrosine kinase inhibitors, PP2 or piceatin, respectively, inhibited the formation of microtubules and reduced the amount of tyrosine phosphorylated proteins in γ-tubulin complexes, suggesting that Src and Syk family members are involved in the initial stages of microtubule formation. This notion was corroborated by pull-down experiments in which γ-tubulin interacted stably with the SH2 and SH3 domains of Fyn kinase. We propose that Fyn and Syk kinases are involved in the regulation of binding properties of γ-tubulin and/or its associated proteins, and thus modulate the microtubule nucleation in activated mast cells.

1657 RNA Depletion of γ-Tubulin as a Tool for Studying γ-Tubulin Role in Organization of Acentrosomal Cells
A. Doskociľová, J. Procházková, V. Cenklčová, P. Binarová; 1Institute of Microbiology, Prague, Czech Republic, 2Institute of Experimental Botany, Olomouc, Czech Republic

We studied the downregulation of γ-tubulin in Arabidopsis thaliana by inducible RNAi technique. The RNAi depletion of γ-tubulin led to serious distortions of development in A. thaliana seedlings. We found that cells with decreased levels of γ-tubulin could progress through mitosis, but late mitotic events and cytokinesis were strongly affected. Particularly, we observed that polar distribution of γ-tubulin during late mitosis was disturbed and the phragmoplast formation failed. In contrast to control cells where anaphase spindles were reoriented into the phragmoplast, long anaphase spindles persisted between separated nuclei in RNAi cells. Rearrangement of mitotic microtubules was delayed relative to the nuclear cycle. The cell plate formation sites were often misaligned. These discrepancies in late mitosis and cytokinesis often resulted in bin- or multi-nuclei cells and disruption of regular cell files was observed. The aberrant cytokinesis was also observed in cultured cells of expressing RNAi for γ-tubulin. It is well known that stomata development follows a strict developmental pattern. The stomata patterning was disrupted in RNAi expressing plants. Clusters of two to four stomata were observed in cells with reduced γ-tubulin levels while in plants with severe depletion of γ-tubulin, the cytokinetic defects of guard cells were found in addition to clustering. Cortical MTs of differentiating A. thaliana cells were sensitive to the reduction of γ-tubulin level by RNAi; γ-tubulin rapidly disappeared from its locations from its cortical MTs that became bundled and randomized. Ectopic root hairs formation was observed in cells with randomized MTs, anisotropic growth was disturbed. We suggest that some functions of γ-tubulin that are important for cytokinesis, cell specification and polar growth might be microtubule independent and require further analysis. Supported by grants A50209302 from GA CAS, grant PC 1545-MSMT CR and grant 204/05/I023 GACR.

1658 The Kinesin KIF1C and Microtubule Plus Ends Regulate Cytoskeletal Dynamics in Macrophages
P. Kopp, 1R. Lammers, 2M. Aepfelbacher, 2G. Woehlke, 1T. Rudel, 1N. Macy, 4W. Steffen, 1S. Linder; 1LMU, Munich, Germany, 2Universitaet Tubingen, Tuebingen, Germany, 3UKE, Hamburg, Germany, 4MPI f. Infektionsbiologie, Berlin, Germany, 5Med. Hochschule, Hannover, Germany

The recruitment of the kinesin KIF1C, a member of the Kinesin-3 family, a plus-end-enriched motor which targets regions of podosome turnover. Expression of mutation constructs or siRNA-/shRNA-based depletion of KIF1C resulted in decreased podosome dynamics and ultimately in podosome deficieny. Importantly, protein interaction studies showed that KIF1C binds to microtubules. The absence of microtubules leads to a defect in the podosome localization of KIF1C. In particular, KIF1C depletion led to a disorganization of podosome patterns, which correlates with an alteration of podosome function. This notion was corroborated by pull-down experiments in which γ-tubulin, the protein as a tool for studying γ-tubulin role in organization of acentrosomal cells. Spindle MTs of differentiating A. thaliana cells were sensitive to the reduction of γ-tubulin level by RNAi; γ-tubulin rapidly disappeared from its locations from its cortical MTs that became bundled and randomized. Ectopic root hairs formation was observed in cells with randomized MTs, anisotropic growth was disturbed. We suggest that some functions of γ-tubulin that are important for cytokinesis, cell specification and polar growth might be microtubule independent and require further analysis. Supported by grants A50209302 from GA CAS, grant PC 1545-MSMT CR and grant 204/05/I023 GACR.

1659 Force Regulation of Microtubule Dynamics in Fission Yeast
C. Tischer, D. Brunner, M. Dogterom; 1AMOLF, Amsterdam, The Netherlands, 2EMBL, Heidelberg, Germany

The microtubule cytoskeleton is crucial for generating long range order inside eukaryotic cells. To properly fulfill this function microtubules must adopt an appropriate length distribution, which is governed by their growth and shrinking rates as well as the rates of switching between growth and shrinkage (“catastrophe” and “rescue”). Here, we use the nodulated yeast (S. Pombe) to address the following fundamental questions regarding the organization of interphase microtubules: Are the rates that govern microtubule length spatially regulated? Do the rates adapt to changes in cell size? And, do compressive forces generated as microtubules grow against the cell boundary locally enhance the catastrophe rate? To address these questions thoroughly we developed an image analysis methodology for the fully automated detection of microtubule tips, catastrophes and growth events from movies of GFP-labeled microtubules. Unlike in previous investigations of actin microtubule dynamics, we find that the rate of catastrophe is insensitive to an increase (10%) of the external force acting on the cell surface distribution of microtubule tips and catastrophes makes it possible to directly map the local catastrophe rate constant (\( \text{Crate} \)) for each position within the cell. Analyzing \( >30000 \) catastrophe and growth events in \( \sim400 \) cells, we find that both cytoplasmic catastrophe rate constants and microtubule growth velocities are almost independent on cell size. Cytoplasmic factors, therefore, do not appear to adapt microtubule length to changes in cell size such as occurring during interphase. Furthermore, we find that \( \text{Crate} \) is approximately two-fold enhanced at the cell end regions. We provide evidence that compressive forces arising from growth of microtubules against the cell boundary contribute to this local enhancement of \( \text{Crate} \). Supported by grants A50209302 from GA CAS, grant PC 1545-MSMT CR and grant 204/05/I023 GACR.
Polarized cells, such as neuronal, epithelial and fungal cells, display a specialized organization of their microtubule (MT) cytoskeleton. In the rod shaped fission yeast, Schizosaccharomyces pombe, the interphase MT cytoskeleton has been extensively described by fluorescence microscopy. We have made a large-scale, electron tomography investigation of S. pombe, preserved by high-pressure freezing and freeze-substitution fixation. The results provide the first 3D reconstruction of a full eukaryotic cell volume at electron tomography resolution. Interphase MTs in fission yeast are commonly single or in pairs. Larger bundles of up to nine MTs can assemble, most frequently in bundles associated with the spindle pole body (centrosome), but only a single MT extends towards the cell's tip. Each time that a single MT contacted the plasma membrane, it did so with a fixed end. Such flares at one MT end, coupled with caps at the other, provide evidence about cytoplasmatic MT polarity, information that improves our understanding of MT organization in interphase fission yeast. Individual MT bundles are often composed of antiparallel MTs. Electron dense bridges between MTs themselves and between MTs and the nuclear envelope were frequently observed. We also found an intimate association between MTs and mitochondria. Our analysis shows that the combination of native cell preservation and electron tomography is ideally suited for describing fine ultrastructural details that were not visible with previous techniques.

Electron Tomography Reveals the Molecular Details by Which Fascin and Filbrin Bundle Actin Filaments

M. E. W. Janssen, E. Kim, S. Almo, P. Matsudaira, D. Hanein; 1The Burnham Institute for Medical Research, San Diego, CA, 2Albert Einstein College of Medicine, New York, NY, 3Whitehead Institute, Cambridge, MA

The three-dimensional organization of filamentous actin is essential for biological processes such as cell shape, division, motility, transport and signaling. Actin filaments can be organized in vivo into tightly ordered bundles, whose structural roles of packing appear to be determined by their respective actin bundling proteins. Two of the most abundant actin binders, fimbrin and fascin, are believed to induce actin bundles through crosslinking via a tandem repeat of actin binding domains. Although both proteins bundle actin filaments, they are not interchangeable. While fascin participates in formation of filopodia, filbrin participates in podosome formation at the leading edge of migrating cells. Our aim is to determine the molecular details of actin crosslinking by fimbrin and fascin. Due to the size and the helical nature of filamentous actin, conventional methods such as NMR spectroscopy and x-ray crystallography respectively are not suitable for studying our actin-crosslinker complexes. However, transmission electron microscopy combined with image reconstruction techniques is an excellent tool to determine the structure of these large molecular assemblies. We used electron tomography to obtain three-dimensional electron density maps of actin filaments crosslinked by fimbrin or fascin. Isolation of fascin or filbrin that crosslink actin filaments by various image analysis tools followed by docking of atomic models made it possible to determine the molecular details of the binding interfaces between actin and its respective bundler.

SmgGDS, a Guanine Nucleotide Exchange Factor, Regulates Myosin Organization and Cellular Contraction in Vascular Smooth Muscle Cells

R. Thill, E. L. Lorimer, C. L. Williams; Pharmacology and Toxicology, Medical College of Wisconsin, Milwaukee, WI

The guanine nucleotide exchange factor SmgGDS, promotes nucleotide exchange by several GTPases in both the Ras and Rho families, especially by RhoA. Although RhoA is an important regulator of vascular smooth muscle cell (VSMC) contraction, the expression and function of SmgGDS in VSMC have not been previously investigated. A7r5 cells transfected with SmgGDS siRNA or RhoA siRNA exhibited reduced [3H] thymidine incorporation suggesting that SmgGDS is likely involved in the regulation of cellular proliferation through a Rho or Ras GTPase signaling pathway. Cells with reduced SmgGDS expression have enhanced spreading and no longer exhibit the elongated shape that is characteristic of the VSMC morphology of A7r5 cells. In contrast, cells with reduced RhoA expression exhibit an elongated shape with only minor cell spreading suggesting that SmgGDS regulates VSMC morphology by controlling the activities of multiple small GTPases in addition to RhoA. Subsequent immunoblotting with a human monoclonal IgM antibody against myosin heavy chains revealed a disruption of the myosin filament organization in the cells with reduced SmgGDS expression, which is consistent with inactivation of the Rho signaling pathway. In order to determine whether the absence of SmgGDS affected myosin dynamics through the inactivation of Rho-kinase, the phosphorylation levels of Thr696 and Thr850 on myosin phosphatase (MYPT1) were evaluated following siRNA transfection. Although treatment of A7r5 cells with 3μM of the pharmacological Rho kinase inhibitor, Y27632, significantly inhibited the phosphorylation of Thr850, transfection of SmgGDS siRNA did not affect phosphorylation of MYPT1 at either Thr696 or Thr850. However, transfection of SmgGDS siRNA or RhoA siRNA resulted in an impaired ability of the A7r5 cells to undergo contraction following depolarization of the cell with 90mM K+. Taken together these results identify SmgGDS as a novel regulator of myosin organization and contraction in VSMC.

SmgGDS, a Guanine Nucleotide Exchange Factor, Regulates Myosin Organization and Cellular Contraction in Vascular Smooth Muscle Cells

R. Thill, E. L. Lorimer, C. L. Williams; Pharmacology and Toxicology, Medical College of Wisconsin, Milwaukee, WI

Taken together these results identify SmgGDS as a novel regulator of myosin organization and contraction in VSMC.

Actin Dynamics and Contractility in Oocyte Wound Healing

B. Burkel, W. Bement; Zoology, University of Wisconsin, Madison, WI

F-actin and Myosin 2 play integral roles in both cytokinesis and the closure of cortical wounds. During these events, the cell rapidly assembles a dynamic contractile ring composed of these core proteins. While the importance of F-actin in these contractile structures has been established for some time, accurately assessing its temporal and spatial dynamics has been hindered in part by the shortcomings in available probes for imaging F-actin in vivo. These shortcomings range from perturbation of filament dynamics to the inability to distinguish F-actin from total actin core proteins. While the importance of F-actin in these contractile structures has been established for some time, accurately assessing its temporal and spatial dynamics has been hindered in part by the shortcomings in available probes for imaging F-actin in vivo. These shortcomings range from perturbation of filament dynamics to the inability to distinguish F-actin from total actin core proteins. Here we have characterized a fluorescent fusion protein comprised of the first 261 amino acids of the actin binding protein, utrophin, that overcomes these shortcomings. This fusion protein, Utu-125, accurately reports F-actin populations, but does not alter actin dynamics or impact myosin 2-based contractility. By using this probe in conjunction with various photoactivation techniques, we have established that these contractile structures are divided into discrete sub-populations that differ sharply with respect to their dynamics. Perturbation of actin dynamics through either dominant negative or pharmacological means dramatically impacts not only actin, but also myosin localization and overall contractility. Furthermore, the elimination of myosin-based contractility alters ring formation and myosin localization. Together the evidence supports proper maintenance of actin dynamics and myosin contractility is essential for efficient ring formation and subsequent wound closure.

The Molecular Mechanism of the Inagination and Oocyst Formation during Chick Embryos Development

X. Sai; Sensory Development, RIKEN CDB, Kobe, Japan

The inner ear is formed on the surface ectoderm of the embryos, first appeared denser than most of the surrounding ectoderm epithelium, as development proceeds it gradually forming a deeper depression, followed by internalization and closure. Although we observed this phenomenon easily, but the detail molecular mechanism including in this morphogenesis remain unknow. Here we evidenced that after anic fate decision of F-actin play an important role to convergence apical region and non-muscle myosin II play an important role to expansion the basolateral membrane of the auditory placode. They cooperation to invaginate and close up the otic primordium.

Elucidating the Roles of PIP5K Kinases in the Regulation of the Actin Cytoskeleton

A. M. Corgan, M. Yamaga, J. W. Wang, K. Luby-Phelps, H. L. Yin; Department of Physiology, The University of Texas Southwestern Medical Center, Dallas, TX

Phosphoinositide-4,5-bisphosphate (PIP2) is an important regulator of the actin cytoskeleton and plasma membrane functions. It is synthesized primarily by the type I phosphatidylinositol 4-phosphate 5 kinases (PIPKIs). Mammals have three PIP5K genes (PIP5Kα, PIP5Kβ, and PIP5Kγ), and the γ isozyme has two splice variants: a long 90 kDa and short 87 kDa form. We found that the depletion of each individual PIP5K isoform by siRNA in HeLa cells generated distinct changes in the actin cytoskeleton and signaling responses. The actin phenotype of the PIP5Kγ knockdown (using siRNA directed against both the 90 and 87 kDa isoforms) in HeLa cells is particularly striking: it results in increased actin stress fiber formation and decreased chemotaxis migration. Although PIP5Kγ has already been implicated in focal adhesion formation, its knockdown alone (using the long form specific siRNA) failed to produce these changes. Therefore, the actin phenotype may be primarily due to the depletion of PIP5Kγ. We sought to identify the molecular mechanisms of this actin phenotype. Immunofluorescent studies demonstrated that focal adhesions, as stained by anti-vinculin antibodies, are more abundant in the PIP5Kγ depleted cells. Using real-time interference reflection microscopy (IRM), we found that the turnover of focal adhesions occurs at a much more retarded rate in the PIP5Kγ depleted cells. These results indicate that the observed actin phenotype of PIP5Kγ knockdown cells may be due to an inability of these cells to disassemble focal adhesions, and that the PIP2 generated by PIP5Kγ regulates the uncoupling of the adhesion sites from the actin cytoskeleton.

1666 Focal Adhesion Kinase Modulates Tension Signaling to Control Actin and Focal Adhesion Dynamics

M. Schober,1 2 S. Raghaavan,2 A. Pasolli,2 M. Nikokova,2 L. Polak,1 H. E. Beggs,1 L. F. Reichardt,1 E. Fuchs2; 1 The Rockefeller University, New York, NY, 2 Columbia University School of Medicine, New York, NY, 3 Department of Physiology, University of California, San Francisco, CA

Integrins function as crucial transmembrane regulators of a diverse array of cellular processes, ranging from cell adhesion, basement membrane assembly and tissue homeostasis to cell migration and wound-healing. In response to αβ integrin signaling, transducers such as focal adhesion kinase (FAK) become activated, relaying to specific machineries and triggering distinct cellular responses. By conditionally ablating Fak in skin epidermis, we show that FAK is dispensable for keratinocyte adhesion and basement membrane assembly, both of which require αβ integrins. By contrast, we discovered a role for FAK downstream of αβ-integrin in regulating cytoskeletal dynamics and orchestrating polarized keratinocyte migration out of epidermal explants. The Fak-null keratinocytes display an aberrant actin cytoskeleton which is tightly associated with peripheral focal adhesions and microtubules. We show that in keratinocytes lacking FAK, FAs are not able to efficiently activate Src, p190 RhoGAP or PAK, which results in increased signaling by Rho/ROCK as well as myosin light chain kinase. The consequential elevated tension signaling accounts for many of the alterations in cytoskeletal organization and FA dynamics that we see in these cells. These findings have important implications for our understanding of the role of FAK in wound-healing and provide a molecular explanation for why the loss of FAK impairs skin tumorigenesis.

1667 A Mechanism for Regulating the Activity of Zyxin-VASP Complexes

M. D. H. Hansen, B. Adams, P. Bell, E. Bushnell, J. Moody; Physiology and Developmental Biology, Brigham Young University, Provo, UT

Zyxin localizes to sites of active actin polymerization in cells, including sites of cell adhesion. Zyxin contains ActA repeats, protein domains that bind actin regulators of the Ena/VASP family. Zyxin has been proposed to drive actin rearrangements as a scaffold protein: by recruiting VASP family members to cellular sites via ActA repeats. In this model, zyxin functions merely to dock VASP at sites of actin reorganization. However, domain analysis of zyxin suggests a novel mechanism for regulating VASP availability. Here we show that the zyxin αβLim domain inhibits actin binding of another actin binding site. This is demonstrated by expression of zyxin mutants lacking αβLim domains in MDCK cells, which results in increased incorporation of VASP into actin networks at cell-cell junctions. This effect is not observed with full-length zyxin and requires ActA repeats. Consistent with a role for the αβLim region in blocking VASP function in zyxin/VASP complexes, recombinant zyxin αβLim domains precipitate endogenous zyxin and VASP from cell extracts. While the mechanism by which αβLim regions block VASP activity remains elusive, our findings show a direct interaction between VASP and zyxin αβLim domains. Based on this, we propose an auto-regulatory system for controlling the activity of zyxin/VASP complexes. In this model, zyxin-VASP complexes exist in either active or inactive forms. In active complexes, VASP is bound to ActA repeats and is free to drive actin polymerization. In inactive complexes VASP is bound to ActA repeats and zyxin αβLim domains simultaneously blocking VASP from contributing to actin polymerization. A biochemical approach using in vitro reconstitution is employed to test this hypothesis.

1668 Regulation of Polarized F-Actin Organization in Chemotaxing Cells via Biased Delivery of Vesicles Containing WASP, CLP1/2, and RacC to the Leading Edge

J. W. Han, L. R. Leeper, J. S. Gruver, C. Y. Chung; Pharmacology, Vanderbilt University Medical Center, Nashville, TN

The actin cytoskeleton is highly polarized in chemotaxing Dictyostelium cells, with F-actin assembled predominantly in the anterior leading edge and to a lesser degree in the cell’s posterior. It has been demonstrated that WASP localizes on vesicles and these vesicles appear to be preferentially distributed at the leading edge and uropod of chemotaxing cells. We have examined the role of the F-actin organizing proteins, CLP1 and CLP2, in the regulation of polarization of WASP localization and F-actin organization. The F-actin organizing proteins include an amino-terminal FCH domain followed by a coiled-coil domain, proline-glutamic acid-serine-threonine-rich (PEST) sequences, and a SH3 domain. CLP1 and CLP2 appear to be functionally redundant and deletion of both CLP1 and 2 cause a loss of polarity and severe defects in chemotaxis. WASP and CLP1 are colocalized on vesicles and interactions between SH3 domain of CLP1/2 and the proline-rich repeats of WASP are required for vesicular localization. Polarized distribution of vesicles is absent in cells lacking CLP1/2 or RacC, a major regulator of WASP in cell migration. Our results suggest that polarized F-actin organization in chemotaxing cells is controlled by biased delivery of vesicles containing WASP, CLP1/2, and RacC to the leading edge and uropod presumably via interaction of FCH domain of CLP1/2 with microtubules.

1669 Role of Oligomerization of Cdc24, a Key Regulator of Budding Yeast Polarized Growth

C. Mironett; Centre de Biochimie, ISDBCNRS UMR6543, Nice, France

Summary: Polarized growth is a fundamental biological process critical for establishment and maintenance of cell asymmetry, necessary for morphological changes. Highly conserved small GTPases, in particular members of the Rho family, like Cdc42, play an essential role in actin cytoskeleton organization. Guanine nucleotide Exchange Factors activate G-proteins by catalyzing the exchange of GDP for GTP. Cdc24 is the unique GEF for Cdc42 in Saccharomyces cerevisiae, is part of the ubiquitous Dbll family defined by a Dbll Homology catalytic domain adjacent to a Plekstrin Homology domain. These GEFs are strictly regulated in space and time, in yeast, Cdc24 localization varies during the cell cycle. In mammalian cells, GEFs, such as Dbll and LARG, have been shown to homo-oligomerize. Dbl and LARG mutants which are unable to oligomerize, have altered transforming potentials, suggesting that this association is important for regulation of these G-protein activators. Using immunoprecipitation and in vitro binding assays, we have demonstrated that Cdc24 forms homo-oligomers. Analysis of different deletion mutants indicates that the catalytic DH domain of Cdc24 is both necessary and sufficient for homo-oligomerization. Examination of point mutants in the Cdc24 DH domain indicates that mutants defective for oligomerization allow growth as the sole copy and conversely mutants that are not viable as the sole copy, oligomerize normally. We have used the inducible oligomerization domain of Fkbp fused to Cdc24 to force oligomerization in vivo. Constitutive Cdc24 oligomerization resulting in a decrease in active Cdc42, determined by the CRIB pull down method. Using a Cdc24-FKBP-GFP fusion we examined whether constitutive oligomerization affects the localization of Cdc24, which normally shuttles between the sites of growth and division. Using a Cdc24-FKBP-GFP fusion we examined whether constitutive oligomerization affects the localization of Cdc24, which normally shuttles between the sites of growth and division. Our results suggest that constitutive oligomerization of Cdc24 affects the localization of Cdc24, which normally shuttles between the sites of growth and division.

1672 Dia2 Regulates Actin Dynamics and Organization in the Lamella for Efficient Epithelial Cell Migration

S. L. Guntup,1 K. Eisenmann2; 1 Cell Biology, Scripps Research Institute, La Jolla, CA, 2 Van Andel Research Institute, Grand Rapids, MI

A dynamically organized filamentous actin (F-actin) cytoskeleton is required for cell migration. In a migrating cell, the dynamic organization of F-actin is spatially modulated by distinct actin-associated proteins, which mediate polymerization, depolymerization, contraction, bundling, or engagement to the substratum through focal adhesions. Dia2 is a member of the Dia family of GTPases, which have been extensively studied in vitro, but their function in the cell has been less well characterized. Here we study the role of Dia2 activity in the dynamic organization of F-actin in migrating epithelial cells. We find that Dia2 localizes in the lamella of migrating epithelial cells, where it is involved in the formation of a stable pool of cortical actin and protection of free filament barbed ends at focal adhesions. Specific inhibition of Dia2 alters the turnover of focal adhesions and reduces migration velocity. We suggest that the protection of free barbed ends at focal adhesions may be necessary for the formation of a stable pool of cortical lamella actin and the proper assembly and disassembly dynamics of focal adhesions, making Dia2 an important factor in epithelial cell migration.

1673 Spatial-Temporal Observation of Stress Fiber Formation in Nonmuscle Cells and Possible Contribution of Filamin A

K. Kato,1 H. Haga,1 Y. Koyama,1 K. Ohishi,1 T. Ito,1 K. Kawahata; 1 Division of Biological Sciences, Graduate School of Science, Hokkaido University, Sapporo, Japan, 2 Department of Biochemistry, Graduate School of Medicine, Hokkaido University, Sapporo, Japan, 3 Department of Biology, Faculty of Science, Chiba University, Chiba, Japan, 4 Division of Biological Sciences, Graduate School of Science, Kyoto University, Kyoto, Japan

Spatial distribution of stress fibers in a nonmuscle cell is one of the most important factors that determine the mechanical behaviors of cells, such as cellular movement and the maintenance of its shape. We consider that filamin A (FLNa), one of the actin-binding proteins, regulates the formation of stress fibers. We previously compared the spatial distribution of stress fibers between FLNa-deficient human melanoma cells (M2 cells) and M2 derived cell line expressing FLNa (A7 cells). In A7 cells, dorsally formed stress fibers were observed, whereas in M2 cells were not. These results indicate that the expression of FLNa affects the spatial distribution of stress fibers. However, the process of stress fiber formation was not elucidated. The purpose of this study is to clarify the dynamics of stress fiber formation and the role of FLNa in this process. Time-lapse observations of stress fibers in A7 and M2 cells were performed immediately after cells were

308

2006 ASCB Annual Meeting Abstracts
plated on a glass substrate. To observe the stress fiber formation, cells were transfected with an expression plasmid for GFP-tagged myosin regulatory light chain were examined using fluorescence confocal microscopy. As the first step of stress fiber formation, bundles of stress fibers were formed at the basal periphery in A7 cells. Then, some of stress fibers unraveled from these basal bundles and moved toward apices of the cells. This upward movement of stress fibers was not observed in M2 cells. We also performed RNAi experiments to specifically knock down FLNa in HT1080 cells, human fibrosarcoma cells. Specific knock down of FLNa in HT1080 cells resulted in the decline of the stress fiber bundles formed at basal periphery in the initial step of stress fiber formation. We consider that the FLNa-dependent formation of stress fiber bundles at the basal periphery is significant in the formation of dorsal stress fibers.

1674 Perturbation of Non-Muscle Myosin IIb by Chromophore-assisted Laser Inactivation (CALI) Leads to Severing of Actin Stress Fibers, Tearing of the Plasma Membrane, and Change of Overall Cell Cytoskeletal Structure

F. -. S. Wang,1 2 D. Lenz,2 J. P. Robinson,2,3,4 X. P. Zeng1; 1Biological Sciences, Purdue University Calumet, Hammond, IN, 2Bindley Bioscience Center, Purdue University, West Lafayette, IN, 3Dept. of Basic Medical Sciences, Purdue University, West Lafayette, IN, 4Weldon School of Biomedical Engineering, Purdue University, West Lafayette, IN

Actin stress fibers are thought to be actively tensed by myosins motors and to function as flexible and resilient cables that structurally reinforce the cytoskeletal structure of a cell. They are important for maintaining cell shape and regulating cell motility (Ingber, 2003; Kumar et al., 2006). Non-muscle myosins have been shown to display periodic distribution along stress fibers and are essential in stress fiber assembly and maintenance (Cramer et al., 1997; Hotulainen and Lappalainen, 2006). In this study, we describe the effect of perturbing non-muscle myosin IIb function by chromophore-assisted laser inactivation (CALI). CALI utilizes laser irradiation to inactivate a protein molecule bound by a specific chromophore-conjugated antibody. The specificity of target selection and the ability for instantaneous inactivation at a specific time and location make CALI a powerful tool in probing functions of biomolecules in physiological processes with a high spatiotemporal resolution. Chicken embryonic fibroblasts transiently expressing EFGP-actin were microinjected with malachite green-labeled anti-non-muscle myosin IIb monoclonal antibodies (Conrad et al., 1995). Selected areas of the cells were subjected to laser irradiation while being monitored by time-lapse video microscopy. Our results show that perturbation of non-muscle myosin IIb function by CALI causes an immediate diffusion of EGF fluorescence away from the center of the laser spot and an instant severing of actin stress fibers within the irradiated area. The severing of actin stress fibers correlates with the breakdown of cell cytoskeletal structures and the tearing of the plasma membrane or a complete disintegration of an entire cell. Maximum tearing of cell membrane is reached within 2 minutes following the severing of actin stress fibers while re-sealing of the plasma membrane is achieved in about 10 minutes. Our data demonstrated that non-muscle myosin IIb is essential in maintaining actin stress fiber integrity, membrane-cytoskeletal structure, and overall cell shape.

1675 Dynamics of Myosin II during Mitosis and Cytokinesis of Drosophila S2 Cells

J. Spudich, R. Uehara, G. Goshima, R. Vale; Physiology Course 2006, Marine Biological Laboratory, Woods Hole, MA

Myosin II is one of the earliest components of the contractile ring to appear in the equatorial cortex during mitosis. In Drosophila S2 cells, myosin is initially localized to the equatorial cortex by signals from rho1 and rho kinase. A second rho1-dependent pathway that leads to formation of a specific actin filament assembly involving formin and profilin is necessary to stabilize the myosin at the equatorial cortex (Dean, S.O., Rogers, S.L., Stueuman, N., Vale, R.D. and Spudich, J.A., Proc Natl Acad Sci USA 102:13473-13478, 2005). We have used FRAP analysis to examine the dynamics of the turnover of myosin II in the equatorial cortex at the earliest stage of recruitment, after stabilization into a contractile ring, and at various times after cytokinesis proceeds. We compared these dynamics to that of a “myosin II cloud” found in the spindle region just prior to initial myosin recruitment to the equatorial cortex. We found that the recovery rate of GFP-tagged myosin II regulatory light chain (GFP-RLC) in the equatorial cortex after photobleaching is slower than that of the myosin II cloud, and it dramatically decreases upon the metaphase-anaphase transition, and further decreases as constriction of the contractile ring occurs. Cells containing GFP-RLC-E20E21 (a phospho-mimic form of the RLC) show delayed fluorescence recovery at all stages compared to wild type cells, indicating the importance of rho kinase phosphorylation control on the myosin dynamics. FRAP of these cells was also used to explore whether the origins of the myosin in the contractile ring are from cortical flow or from the equatorial cytoplasm.

1676 Development of a Fluid Dynamical Model, the Cylinder-thinning Model, for Cytokinesis

E. M. Reichl,1 M. Delanoyx,1 J. Effler,2 D. N. Robinson3; 1Cell Biology, Johns Hopkins University, Baltimore, MD, 2Electrical and Computer Engineering, Johns Hopkins University, Baltimore, MD

Cytokinesis is the process by which a mother cell divides to form two daughter cells. Historically, this process was modeled as a constriction of concentric rings of actin and myosin (the Purse-string Model). Our studies of the cleavage furrows of dividing Dicystostelium cells by electron microscopy and fluorescent microscopy do not show the presence of a ring structure. Instead, actin filaments appear disordered or interpolar. Furthermore, Dicystostelium cells lacking myosin II are able to complete cytokinesis, but with altered bridge morphology and furrow-thinning kinetics. Addition of a 10-fold slower myosin II rescues the myosin II mutant morphology and kinetics of furrow-thinning, but not the stress modulus. The global actin crosslinkers dynamin and fimbrin also contribute to the dynamics and cortical mechanics of Dicystostelium cells. Removal of these crosslinkers increases the rate of furrow-thinning and reduces the stress modulus compared to wild type cells. These results suggest that an alternate model for the forces driving cytokinesis is necessary. Our data is being used to evolve the Cylinder-Thinning Model, which includes both passive and active properties of the cortex to account for cytokinesis. Overall, our structural and mechanical data are providing insight into the contractile mechanism of cell division.

1677 Interaction of the Calmodulin-like Domain of α-Spectrin with β-Spectrin and Its Regulation by Calcium

Z. Zhang,1 X. An,1 X. Gao,1 A. Baines,4 N. Mohandas; 1Red Cell Physiology, New York Blood Center, New York, NY, 2Department of Biosciences, University of Kent, Canterbury, Kent, United Kingdom

Erythrocyte spectrin is composed of α- and β-spectrin subunits which form anti-parallel dimers through lateral association, and tetramers through head-to-head association of dimers. The subunits are arranged in an anti-parallel fashion such that the N-terminus of β-spectrin is in apposition to the C-terminus of α-spectrin. At the C-terminus of the α-chain is a calmodulin-like domain (CLD) that has four EF hands. The N-terminal region of β-spectrin contains the actin/4.1 binding domain (ABD) and the first triple helical repeat (R1). In another member of the spectrin superfamily, α-actinin, the CLD interacts with the ABD-R1 region on the opposite subunit. We hypothesized a similar interaction in erythrophil spectrin. In this study, we construct a β-spectrin containing the N-terminal ABD through R1 (β CLD) that is able to interact with the α CLD domain. The interaction was observed by fluorescence energy transfer experiments suggested a conformational change in the CLD and EF 3-4 fragment upon calcium binding. The short linker in β-CLD-spectrin that joins the ABD to R1 contains a region predicted to form a basic amphiphilic α-helix, reminiscent of sequences likely to bind calmodulin. We tested the significance of this region by mutagenesis. Mutation of highly conserved valine residues to alanine or glutamic acid significantly reduced the interaction. We conclude that α-CLD binds to the region of β-CLD that links the ABD to R1 in a Ca2+-sensitive manner. Since residues critical for this interaction are conserved in many β-spectrins, this interaction is likely to occur in most, if not all, spectrins.

1678 Characterization of Cellular Titin in Human Megakaryocyte, Mouse Fibroblast, and Deer Fibroblast Cell Lines

P. J. Cavanr, S. G. Olenych, T. C. Keller; Department of Biological Sciences, Florida State University, Tallahassee, FL

We previously discovered a large titin-like protein - c-titin - in chicken epithelial brush border and human blood platelet extracts that binds alpha-actinin and organizes arrays of myosin II bipolar filaments in vitro. We have investigated the molecular relationship between c-titin and striated muscle titin by RT-PCR analysis of total RNA from human megakaryoblastic (CHRF-288-11) and mouse fibroblast (3T3) nonmuscle cells. Amplified products obtained contain sequences identical to known titin gene exon sequences that encode parts of the Z-line, I-band, PEVK domain, A-band, and M-line regions of striated muscle titins. Products containing Z-line exons encode the Z-repeat domains Zr1-3 and 7 and the Zq domain, which bind alpha-actinin in striated muscle titins. I-band region sequences encode the ZA2 exons, but none of the exons distinctive for the N2B or Novex I and II isoforms. Products from the A-band and M-line regions contain the long titin gene exon that encodes an Ig-FN3 domain superrepeat region important for myosin filament binding and the exon that encodes the kinase domain. We found two variants containing PEVK-encoding exons not known to be expressed in muscle. These sequences are differentially spliced in patterns not reported for any striated muscle titin isoform. The data suggest that rabbit polyclonal antibodies raised against expressed protein fragments encoded by the Z-repeat and kinase domain regions to investigate the relationship between the RT-PCR products and the c-titin protein. Both antibodies react with the c-titin band in Western analysis of platelet extracts and immunoprecipitate c-titin in whole platelet extracts. Immunofluorescent localization
reveals the majority of the c-titin colocalizes with alpha-actinin and actin in 3T3 and Indian Muntjac deer skin fibroblast stress fibers. Our results suggest that differential expression of titin gene exons in nonmuscle cells yields multiple novel isoforms of the protein c-titin which are incorporated with the actin stress fiber structures.

1679 Smitin Interactions with Smooth Muscle Contractile Apparatus Proteins
R. J. Chi, A. R. Simon, S. G. Olenych, T. C. S. Keller; Biological Science, Florida State University, Tallahassee, FL
The striated muscle Z-line is a complex network of proteins in which N-terminal domains of titin interact with the actin filament cross-linker alpha-actinin, the titin cross-linker telethonin/Tcap, and other proteins to establish and maintain the structural integrity of the sarcomere. We previously discovered a titin-like protein - smitin - in smooth muscle cells suggesting that similar interactions may exist in the alpha-actinin rich dense bodies and dense plaques that act as the smooth muscle equivalent of the Z-line. RT-PCR analysis of smooth muscle RNA and western blot analysis with titin domain-specific antibodies has revealed that smitin contains the alpha-actinin-binding Z-repeat 1-3, and Zq domains and telethonin/Tcap-binding Z1-Z2 domain encoded by the titin gene. We have investigated whether loops in the alpha-actinin R2 and R3 spectrin-repeat domains that are modeled to lie in proximity on the surface of the central rod and are highly conserved between smooth and striated muscle alpha-actinins constitute the binding site for the Zq domain. We have found the mutations A423A, T425A or T427D in the R2 loop and N586A in the R3 loop decrease binding to expressed Zq domain in GST-pulldown and solid phase binding assays. We also have found expressed Zq peptide migrates on HPLC size exclusion chromatography as an apparent helical dimer, further supporting our proposed model for the R2-R3 loop interaction with the Zq domains of titin and smitin. Further sensitive RT-PCR analysis of RNA from multiple smooth muscle sources revealed evidence for T-cap transcripts in commercially available human bladder, uterus and carotid artery smooth muscle RNA and in A7r5 rat aortic smooth muscle cell RNA. These results suggest T-cap may be present in smooth muscle cells, where it could provide additional stability to the smitin anchorage in the dense bodies, functionally similar to its role in striated muscle.

1680 Focal Adhesions: Structural and Signaling Platforms for Keratin Filament Precursor Formation
F. W. Flitney,1 K. M. Ridge,2 R. D. Goldman1; 1Cell & Molecular Biology, Northwestern University, Chicago, IL, 2Division of Pulmonary & Critical Care Medicine, Northwestern University, Chicago, IL
A Soluble Pool of Keratin 18 Is Incorporated into Endogenous Intermediate Filaments(IF) in Human Alveolar Epithelial Cells Under Flow
F. W. Flitney, K. M. Ridge,2 R. D. Goldman1; 1Cell & Molecular Biology, Northwestern University, Chicago, IL, 2Division of Pulmonary & Critical Care Medicine, Northwestern University, Chicago, IL
The keratin intermediate filament (IF) network in lung epithelial cells is severely disrupted when cells are exposed to shear stresses of ~30 dynes/cm² for up to 24 hr. Here we report on the effects of shorter periods of flow (<6 hr) at lower shear forces (7-15 dynes/cm²) on keratin IF in human A549 alveolar epithelial cells. Cells were grown on glass microscope slides and placed in a laminar flow chamber generating uniform shear stresses of 7 or 15 dynes/cm² for up to 6 hr. They were then either (a) fixed in formaldehyde or methanol and immunostained with a rabbit anti-keratin antibody, or (b) extracted briefly (5 min, on ice) with 0.5% Triton-X100 in an IF stabilization buffer, to examine the protein composition of TX-100 soluble and insoluble fractions. Control cells were not exposed to flow but were maintained under static culture conditions throughout. Immunofluorescence revealed an extensive but delicate meshwork of fine IF in control cells. Western blots showed that a significant quantity of K18 was present in the TX-100 soluble fraction in untreated cells (n = 9), amounting to ~ 9% of the total cellular K18. This pool of K18 decreased substantially (~60%) when cells were exposed to flow (p<0.02; n = 7). Immunostaining showed that the reduced solubility of K18 caused by shearing the cells coincided with the appearance of thicker, often ‘wavy’ bundles of keratin IF (tonofibrils). This was verified at higher resolution by electron microscopy. Our results suggest that shear stress causes the soluble pool of K18 to become integrated into the endogenous IF network. We postulate that the enhanced filament ‘bundling’ induced by flow serves to reinforce the network and improve the ability of cells to resist mechanical forces. Supported by NHLBI.

1684 Cytokine-controlled Organization and Scaffolding Functions of Keratin Filaments: Implications for MAP Kinases-regulated Migration
S. Osmanagic-Myers, M. Gregor, G. Walko, G. Burgstaller, S. Reipert, G. Wiche; Molecular Cell Biology, University of Vienna, Vienna, Austria
Plectin is a major intermediate filament (IF)-based cytokine protein that stabilizes cells and tissues mechanically, regulates actin filament dynamics, and serves as a scaffolding platform for signaling molecules. Our recent studies with primary and immortalized mouse keratinocytes showed that plectin deficiency causes an aberrant organization of the keratin cytoskeleton. As revealed by electron microscopy, keratin IFs in plectin-deficient cells lack orthogonal cross-bridges, leading to lateral bundling and increased mesh-size of IF networks. Such keratin networks...
were found to be more susceptible to osmotic shock-induced fragmentation from peripheral areas, and their okadac acid-induced disruption (paralleled by stress-activated MAP kinase p38 activation) proceeded faster. Furthermore, we found basal activities of MAP kinase Erk(1/2) and of the membrane-associated upstream protein kinases c-Src and PKCδ to be significantly elevated, and migration rates to be increased. The latter was assessed by in vitro wound closure assays and time-lapse microscopy of single cells. Forced expression of RACK1, which is the plectin-binding receptor protein for activated PKCδ, in wild-type keratinocytes elevated their migration potential close to that of plectin-null cells. These data establish a link between cytoskeleton-controlled cytoscape/substrate scaffolding of keratin IFs and specific MAP kinase cascades mediating distinct cellular responses.

1685 Monitoring of Caspase Activation Using Novel Keratin Fragment-specific Antibodies
G. Tao,1 M. Teivola,1 Q. Zhou,1 P. Strnad,1 N. Sandersona,1 D. H. Li,1 A. Hong,2 M. B. Ormay1; 1Palo Alto VA Medical Center and Stanford University, Palo Alto, CA, 2AnSpec, Inc, San Jose, CA
Keratins 18 and 19 (K18/K19) are epithelial type I intermediate filament (IFs) that form an intracellular fibrillar network with their type II IF partner, K8. Previous studies demonstrated apoptosis-induced caspase cleavage at the highly conserved K18 or K19 Asp237, but this cleavage can only be assessed using biochemical means such as immunoblotting. During apoptosis, K18 is initially cleaved at Asp396 followed by digestion at Asp373. In order to more effectively study K18 and K19 proteolysis during apoptosis, we generated antibodies that selectively recognize the K18 and K19 Asp373-cleaved products by immunizing rabbits with K18 and K19 peptides that expose the Asp373. The generated antibodies recognized only cleaved but not intact K18 and K19 as determined by blotting or immunofluorescence staining of cultured human HT29 cells treated with anisomycin or of livers isolated from mice injected with Fas to induce hepatocyte apoptosis. The antibodies to the K18 and K19 peptides both recognized the common VEVD motif as determined by immunoblotting lysates of cells transfected with K8/K18 or K8/K19. Specificity of the antibodies to the K8/K19 caspase motif was further confirmed by their inability to recognize the caspase-targeted sequence VEMD in the stratified epithelial keratins, K14-K17, as determined by immunoblotting purified K14 that was pre-incubated with caspase-3. Versatility of the antibodies was also verified by their ability to selectively immunoprecipitate cleaved K18 or K19 after induction of apoptosis in cultured cells. Apoptosis-induced sequential cleave of K18 at Asp396 then Asp373 was confirmed by blotting lysates of HT29 cells that were treated with anisomycin for various times. Therefore, the newly generated anti-K18/K19 Asp373 directed antibodies provide an important adjunct for studying K18 and K19 apoptosis in various human and mouse epithelia using biochemical or biophysical or tissue imaging modalities.

1686 Interaction of the C-terminal Kinesin KIFC3 with Keratins in Polarized MDCK Epithelial Cells
A. R. Belkin, D. Cohen, A. Munch; Tyson Vision Research Institute, Cornell Medical College, New York, NY
Epithelial cell polarization results in distinct apical and basolateral cellular domains and is accompanied by microtubule reorganization from a radial, centrosome-focused array into a non-centrosomal array. This microtubule organization is thought to facilitate polarized vesicular transport, and microtubule disruption inhibits the maintenance of epithelial luminal domains in vivo. Keratin intermediate filament array is abundant around the centrosome and connect to both the subapical and lateral cell cortex. Keratins are therefore good candidates to play a role in microtubule organization. We studied the function KIFC3, a minus-end directed microtubule motor of the kinesin-14 family, in polarized MDCK cells. Expression of a dominant negative KIFC3 (DN-KIFC3) lacking the microtubule motor domain results in a failure of cells to polarize. Cells form junctions, but fail to deliver normal amounts of an apical marker gp135/podocalyxin to the apical cell surface, fail to compact and grow to a normal size, fail to reorganize microtubules into a polarized array, and fail to form a lumen in a collagen overlay assay, an assay that mimics the formation of lumen by polarized epithelia in vivo. KIFC3 localizes to the centrosome and to desmosomes of polarized MDCK cells. In addition, puncta of KIFC3 colocalize with keratin 19 (K19). Expression of GFP-KIFC3 brought a fraction of K19 from the Triton-insoluble fraction into the soluble fraction. HA-tagged KIFC3 or DN-KIFC3 expressed in a GFP-K19 cell line that incorporates the recombinant keratin into filaments, efficiently co-immunoprecipitated with GFP-K19. Microtubule regrowth after cold depolymerization showed that microtubules grew from the centrosome into desmosomes. However, microtubule regrowth in cells expressing DN-KIFC3 was characterized by fewer microtubules that grew in a disorganized fashion without a central aster. We speculate that KIFC3 could be important for keratin organization along keratin filaments. Defects in cell polarity due to DN-KIFC3 could stem from a role of KIFC3 in microtubule organization.

1687 Relationship between Keratins and AKT Anti-apoptotic and FAS Pro-apoptotic Signaling Pathways in Human Hepatocellular Carcinoma Cells HepG2
I. Laboubu, A. Fortier, V. Villemagne, É. Asselin, M. Cadrin; Cellular and Molecular Biophysics Group, Departments of Chemistry and Biology, University of Québec at Trois-Rivières, Trois-Rivières, PQ, Canada
Keratin 8 and 18 (K8/18) are the only intermediate filament (IF) proteins present in hepatocytes. One of their functions is to protect hepatocytes from mechanical and non-mechanical stresses. The molecular mechanisms underlying this function are not yet fully understood. Hepatocellular carcinoma cells HepG2, which contain only K8/18 were used as a model system to investigate keratin regulation following a treatment with griseofulvin (GF) [0,07 and 0,2 μg/ml in 0.1% DMSO] for 8, 24, 48 and 72h. Because the serine/threonine kinase Akt/PKB (pAkt) plays a pivotal role in hepatocytes cell survival and that Fas receptor (Fas-r) is an important inducer of the extrinsic apoptosis signaling pathway we investigated if a relationship exist between K8/18 and these molecules. We first analyzed by Western blotting the effects of GF treatments on K8/18 phosphorylation. K8 pS73 and pS341 and, K18 pS52 were significantly increased following treatment with GF. K18 pS52 was increased but to a lesser extent. Treatment of cells with P53 inhibitors (Wortmannin and LY294002) inhibited Akt phosphorylation and K8 phosphorylation on S73 suggesting that K8 is a substrate for pAKT. By double immunofluorescence staining we show that Fas-r and pAkt co-localize with IF network in some cells. GF treatment increases Fas-r and pAKT rearrangement and they both re-localize at the plasma membrane to form a membrane cap. Phosphorylated keratins are associated with these structures. These results suggest that keratins accomplish their protective roles by interacting with pAKT a central player in cell survival. Keratins also associate with Fas-r an important receptor involved in transmission of death signal. Changes in K8/18 phosphorylation could be involved in the translocation and release of the regulatory molecules pAKT or Fas-r to the membrane. Keratins could act as a key regulator in maintaining the delicate balance between pro and anti-apoptotic signal molecules in hepatocytes. (Supported by NSERC)

1688 CAPC Is Associated with Intermediate Filament Cytokeratin18 and Expression of CAPC Stimulates Malignant Phenotypes In Vitro
X. Liu, T. Beri, D. Ha, Y. Man, B. Lee, I. P nasti; NC1, NIH, Bethesda, MD
CAPC is a recently discovered gene; its RNA is expressed at a high level in many cancers, including breast cancer, prostate cancer, colon cancer and pancreatic cancer. In normal tissues CAPC RNA is highly expressed in normal prostate and salivary gland, very weakly expressed in colon, pancreas, intestine and not detectable in other tissues. Using a polyclonal antibody to CAPC we have found that CAPC protein co-localizes with intermediate filaments and cytokeratins in the breast cancer MCF 7 cell line. We now further characterized CAPC by western blot analysis and confocal microscopy studies. CAPC protein is elevated during mitosis in many cancer cell lines including the pancreatic cancer cell lines HTB-79 and HTB85; ovarian cancer cell lines OVCAR3 and HTB77; prostate cancer cell line LNCAP and PC3; colon cancer cell lines Lovo and SW403; breast cancer cell lines MDA-231, BT20 and MCF7, but not in normal human fibroblasts, WI-38, and normal breast cell line MCF-10A. CAPC is highly enriched in the cytoskeleton fraction and by confocal microscopy co-localizes specifically with keratin 18, but not keratin19. Using a Boyden chamber assay stable over-expression of CAPC in MDA-MB-231 cells leads to increased cell migration and invasion compared to the parental cell line. Taken together, CAPC is associated with keratin 18 and appears to be involved in regulating cancer cell motility and invasion.

1689 The Functional Significance of Vimentin IF Expression during the Epithelial to Mesenchymal Transition (EMT) in Human Embryonic Stem Cells (hESC) and in Mammary Duct Epithelial Cells
M. G. Méndez, R. D. Goldman; Cell and Molecular Biology, Northwestern University, Chicago, IL
Pluripotent hESC are cuboidal epithelial cells that express keratins (Type I and II IF). We have found that vimentin (Type III IF) and nestin (Type IV IF) are also expressed during the EMT which represents the earliest stage of hESC differentiation. Expression of vimentin, and in some cases nestin, also accompany the EMT in metastatic cells of epithelial origin. Morphometric analyses show that the expression of vimentin and nestin are closely correlated with the alterations in cell shape and migratory behavior that take place during the EMT at the periphery of hESC colonies. Pluripotent hESC grow in tightly-packed colonies of cuboidal epithelial cells. The cells at the edges of these colonies are induced to undergo the EMT by cessation of daily medium changes, during which nestin is expressed as non-filamentous particles. Subsequently, vimentin is subsequently expressed as particles, which are converted into short IF that also contain nestin. As these short IF link up into long vimentin/nestin IF, the hESC acquire the typical shape and motile behavior of mesenchymal cells. Likewise, only keratin IF are expressed in MCF-7 mammary gland ductal epithelial cells. Following the microinjection of vimentin protein, particles, short and eventually long IF are assembled as these cells assume a more
messenchymal shape. Following transfection with vimentin cDNA, vimentin-IF expressing MCF-7 cells are mesenchymal in shape and more motile, as demonstrated by their accumulation at colony edges and their migration away from colonies. We have initiated experiments to determine the function of vimentin and/or vimentin/nestin in the changes in cell shape and motility seen in the EMT. We hypothesize that vimentin expression in epithelial cell lines introduces a new type of cytoskeletal crosstalk between IF, microtubules and their associated motors, which underlies the EMT. Variant Isoforms of the Intermediate Filament, Synemin, Regulate Its Subcellular Location and the Function of Its AKAP Domain
J. P. Kerr,1 L. Lund,2 M. Russell,3 M. Bond,3 Department of Physiology, University of Maryland, Baltimore, Baltimore, MD, 4Department of Biological Sciences, Kent State University, Warren, OH

Synemin, an intermediate filament (IF) which is believed to crosslink Z-discs and myofilaments with the costamere and intracellular organelles, is able to bind the regulatory (RII) subunit of cAMP-dependent protein kinase A (PKA) through an amphipathic helical domain within its C-terminal tail, making synemin an A-kinase anchoring protein (AKAP). AKAPs regulate PKA distribution by binding RII to target PKA near substrates. Using plazqe display with a human heart library to identify novel RII-binding peptides, our lab identified synemin as a potential AKAP. In confirmation of these results, we further demonstrated that synemin binds RII via blot overlays and co-immunoprecipitates with RII from adult cardiomyocytes. In order to explore the functional relevance of synemin’s AKAP domain, we showed colocalization of synemin with RII at Z-lines and the perinuclear region using immunohistochemical studies with adult rat ventricular myocytes. Interestingly, in isolated rat neonatal CMs, synemin localized to the sarcolemma but did not colocalize with filamentous, cytoplasmic desmin. Furthermore, there are two known isoforms of synemin (α and β) that differ by a 932bp deletion in the C-terminal domain. Using antibodies specific to each isoform, we demonstrated that the two isoforms differ in the subcellular location and that α- and β-synemin preferentially distribute to cellular striations. A polyclonal antibody generated against α-synemin recognizes the 210KDa α isoform, and also recognizes a 100KDa band via western blots of cell lysates from cardiomyocytes, suggesting a new putative isoform. Using affinity-tagged synemin constructs with cultured cells, we are isolating the multimolecular protein complexes formed by each synemin isoform. We hypothesize that these isoforms will have variable subcellular locations and binding partners. We conclude that synemin isoforms have different functions and may act to target PKA near different substrates within the myocyte.

Interactions of Intermediate Filament Protein Synemin Isoforms with Vinculin in Mammalian Muscle Cells
N. Sun,1 Z. Li,2 D. Paulin,3 D. R. Critchley,1 R. M. Robson,1 Muscle Biology Group, Iowa State University, Ames, IA, 2Pierre et Marie Curie University, Paris, France, 3Biologie Moleculaire de la Differentiation, Universite Paris, Paris, France, 4Department of Biochemistry, University of Leicester, Leicester, United Kingdom

Synemin is a large, unique member of the intermediate filament (IF) protein superfamily. Synemin with desmin, the major IF protein in striated muscle cells, comprise the heteropolymeric IFs that encircle and link the Z-lines of all adjacent myofibrils, and the Z-lines of the peripheral layer of cellular myofibrils to the costameres located periodically along and subjacent to the sarcolemma. Synemin is expressed as only one form within avian muscle cells, but as at least two isoforms, α and β, within mammalian muscle cells. α-Synemin, considered the ortholog of avian muscle synemin, is larger than β-synemin, containing an extra 312 amino acid insert near the end of the long C-terminal tail. Previous studies from our lab showed that tissue-purified α-synemin interacts with α-actinin and vinculin. However, primary sequence identity between avian and mammalian synemins is less than 37%. In this study we examined interaction of mammalian α- and β-synemin isoforms with both vinculin and the slightly larger isoform, metavinculin. Solid-phase protein-protein binding assays (blot overlays) demonstrated that the specific region within mammalian α-synemin (312 amino acid insert) interacts directly with both vinculin and metavinculin in vitro. Co-immunoprecipitation studies, using antibodies to vinculin, precipitated both vinculin and synemin from cultured rat smooth muscle (A-10 cells) lysates. Immunofluorescence staining of A-10 cells showed co-localization of synemin and vinculin within focal adhesions. Transient expression of the enhanced green fluorescent protein (EGFP) recombinant 312 amino acid insert of α-synemin in A-10 cells indicated this insert was specifically incorporated within focal adhesions and actin stress fibers. These results suggest that α-synemin may serve a critical cross linking role enabling desmin/synemin-containing heteropolymeric IFs to link the Z-lines of all adjacent myofilbrils and the Z-lines of peripheral layer of cellular myofibrils to the costameres located periodically along and subjacent to the sarcolemma. A Model for the Mechanism of GFAP Mutation in Alexander Disease
R. Tian; Physiology, Columbia University, New York, NY

Most cases of Alexander Disease (AxD) are associated with mutations in glial fibrillary acidic protein (GFAP), an intermediate filament protein predominantly expressed in astrocytes. To determine the effects of GFAP mutations, we have developed an efficient and reproducible method to generate astrocytes stably expressing mutant GFAP (R239C GFAP) by retroviral gene expression and 8-bromo-cAMP (8C-cAMP) differentiation. RC2.E10 cells were derived from primary embryonic cells (E16) of the rat cortex and immortalized by stable retroviral infection with the temperature-sensitive mutant of the SV40 T antigen at 33 °C. Upon infection with retroviral construct expressing eGFP, wildtype GFAP-eGFP and mutant GFAP-eGFP respectively, green cells were selected by FACs and maintained at 33 °C. The stable clonal cells were then transferred to 37 °C to inactivate the SV40 T antigen activity and a cessation of proliferation. The astroglial differentiation was initiated by adding 8b-cAMP and continued by incubation at 37 °C for 4 days. Astrocytes derived in this manner are GFAP+, S-100β+, Vim+, GLT-1 and GLAST+, MBP+, Tuj1+, Pax6-, NeuN-, Oligo2-. Particularly, the heterogeneity in the GFAP expression mirrors a typical histopathological feature of astrocytes in brain tissues of Alexander patients. Thus, these transformed astrocytes appear to be an excellent experimental model for AxD.

1694

Aggregations of GFAP after Thermal Stress in C6 Glioma Cells
T. W. Tseng, K. Lu, W. Lee, C. Chien; Anatomy and Cell Biology, National Taiwan University, College of Medicine, Taipei, Taiwan

Some intermediate filament (IF) proteins expressed in the development of glia include nestin, vimentin, and glial fibrillary acidic protein (GFAP). However, GFAP is the major intermediate filament protein of mature astrocytes. To determine the organization of GFAP in glial cells, rat GFAP cDNA tagged with enhanced green fluorescent protein (EGFP) was transfected into the rat C6 glioma cell line. After selection, two stable C6-EGFP-GFAP cell lines were established. Stable C6-EGFP-GFAP cell lines with or without heat shock treatment were analyzed by immunocytochemistry, electron microscopy, and Western blot analysis. In the transient transfection study, EGFP-GFAP transiently expressed in C6 cells formed punctate aggregations in the cytoplasm right after transfection, but gradually a filamentous structure of EGFP-GFAP was observed. The protein level of nestin in the C6-EGFP-GFAP stable cells was similar to that in the pEGFP-C1 transfected C6 stable clones and non-transfected C6 cells, whereas the level of vimentin was reduced in Western blotting. Interestingly, the expression level of small heat shock protein 9B-crystallin in C6-EGFP-GFAP cells was also enhanced after EGFP transient expression. The aggregation of GFAP was dispersed as a fine filamentous structure. However, after heat shock treatment, GFAP formed IF bundles in C6-EGFP-GFAP cells. In the meantime, α-crystallin also colocalized with IF bundles of GFAP in C6-EGFP-GFAP cells. We have developed an efficient method to generate astrocytes stably expressing mutant GFAP (R239C GFAP) by retroviral gene expression and 8-bromo-cAMP (8C-cAMP) differentiation. RC2.E10 cells were derived from primary embryonic cells (E16) of the rat cortex and immortalized by stable retroviral infection with the temperature-sensitive mutant of the SV40 T antigen at 33 °C. Upon infection with retroviral construct expressing eGFP, wildtype GFAP-eGFP and mutant GFAP-eGFP respectively, green cells were selected by FACs and maintained at 33 °C. The stable clonal cells were then transferred to 37 °C to inactivate the SV40 T antigen activity and a cessation of proliferation. The astroglial differentiation was initiated by adding 8b-cAMP and continued by incubation at 37 °C for 4 days. Astrocytes derived in this manner are GFAP+, S-100β+, Vim+, GLT-1 and GLAST+, MBP+, Tuj1+, Pax6-, NeuN-, Oligo2-. Particularly, the heterogeneity in the GFAP expression mirrors a typical histopathological feature of astrocytes in brain tissues of Alexander patients. Thus, these transformed astrocytes appear to be an excellent experimental model for AxD.

Proper Perinuclear Localization of the BLOC-1-linked TRIM-like Protein Myosynr Requires Its Binding Partner Desmin
A. Kouloumenta, M. Mavroidis, Y. Capetanaki; Cell Biology, Foundation for Biomedical Research, Academy of Athens, Athens, Greece

Desmin, the muscle specific intermediate filament protein, surrounds the Z-discs, interconnects them to each other and links the entire contractile apparatus to the sarcolemmal cytosome, cytoplasmic organelles and the nucleus. In an attempt to explore the molecular mechanisms of these associations we have performed a yeast two-hybrid screening of a cardiac cDNA library. Here we show that the domains (NS5a +103a) of desmin molecule binds to a 413KDa protein, called myosynr, which is expressed in cardiac and skeletal muscle. Myosynr has been found to interact with dystrobin, which is a component of the soluble fraction of Biogenesis of Lysosomes Related Organelles Complex 1 (BLOC-1) which is involved in protein trafficking and organelle biogenesis. Binding of desmin with myosynr was confirmed in vitro, with GST pull down assay and co-immunoprecipitation of in vitro transcribed/ translated myosynr and desmin. Deletion analysis revealed that only the NS5a +103a fragment of desmin can bind to myosynr and this association takes place through the 24a long C-terminal end of the SPRY domain of myosynr. Using an antibody against the COOH terminus of myosynr we determined that myosynr co-localizes with desmin at the periphery of the nucleus of mouse neonatal cardiomyocytes in addition to adult heart muscle, the two proteins co-localize, predominantly, in intercalated discs and costameres. Desmin seems to be essential for the appropriate perinuclear localization of myosynr since its pattern is altered in cardiomyocytes from desmin null neonatal mice. The association of myosynr with intermediate filaments, suggests a potential role of desmin in vesicle trafficking.
Nestin Mediates the Interaction between Intermediate Filaments and Insulin Degrading Enzyme

Y. Chou, W. Kuo, M. Rosner, R. Goldman; Cell and Molecular Biology, Northwestern University, Chicago, IL, Ben May Institute for Cancer Research, University of Chicago, Chicago, IL

Nestin, a type IV intermediate filament (IF) protein, is transiently expressed in proliferating progenitor stem cells. Nestin is a large IF protein with an extremely long C-terminal domain (over 1200 amino acids) of no known function. To begin to investigate the function of nestin, we expressed a peptide fragment (nestin 657-853) derived from the conserved 11 amino acid repeat region of the nestin tail and used it for affinity chromatography to identify potential binding partners from soluble frog egg extracts. To date, a 110 KD protein has been found to be specifically absorbed by this nestin fragment. Mass spectrometric and immunoblotting analyses identify this protein as the insulin degrading enzyme (IDE). When assayed with a fluorogenic peptide substrate, the highly purified egg IDE has an active enzymatic activity comparable to that of the recombinant human IDE expressed in and purified from insect cells. Neither egg nor recombinant human IDE possesses any detectable proteolytic activity toward vimentin, nestin or other protein components present in purified native IF preparations. Interestingly, the activity of both egg and human IDE is enhanced about 100% by nestin 657-853 or a longer nestin fragment 1-1177. By immunofluorescence, IDE does not appear to be associated with vimentin IF networks in interphase HeLa cells. However, a partial colocalization of IDE with disassembled vimentin IF (i.e., vimentin particles) is observed in dividing HeLa cells. We have reported previously that formation of vimentin particles in mitotic cells is a feature associated with progenitor cells expressing nestin. Taken together, our results suggest that IDE, an enzyme involved in regulating the turnover of many small peptide hormones, can be modulated spatially and temporally by its association with the IF protein nestin in progenitor cells. Autophagy Helps Clear Intracellular Mallory Body Inclusions in Mouse Liver

M. Harada, D. Toiviola, P. Strnad, M. B. Omary; Medicine, VA Palo Alto Health Care System and Stanford University, Palo Alto, CA, Medicine, Kurume University School of Medicine, Kurume, Japan

Intracellular inclusions in liver and neurodegenerative diseases consist of mixed proteins that may ultimately lead to cell death. Hepatocyte inclusions, termed Mallory bodies (MB), consist primarily of keratins 8 and 18 (K8/K18). A K8:K18 ratio is essential for MB formation, but the significance and turnover of MBs are poorly understood. Autophagy, which degrades cytosolic proteins and organelles, is a potential mechanism for eliminating neuronal inclusions, though its relationship to MB clearance is unknown. We hypothesized that autophagy plays an important role in clearing hepatocyte inclusions in vivo. Mouse MBs were induced by feeding a 3,5-diethoxycarbonyl-1,4-dihydrocollidine (DDC)-containing diet for 3 months. K8-overexpressing transgenic mice, which develop inclusions spontaneously and have increased susceptibility for MB formation, were also treated with a proteasome inhibitor. Autophagic activity was determined by immunoblotting for light chain (LC3), and inclusions were identified by electron microscopy and immunofluorescence co-staining of K8/18 and ubiquitin. DDC-treated mouse livers develop numerous inclusions, in association with conversion of LC3-I to II which indicates activation of autophagy. Untreated K8-overexpressing mice had few inclusions that increased upon treatment with the proteasome inhibitor, and this increase was inhibited by induction of autophagy with rapamycin. Rapamycin also reduced the formation of spontaneous inclusions in K8-overexpressing mice. In contrast, transgenic mice treated with a proteasome inhibitor do not develop inclusions. Ultrastructural analysis showed that the inclusions consist of filamentous and electron-dense material that was also noted in the autophagic vacuoles and lysosomes of both mouse models. In conclusion, autophagy can play a significant role in eliminating hepatocyte inclusions. Manipulation of autophagy may be a useful strategy for various inclusion body associated diseases.

The SMRT Way to Resist Death

K. K. Tsai, C. Chatterjee, J. N. Lakins, V. M. Weaver; Department of Pathology, University of Pennsylvania, Philadelphia, PA

Apoptosis resistance plays a key role in malignant transformation, tumor metastasis and treatment response. While much is known about the pathways that regulate survival in non-differentiated cells, we know less about how apoptosis is regulated in three-dimensional (3D) multi-cellular tissues or tumors in vivo. Analogous to differentiated tissues in vivo, 3D reconstituted basement membrane-differentiated mammary acini are highly resistant to an array of exogenous apoptotic insults including gamma radiation, chemotherapy agents and immune receptor stimuli. Here we report that tissue morphogenesis and apoptosis resistance are associated with global repression of multiple stress-response genes, and that the enhanced survival phenotype of differentiated tissues is functionally-linked to active repression of stress response genes by the nuclear receptor corepressor SMRT (silencing mediator of retinoic acid and thyroid hormone receptor). We found that mammary epithelial cell (MEC) morphogenesis correlates with an up-regulation of SMRT that is associated with apoptosis resistance because stable knockdown of SMRT rendered 3D differentiated mammary tissues sensitive to exogenous death stimuli. Likewise we observed that phenotypic reversion of mammary tumor tissue was associated with a significant increase in SMRT expression and acquisition of apoptosis resistance. Consistently, ectopic expression of SMRT permitted acquisition of apoptosis resistance in 3D tumor tissues and isolated tumor cells. The SMRT-mediated death resistance was found to be functionally-linked to chromatin remodelling-mediated gene silencing through activation of the histone deacetylase (HDAC). HDAC3, because either treatment with trichostatin A or stable knockdown of HDAC3 could restore the death sensitivity of apoptotically-resistant SMRT-expressing MECs. Moreover, stable expression of a mutant SMRT (K449A) that neither recruits HDAC3 into nuclei nor permits its activation rendered MECs hypersensitive to exogenous death induction. The relevance of SMRT/HDAC3-dependent epigenetic regulation of apoptosis resistance to treatment resistant, recurrent cancers is now being actively explored. (Supported by DOD BCRP W81XWH-05-1-330 and NIH CA078731 to VMW)

The Breast Tumor Modulator HoxA9 Regulates BRCA1 and Integrin-mediated Adhesion

P. M. Gilbert, J. K. Mow, M. K. Gbegnon, J. N. Lakins, V. M. Weaver; Institute for Medicine and Engineering/Pathology and Lab Medicine, University of Pennsylvania, Philadelphia, PA

Stromal-epithelial interactions drive development and maintain tissue homeostasis through a network of soluble and insoluble factors that operate within a three-dimensional (3D) tissue. Genetic and epigenetic changes in mammary epithelial cells (MECs) cooperate with a modified tissue microenvironment to drive malignant transformation of the breast. We have been studying how altered expression of developmental regulators contributes to breast tumorigenesis and have specifically focused on investigating their influence on integrin expression and/or activity. Homeobox genes play a critical role in tissue development, are frequently lost in tumors, and can regulate integrin and ECM expression. We showed that HoxA9 is lost in invasive human breast tumors and that re-expressing HoxA9 in breast cancer cells decreases migration, invasion, and anchorage independent growth in culture. Additionally, HoxA9 re-expression reduces proliferation and drives phenotypic reversal of breast tumor cells grown within a 3D reconstituted basement membrane (rBM), but not on tissue culture plastic. HoxA9 represses the malignant phenotype of breast cancer cells in vivo as well as in 3D rBM and this reversion is coincident with BRCA1 induction and normalization of adhesion and integrin expression. Ablating BRCA1 function through expression of the delta exon-11b BRCA1 mutant or a BRCA1 R1105H disrupts rBM morphogenesis in normal MECs and inhibits reversion of HoxA9 re-expressing breast cancer cells. Accordingly, we are exploring functional and mechanistic links between HoxA9, BRCA1 and integrin dependent tissue behavior. In addition, we are studying the effects of altered HoxA9 expression on the biophysical properties of the stroma and how in turn, changes in the mechanical properties of the extracellular matrix during normal development and mammary tumorigenesis can influence HoxA9 expression. (Support: D1SS042047, DOD/RO1WXH-05-1-330, NCI CA078731 and DAMD17-01-1-0368)

IGSF9 Is Upregulated in Primary Colon Tumors and Mediates Tumor Cell Adhesion

R. Chalam, N. W. O'Brien, B. L. Colton, S. Ho, X. Cao, F. Huang, B. Shestowsky, J. M. Daniels, K. R. McLachlan; Biogen Idec, San Diego, CA, Path Inc., San Diego, CA

IGSF9 is a cell surface protein belonging to the Ig-cell adhesion molecule (Ig-CAM) family. It is expressed in the developing nervous system and thought to play a role in synapse formation in the rat. Other members of this family mediate adhesion interactions and are frequently dysregulated in cancer. IGSF9 was identified as a pan-tumor antigen through microarray data analysis and the protein is upregulated in various cancers including ovary, breast, colon, and lung. Overexpression of IGSF9 in a colon tumor cell line resulted in altered migration and adhesive properties of the cells. Some of these phenotypic changes were integrin mediated. Taken together, this data suggests that IGSF9 may play a complex role in tumor biology.

**PEG-based Synthetic Extracellular Matrices with Tunable Mechanical Properties That Regulate Smooth Muscle Cell Behavior**

S. R. Peyton, C. C. Rauh, V. P. Keskinur, A. J. Putnam, C. Chemical Engineering and Materials Science, University of California, Irvine, Irvine, CA, D. Biomedical Engineering, University of California, Irvine, Irvine, CA,

The mechanical properties of blood vessels are dramatically altered in a variety of cardiovascular pathologies due to extensive remodeling of the extracellular matrix (ECM). We hypothesize these mechanical changes may provide instructive cues to vascular smooth muscle cells (SMCs) in the medial layers of the vessel wall. To address this hypothesis we have adapted polyethylene glycol) (PEG)-based hydrogel model systems, in part, to the ease with which their mechanical and cell adhesive properties can be independently controlled. In 2-D, SMC attachment and spreading occurred on RGD and full-length matrix protein-modified PEG surfaces, but not on unmodified control surfaces or scrambled peptide sequences (RGD) after 24 hours of incubation. However, the extent of cell spreading was not significantly influenced by ECM mechanics across a wide range of elastic moduli (13.7 kPa - 423.9 kPa), nor by ligand density or identity (RGD, KQACD, fibronectin, or collagen-I). In contrast, quantitative analysis revealed that focal adhesion size and elongation were in fact dependant on substrate stiffness and ligand density. Moreover, the histological maturation of isolated SMCs was associated with increased proliferation and increased substrate stiffness, with increased proliferation and increased substrate stiffness. It is well known that unloading of skeletal muscle with spaceflight or tail suspension leads rat soleus muscle atrophy. However, it is unclear how muscle atrophy is caused and how muscles respond to microgravity. We addressed the response of collagen and its chaperone system to gravitational forces. We show here that expression of HSP47, a collagen-specific molecular chaperone, responds to gravitational changes, including microgravity and hypergravity, in vitro and in vivo. By using a method of hindlimb suspension of rats which mimics microgravity conditions, we demonstrated that the expression of Hsp47 mRNA decreased within one day and the mRNA levels of collagen types I and IV were subsequently reduced. In contrast, hypergravity stimulated HSP47 expression. Intriguingly, HSP47 mRNA levels in cultured myoblasts increased significantly with hypergravity treatment at 40G for 2 h, and decreased with microgravity treatment at almost 0G for 1-2 h. Collagen mRNA levels were also altered, although changes were slower and less pronounced compared with those for HSP47. Next, we examined the effect of MG on the mRNAs of TGFβ-1, which is known to induce Hsp47 expression, in cultured myoblasts by semi-quantitative RT-PCR. At 1h of MG treatment, the expression of TGFβ mRNA in myoblasts was significantly decreased. From these results, the gravity-regulated HSP47 may play a role in the maintenance of the extracellular matrix by modulating collagen production at the primary stage of adaptation.

**Extracellular Matrix Composition and Modulation Differs in Dystrophic and Control Primary Human Myotubes**

S. Zanotti, S. Saredi, A. Ruggieri, S. Romaggi, L. Morandi, M. Mora; Neuromuscular Diseases and Neuroimmunology, National Neurological Institute C. Besta, Milano, Italy.

In muscular dystrophies disease severity is generally related to the extent of muscle fibrosis. To determine whether extracellular matrix (ECM) components contribute to the severe fibrosis seen in Duchenne muscular dystrophy (DMD), we quantified RNA transcript levels of several ECM constituents by competitive PCR in primary myotubes from 7 DMD patients and 5 controls. We found a significant increase of basal MMP-2, TIMP-1 and TIMP-2 transcript levels, while no significant variation were observed for MMP-9 and TIMP-3. By zymographic analysis MMP-2 activity was significantly increased in DMD myotubes while there was no variation in MMP-9 activity. Transcript levels of fibronectin, vitronectin and vimentin were similar in pathological and control cells, while collagen I and VI transcripts were variably increased. Cell transfection with a decorin antisense oligonucleotide, determined the following mRNA level changes: TGFβ-beta increase in control and DMD fibroblasts, vimentin increase in control and no change in DMD fibroblasts, TIMP-2 increase in control and decrease in DMD myotubes. Our results suggest that the expression of several ECM components is different in the two cell populations, that the activity of some of them is also altered, and that there is a different response to decorin inhibition in DMD versus control muscle cells. This disregulation may contribute to the development of excessive fibrosis observed in DMD muscle.

**Protein Conformational Changes Occur during Cardiomyocyte Contraction on Rigid, but Not Flexible Matrices**

Cardiomyocytes lose function within hours to days when plated on traditional collagen-coated rigid substrates or when observed in disease models where fibrotic scarring impairs cardiac output. Recent work has shown prolonged palstic contralactility when cells are cultured in matrigel, but the mechanism behind this, however, is still poorly understood. Using polyacrylamide matrices, we demonstrate that compliant microenvironments, which mimic the developing myocardial microenvironment, e.g. cells on flexible matrices with an elasticity of 10kPa, promote a contractile phenotype with beating at 1Hz, optimal spread area and shape, and preserved actomyosin striations. Matrices with elasticity similar to stiffer external layers of perimyocardial fibroblasts are less desirable, while cells on more rigid matrices, even when clustered together, cannot preserve contractions and normal beat frequency for extended periods of time. Analysis of matrix deformation on more rigid matrices points to a potential mechanism: mismatched intracellular contractions and subsequent displacement fields observed at the cell-matrix interface suggest a putative mechanochemical transformation, or one resulting from an increased mechanical mismatch between myocytes and extracellular matrix (ECM).

β1 integrin (V737N) expression in pre-malignant MCF10DCIS-MECs promotes their malignant transformation in 3D bM culture and in vivo. Results showed that xenografts of pre-neoplastic MCF10DCIS-MECs with increased numbers of mature focal adhesions formed larger palpable tumor masses of significantly increased mass as compared to their DCTS controls. Histologically forced focal adhesion maturation promoted malignant transformation evidenced by tumor invasion, increased angiogenesis and enhanced tumor cell survival. Studies are currently underway to explore effects on tumor metastasis and to delineate molecular mechanisms for these effects. (Supp: NIH T32HL00795404 to KRJ; DOD W81XWH-05-1-330 and NIH CA078731 to VMW).

Affect of Substrate Rigidity on Force Generation and Sarcomeric Organization in Neonatal Rat Cardiac Myocytes

J. G. Jacot, S. G. Campbell, E. J. Howard, A. D. McCulloch, J. H. Omens; Bioengineering, University of California, San Diego, La Jolla, CA

Many cell types respond to the rigidity of their environment by altering their proliferation, migration, or differentiation. We hypothesize that substrate rigidity affects sarcomeric organization and force generation in neonatal rat cardiac myocytes (NRMCs), whose morphology and myofilibril architecture are less differentiated than that of adult cardiac myocytes. We plated primary NRMCs at 10,000 cells/cm² on polyacrylamide gels containing varying amounts of crosslinker to produce a shear modulus ranging from 400 Pa (soft) to 20 kPa (stiff), and coated with type I collagen. We measured the deformation of the gel during cell contractions by tracking fluorescent beads embedded in the gel, and transformed these deformations into a map of traction forces using custom software. Cells on soft gels formed sarcomeres apparent under phase-contrast microscopy at 48 hours after harvesting and about 20% of these cells beat spontaneously, while cells on stiff gels displayed no organized structure and did not beat spontaneously. By 7 days, sarcomeres were visible on both gel rigidities and both cell types beat spontaneously. NRMCs on stiff gels had an average sarcomere length around 2.1 microns while NRMCs on soft gels had an average sarcomere length of 1.7 microns. Cells on stiffer substrates generated 6 times as much force as cells on soft substrates. A numerical model incorporating sarcomere length-dependent myofilament interactions and single-cell mechanics predicts a similar 6-fold change in force generation based solely on the resistance to cell shortening. We thus conclude that, although NRMCs on soft substrates develop a distinct sarcomeric structure more quickly than those on stiff substrates, cells on either substrate generate a total force after 7 days in culture that is predictable based on the sarcomere length and resistance to shortening.

Matrix Elasticity Directs Stem Cell Differentiation through Non-muscle Myosin II

A. Engler, H. Lee Sweeney, S. Sen, D. Discher; University of Pennsylvania, Philadelphia, PA

Stem cells are known to differentiate into multiple soft tissue cell types, but the role of the physical microenvironment has not been assessed. We show that the distinct softness of various tissues strongly influence stem cell differentiation through the contractile activity of myosin (Engler et al, Cell 2006). Tissue elasticities are mimicked with a range of collagenated gels, and we show that Mesenchymal Stem Cells express non-muscle myosin isoforms that allow the cells to contract and respond distintively to matrix stiffness. Non-lineage-specific growth factors are needed - just physical cues from the microenvironment. Elasticity-specific up-regulation of key tissue markers (eg. MyoD for myogenesis, CBFα1 for osteogenesis) is similar in magnitude to expression induced by soluble factors typically added to induce differentiation. The results highlight the importance of the physical character of the microenvironment and have significant implications for developmental processes as well as stem cell repair and regeneration of soft tissues.

Jnk Activity Is Required to Suppress Erk-Dependent Cell Proliferation, Cell Survival, and Emt-like Changes during 3D-Mammary Epithelial Acini Formation

E. T. R. McArdle; UCD School of Biomolecular and Biomedical Research, Conway Institute, Dublin, Ireland

Hypothesis that one possible mechanism by which ECM compliance exerts its influence on osteogenesis is by modulating the mitogen activated protein kinase (MAPK) pathway. To address this hypothesis, MC3T3-E1 cells were cultured on dextran hydrogels evaluated on the basis of morphology and expression of SMC-specific markers, such as smooth muscle actin, myosin, caldesmon and calponin. The two latter proteins have been previously reported to be downregulated in traditional tissue culture systems, suggestive of phenotypic loss by SMCs under such conditions. Recovery and maintenance of the phenotype of cells ex vivo in tissue culture systems are essential for future applications in cell-based therapies.

The Regulation of Osteogenesis by Ecm Rigidity in MCT3-E1 Cells Requires Mapk Activation

C. B. Khatiwala, S. R. Peyton, J. J. Putnam; 1Chemical Engineering and Material Science, University of California, Irvine, Irvine, CA, 2Biomedical Engineering, University of California, Irvine, Irvine, CA

Recent efforts to develop synthetic biomaterials as extracellular matrix (ECM) analogs capable of controlling cell fate have begun to exploit the idea that mechanical cues in the microenvironment influence tissue development. In prior studies, we demonstrated that tuning ECM mechanics can directly regulate the behavior of pre-osteoblastic MC3T3-E1 cells. We hypothesized that one possible mechanism by which ECM compliance exerts its influence on osteogenesis is by modulating the mitogen activated protein kinase (MAPK) pathway. To address this hypothesis, MC3T3-E1 cells were cultured on poly(ethylene glycol) (PEG)-based model substrates with tunable mechanical properties, and their differentiation assessed over a period of 14 days. Alkaline phosphatase (ALP) levels at days 7 and 14 were found to be significantly higher in cells grown on stiffer substrates (423.9 kPa hydrogels and rigid tissue culture polystyrene (TCP) control) than on a soft hydrogel (13.7 kPa). Furthermore, osteocalcin (OCN) and bone sialoprotein (BSP) gene expression levels followed a similar trend. These differences correlated with significantly elevated MAPK activity in cells cultured on stiffer substrates at both time points. Inhibiting this activation pharmacologically, using PD98059, resulted in significantly lower ALP levels, OCN, and BSP gene expression levels on the hydrogels. Interestingly, the effectiveness of PD98059 was itself dependent on substrate stiffness, with marked inhibition of MAPK phosphorylation in response to stiff hydrogels, but less robust reduction on TCPs. Combined, these data confirm MAPKs involvement in the regulation of osteogenic differentiation by ECM compliance. Furthermore, the activation of Caspase-3 and Bcl-2 gene expression were not significantly affected by ECM compliance, indicating that MAPK pathway is not involved in the regulation of apoptosis in these cells.

Regulation of Jnk Activity by Matrix Stiffness Mediates Apoptosis Induction in a Mammary Epithelium

N. Zahir, J. L. Leigh, J. L. Lakins, B. Alston-Mills, K. K. Tsai, V. M. Weaver; 1Pathology, University of Pennsylvania, Philadelphia, PA, 2Department of Animal Science, North Carolina State University, Raleigh, NC

We show that Mesenchymal Stem Cells express non-muscle myosin isoforms that allow the cells to contract and respond distintively to matrix stiffness. Non-lineage-specific growth factors are needed - just physical cues from the microenvironment. Elasticity-specific up-regulation of key tissue markers (eg. MyoD for myogenesis, CBFα1 for osteogenesis) is similar in magnitude to expression induced by soluble factors typically added to induce differentiation. The results highlight the importance of the physical character of the microenvironment and have significant implications for developmental processes as well as stem cell repair and regeneration of soft tissues.
The composition and spatial organization (3D) of the extracellular matrix (ECM) influence apoptosis responsiveness of mammary epithelial cells (MECs) to cancer therapeutics (Weaver et al., Cancer Cell, 2002). Because the 3D organization of the ECM determines its mechanical properties, the question of whether and how matrix stiffness could modify therapeutic efficacy in a mammary epithelium was investigated. Distinct microenvironments were established by utilising basement membrane (BM) crosslinked polyacrylamide gels of calibrated stiffness (elastic modulus, E). Similar to normal mammary acini residing within a soft tissue in vivo (E = 170 Pascals), MECs grown on soft 3D BM-gels (E = 140 Pascals) formed polarized acini and exhibited resistance to Taxol, TRAIL and gamma radiation. In contrast, MECs grown on a 3D BM-gel with a similar stiffness to mammary tumors (E = 5000 Pascals) formed disorganized structures and displayed a marked sensitivity to exogenous apoptotic cues, despite growth rates similar to MEC matrix. Matrix stiffness resulted in an increase in the magnitude and duration of JNK activation. Moreover, JNK activity was necessary for cancer therapy-dependent apoptosis induction in 3D MEC tissues. Whether JNK activity is sufficient for apoptosis induction in 3D MEC tissues is now under investigation. These data illustrate how the mechanical properties of the tissue microenvironment could alter the efficacy of anti-cancer treatments through by modulating adhesion-dependent growth and survival signaling. RPTPa Is Required for Fibronectin-specific Rigidity Response at the Leading Edge of the Growth Cones in Hippocampal Neurons

A. Kostic, J. Jap,’ M. P. Sheetz;’ Department of Biological Sciences, Columbia University, New York, NY, ’Institute for Molecular Pathology, University of Copenhagen, Copenhagen, Denmark

Although the importance of mechanosensing has been long recognized, the molecular details of cellular response to the physical properties of the environment remain elusive. Based on work by our lab and others, receptor protein tyrosine phosphatase α (RPTPα) appears to be an essential component of force-dependent integrin signaling and rigidity response. Our previous studies in fibroblasts have shown that RPTPα-deficient mice has revealed no overt abnormalities apart from striking morphological and functional defects in the hippocampus. Further, RPTPα was implicated in neurite extension regulation, neuronal development, learning, memory, and anxious behavior. Here, we report that RPTPα is required for fibronectin rigidity response in hippocampal neurons. While the axon extension is inhibited on rigid fibronectin matrices in the presence of RPTPα, the neurons isolated from RPTPα knockout hippocampi fail to discriminate between the substrates of various rigidities. Moreover, axon differentiation seems to be dependent on both RPTPα-related activities and soft matrices. We speculate that RPTPα is required for the reinforcement of cytoskeleton-integron bonds, which is critical in the processes of neurite extension and differentiation. By using optical trap, we were able to confirm that RPTPα-/- neurons exhibit impaired reinforcement of FN-coated beads. Additionally, RPTPα dependence of rigidity response in neurons appears to be fibronectin-specific, and requires α5β1 integrin recruitment to the leading edge of the growth cones. Furthermore, the recruitment of downstream targets of RPTPα, in particular Src family kinases, and their substrate, p130Cas to the leading edge is also rigidity-dependent.

Dynamic Changes in Epithelial Organization and Interjunctional Cells during Mammary Epithelial Invasion and Morphogenesis

A. J. Ewald, M. Duong, Z. Werb; Anatomy, University of California, San Francisco, San Francisco, CA

Collective cell movements are required to build and remodel many vertebrate epithelial organs, yet relative little is known about how cells move and rearrange while remaining part of an epithelial sheet. We have focused on the cell behaviors extending under formation and bifurcation of mammary ductal epithelial tubes. We have taken a combined imaging, cell biological, and pharmacological approach to determine the cell behaviors and adhesive interactions underlying these movements. We cultured primary murine mammary epithelium in Matrigel. These explanted tissues begin as a partially polarized epithelium, with myoepithelial cells basal to luminal epithelial cells. Initially, they have multiple cell layers and solid cores. The cells then rearrange to constitute a bilayer of myoepithelial cells, then luminal epithelial cells surrounding a fluid filled lumen. Following lumen formation there is a growth factor- and matrix metalloproteinase-dependent change in luminal epithelial organization at discrete sites. This reorganization is characterized molecularly by a high level of F-actin, multiple luminal cell layers, and small pockets of ZO-1. Using long-term (100+ h), 3D confocal imaging we observed that new ducts extend from these sites through vigorous cellular rearrangements within a multilayered invasion front. These rearranging cells have E-cadherin at all luminal-luminal cell boundaries and ZO-1 at their apical surfaces. Polymerized actin is concentrated at the apical and lateral surfaces; the cell-matrix border (basal surface) is low in polymerized actin. Several cell diameters behind the front full epithelial polarity is re-established, with tight and adherens junctions, and a fluid filled lumen. Treatment with inhibitors for Rac1 and ROCK1 changes the final tissue architecture, cell behaviors and junctional status of these organ cultures and analysis of these differences has given us insights into the cellular and molecular mechanisms underlying this novel collective cell behavior. Supported by NCI CA057621 and by a CBCRP fellowship (11FB-0015).

Force-dependent Mammary Morphogenesis and Malignancy in a Tunable 3D Model System

Epithelial morphogenesis proceeds within a 3D tissue in which soluble, cellular and physical cues cooperate to direct tissue form and function. Although we understand much about the role of soluble factors and cell interactions in homeosis and tumorigenesis, we know little about the role of spatial organization and mechanical force in these processes. Key to understanding tissue behavior is the availability of tractable model systems in which biochemical, spatial and mechanical variables can be independently manipulated. Here we report the development, analysis and morphogenetic assessment of 2D and 3D gels for the study of mammary epithelial cell (MEC) behavior including: collagen I/reconstituted basement membrane (COL/rBM-gel), rBM polyacrylamide (rBM-PA-gels), self-assembling peptide/rBM (SAP/rBM-gel), and peptide-conjugated polyethyleneglycol (PEG-conj-gels). MEC morphogenesis can be recapitulated using rBM-gels, COL/rBM-gels, and rBM-PA-gels with elastic moduli similar to that of normal mammary gland. However, 3D models employing natural biomaterials (rBM-gels, COL/rBM-gels) are biomechanically and chemically non-uniform; thus, in these undefined systems it is difficult to derive definitive conclusions relating force, ligand density and epithelial behavior. Additionally, while synthetic biomaterials, e.g., rBM-PA-gels, permit precise control of matrix stiffness and ligand density, PA gels are incompatible 3D and in vivo. SAP/rBM-gels offer a versatile 3D matrix with calibrated stiffness and ligand presentation. Unfortunately SAP gels are not easily adapted for studies directed at 3D epithelial morphogenesis and migration/invasion because matrix stiffness depends upon increasing matrix density and the peptide backbone is not easily remodeled by embedded cells. Although PEG gels that can be mechanically and biochemically modified offer an attractive alternative, traditional chemistry has been optimized for relatively stiff materials, e.g., cartilage and muscle. Accordingly, we are investigating soft PEG-conj-gels with adhesive laminin-derived ligands and collagenase-digestible linkers by testing their suitability as a tractable biomaterial for reconstituted multi-cellular epithelial morphogenesis studies. Here we will summarize our strategy and biological characterization.

A Novel Human Biomatrix Model for Real-time Analysis of Angiogenesis

R. Singh, M. Belousova, E. Seales, D. Hamrick, M. Klinger; Vivo Biosciences Inc, Birmingham, AL

Current in vitro models of angiogenesis mostly employ animal-derived purified or reconstituted biomatrix substrates and therefore do not reliably predict the complex human tissue biology. For example, common Matrigel system contains many mitogenic and angiogenic agents (EGF, FGF). To overcome this limitation, we developed an improved angiogenesis bioassay incorporating a new human-derived biomatrix, named HuBiogel. Unlike Matrigel, it contains all major matrix components but is GF-free. Human umbilical vein endothelial cells (HUVEC) were seeded onto collagen I, HuBiogel or Matrigel, and both early (proliferation) and late-stage (sprouting & tube formation) angiogenesis events were quantitated by real-time morphologic analysis. EC on collagen I grew poorly (<60% viability). EC on HuBiogel grew and proliferated normally (~15% sprouting without differentiation), and maintained high viability out to 15 days. In contrast, Matrigel induced rapid, uncontrolled tube formation within 8 hrs. A focused microarray analysis showed higher expression of angiogenic markers in EC on Matrigel versus HuBiogel, e.g.; notch-4, ephrin-A1 and angiopoietins. To demonstrate the biological utility, we plated EC on HuBiogel enriched with purified bFGF (10-50 ng/ml). A time and dose dependent angiogenesis activity was observed. For mimic tumor angiogenesis, EC were co-cultured on HuBiogel with human glioma cells which secrete soluble VEGF. A positive correlation was found between secreted levels of VEGF and angiogenic activity in HuBiogel assays. Matrigel failed to distinguish these functional parameters. We therefore conclude that HuBiogel-based assay system allows precise evaluation of cellular & molecular signaling pathways and their biological endpoints. This defined or controllable bioassay will positively impact neovascularization and cancer research areas. (Supported by HL62736 & CA108118)
Pulmonary vasculogenesis, angiogenesis and normal alveolar development rely upon the paired-related homeobox gene transcription factor, Prx1, which is expressed in the embryonic lung mesenchyme. Mechanistically, Prx1 controls expression of tenasin-C (TN-C), an extracellular matrix glycoprotein required for normal vascular development and lung branching morphogenesis. To further understand how Prx1 controls lung development, we focused on tropoelastin and fibrillins (1 & 2): microarray and immunohistochemical studies involving tissue derived from wild type and Prx1-null fetal mouse lungs demonstrated that expression of these extracellular matrix genes relies upon Prx1. Also, since fibrillins regulate TGF-β activity, we compared expression of phosphorylated Smad-2 (P-Smad-2; a downstream effector of TGF-β signaling), as well as the levels of α-smooth muscle actin and TN-C (targets of TGF-β) in wild type and Prx1-null lungs. These studies revealed major deficits in TGF-β signaling (both in the embryonic lung epithelium and mesenchyme), as well as differences in TN-C expression and recruitment of α-actin-positive cells to the pulmonary vasculature. Currently, we are using an organotypic culture system involving de-cellularized fetal lung scaffolds derived from wild type and null mice to evaluate how Prx1 controls the expression of TN-C, tropoelastin and fibrillins, and how these extracellular matrix proteins control vascular and epithelial cell behavior in the developing lung.

During myogenesis in vitro, myoblasts undergo cell cycle arrest, migrate, and fuse with one another to form multinucleated myotubes. Extracellular matrix (ECM) molecules play critical roles during these processes. Matrix metalloproteinases (MMPs) are neutral endopeptidases capable of degrading ECM components. Although the role of MMPs in myogenesis has been investigated, almost nothing is known about the role of their inhibitors, the tissue inhibitor of metalloproteinases (TIMPs). Here, we report that TIMP-2, MMP-2, and MT1-MMP are differentially expressed during mouse myoblast differentiation in vitro. Furthermore, we show that TIMP-2/- myotube size is altered: when differentiated in horse serum-containing medium, TIMP-2/- myotubes are larger than control myotubes. In contrast, when serum-free medium is used, TIMP-2/- myotubes are much smaller than controls. Regardless of culture condition, myotube size is directly correlated with MMP activity and inversely correlated with beta integrin expression. The reduced TIMP-2/- myotube size can be rescued by co-culturing with wild-type myoblasts in close apposition, without direct contact, suggesting that soluble factor(s) are responsible. Furthermore, reduced myotube size can be rescued by treatment with either recombinant MMP-2 or TIMP-2. Elucidating the role of TIMP-2 in myogenesis in vitro may lead to new therapeutic options for myogenic defects in vivo.

Tenascin-C (TNC) is an extracellular matrix glycoprotein not detected in normal adult myocardium but expressed under various pathological conditions. To elucidate the role of TNC in myocardial fibrosis in hypertensive heart, we treated mice. Balb/c wild type (WT) mice and TNC knockout (TNKO) mice were treated with 560 ng/kg body weight/min AgII subcutaneously by osmotic minipump for 4 weeks. In both wild type and TNKO mice, AgII treatment increased blood pressure, heart weight/body weight ratio, and sizes of cardiomyocytes but no significant differences were detected between WT/AgII and TNKO/AgII mice. AgII treatment also caused increase of interstitial collagen fibers at perivascular regions. Increase of interstitial collagen fibers were less than those in WT/AgII. In both wild type and TNKO mice, relative mRNA level of collagen I, III and TGF-β1 gene expression were both significantly increased, but no significant differences were detected between WT/AgII and TNKO/AgII mice. In WT/AgII mice, accumulation of macrophages positive myotubes were observed at perivascular region but reduced in TNKO/AgII mice. Alcin Blue staining showed dense deposition of glycosaminoglycans (GAGs) at perivascular area in WT/AgII. In contrast, TNKO/AgII showed sparse and rough fibrillar staining pattern. Immunostaining demonstrated that deposition of PGM/versican, a chondroitin sulphate proteoglycan was reduced in TNKO/AgII mice. More PDGF-B positive cells were found that in TNKO/AgII at peri-vascular region. These results suggest that, TNC may promote fibrosis in hypertensive heart by enhancing macrophages accumulation and deposition of proteoglycans.

Deposition of Elastin to Microfibrillar Fibers in the Presumptive Dermis of the Chick Embryonic Tarsometatarsus.

Y. Yamazaki,1,2 K. Isokawa,2 M. Yuguchi,1 M. Shirai,3 K. Shinozuka,1 S. Usami1; 1Department of Anatomy, Nihon University School of Dentistry, Tokyo, Japan, 2Division of Functional Morphology in Dental Research Center, Nihon University School of Dentistry, Tokyo, Japan, 3Department of Oral and Maxillofacial Surgery, Nihon University School of Dentistry, Tokyo, Japan

Fibrillin microfibrils are integral components of elastic fibers and serve as a scaffold for elastin deposition. However, microfibrillar fibers (MFs) are not necessarily committed to develop into so-called elastic fibers. In dermis, elastin-free oxytalan MFs originating from the dermo-epidermal junction are continuous to elastin-type MFs (with a small amount of elastin) in the deeper papillary dermis, whereas the reticular dermis contains horizontally arranged elastic fibers, or MFs embedded largely in elastin. In this study, we have investigated temporospatial pattern of elastin deposition in the MFs of tarsometatarsal presumptive dermis. While the earliest expression of elastin was demonstrated immunohistochemically as early as embryonic day 4 (ED4) in the wall of cardiac outflow and pharyngeal arch arteries, its deposition in the tarsometatarsus was first detected at ED6 in the deeper or core mesenchyme and at ED13 in the subcuticular mesenchyme. In the latter tissue, MFs had become perpendicularly to the covering ectoderm by ED4, quite before an overt accumulation of collagenous matrix; the onset of accumulation was at about ED9-10 when examined by picrosirius-polarization method. Elastin deposition observed initially in a punctate manner at ED13 became linear along subectodermal MFs. During these processes. Matrix metalloproteinases (MMPs) are neutral endopeptidases capable of degrading ECM components. Although the role of MMPs in myogenesis has been investigated, almost nothing is known about the role of their inhibitors, the tissue inhibitor of metalloproteinases (TIMPs). Here, we report that TIMP-2, MMP-2, and MT1-MMP are differentially expressed during mouse myoblast differentiation in vitro. Furthermore, we show that TIMP-2/- myotube size is altered: when differentiated in horse serum-containing medium, TIMP-2/- myotubes are larger than control myotubes. In contrast, when serum-free medium is used, TIMP-2/- myotubes are much smaller than controls. Regardless of culture condition, myotube size is directly correlated with MMP activity and inversely correlated with beta integrin expression. The reduced TIMP-2/- myotube size can be rescued by co-culturing with wild-type myoblasts in close apposition, without direct contact, suggesting that soluble factor(s) are responsible. Furthermore, reduced myotube size can be rescued by treatment with either recombinant MMP-2 or TIMP-2. Elucidating the role of TIMP-2 in myogenesis in vitro may lead to new therapeutic options for myogenic defects in vivo.
Tarsometatarsal (TMT) skeleton of the avian leg is peculiar in development. In the chick embryo, the 2nd to 4th metatarsal bone primordia elongate and merge into a TMT skeleton with a long bone morphology. However, the chronology of TMT bone development has not been investigated in detail. In this study, progression in morphogenesis and ossification of the TMT bone has been examined in conjunction with ultrastructural and immunohistochemical surveys on the development of periosteal elastic microfibrils. Three cartilage rudiments in the metatarsus showed a rapid elongation from the embryonic day 5 (ED5). Their proximal ends incorporated tarsal cartilage(s) to form TMTs by ED10. Calcification from the forming ossified bone collar occurred by ED8 at the mid-diaphyseal region and extended cylindrically on the surface of cartilage rudiments in the proximal and the distal directions. The length of bone collar increased from about 2 mm at ED9 to more than 12 mm at ED17, but epiphyses remained cartilaginous even just before hatching. Thickening of bone collar resulted in lateral osseous fusion of the initially independent three TMTs. This fusion began by ED17 and TMTs became unseparable by ED20, while cavities of the bone marrow remained separated incompletely. Along with these changes, perichondrium at early stages was converted into periosteum, which wrapped TMTs individually and afterwards enmeshed an united TMT entirely. Perichondrium and peristeme were rich in fibrillin-positive microfibrils largely arranged parallel to the long axis of TMTs. Elastin deposition was detected immunohistochemically at ED10 and became distinct ultrastructurally by ED13. Morphometrically, the cross sectioned area of microfibrillar bundles increased 4 times during ED10-20. Our findings provide useful chronological landmarks for the developmental studies of TMT skeleton. Supported from the Promotion and Mutual Aid Corporation and by grants from the Sato Fund and Dental Research Center in NUSD.

Molecular Biological Characterization and Expression of Female Specific Lecitin Involved Gamete Recognition of Marine Red Alga Agloathamnion oosumiense (Ceramidae Rhodophyte)

B. H. Jo, G. H. Kim; Department of Biology, Konkuk National University, Konkuk, Republic of Korea
Rhodobindin is a lecin protein involved in gamete recognition of a red alga, Agloathamnion oosumiense. This lecin was previously identified to be present on the female trichogyne and be involved in recognition with the male surface glycoproteins. This protein has specificity to N-acety1-d-galactosamine, it was purified by N-acety1-d-galactosamine affinity chromatography column. The protein is monomeric, with a molecular weight of 21 kDa. Result of 2DE analysis conformed that it was female-specific protein. The analysis of cDNA/ EST sequences was performed and the database for Agloathamnion oosumiense was constructed. Specific primer was produced based on the discovered amino acid sequence and coincided Cluster DNA sequence in ESTs database, then and the full sequence of the lecin was obtained. PCR amplification with an open reading frame (ORF) to the non-composite restriction enzyme site and expression vector for transformation into the E. coli competent cell was performed. Expression of the large quantity of Rhodobindin recombinant protein was induced in transformed E. coli by induction of IPTG. Thereafter the recombinant protein was purified by affinity chromatography column and Tagging protein was removed by protease. This study presents first report on both purification of red algal lecin and production of large scale recombinant protein.

Lectin/Glycan Interactions Play a Role in Recognition in a Coral/Dinoflagellate Symbiosis

E. M. Wood-Charchori,1 L. L. Hollingsworth,2 D. A. Krakp,2 V. M. Wei,1 Zoology, Oregon State University, Corvallis, OR, 3University of Hawai, Hawai’i Institute of Marine Biology, Kamehameha Schools, Windward Community College, Kailua, HI
Cell-cell recognition is an important step in the establishment of highly specific mutualistic associations. Yet, for the majority of symbioses, very few of the mechanisms responsible for recognition between symbiotic partners are well-understood. In this study, we provide evidence that a lectin/glycan interaction is functioning as a cell-cell recognition mechanism during initial contact between larvae of the coral Fungia scutaria and their endosymbiotic dinoflagellate algae. Symbiont-free F. scutaria larvae developed from artificially fertilized gametes. Symbiotic algae were extracted from adult F. scutaria and incubated with enzymes to remove components of the algal cell surface or with FITC-lectins to bind glycans on the algal cell surface. Symbiont cell surface labeling by FITC-lectins was quantified using flow cytometry. Treated symbionts were used to infect symbiont-free larvae, and infection success was compared to control infections with untreated larvae. We determined that an intact larval cell surface was required for successful infection of F. scutaria larvae. Modification of the algal cell surface by enzymatic digestion with trypsin (cleaves at Arg and Lys) or N-glycosidase (cleaves N-linked glycoproteins) significantly reduced infection success, and implicated algal cell surface glycans in recognition. Using flow cytometry, FITC-lectin binding identified α-mannose/α-glucose and α-galactose residues as potential recognition ligands on the algal cell surface. Finally, inhibition of these cell surface glycans by lectins significantly reduced infection of F. scutaria larvae by the algae. We found that the expression of these surface glycans helps promote infection of F. scutaria larvae.

Stochastic Analysis of Transcription Regulation in Lux-based Quorum Sensing

K. Timp1, W. Timp,1 U. Mirsadov,1 G. Timp,1 Y. Freycone,1 P. Matsudaira1; 1Molecular and Cellular Biology, University of Illinois at Urbana-Champaign, Urbana, IL, 2Electrical Engineering, Massachusetts Institute of Technology, Cambridge, MA, 3Electrical Engineering, University of Illinois at Urbana-Champaign, Urbana, IL, 3Biology, Massachusetts Institute of Technology, Cambridge, MA
In order to synchronize behavior between cells for biological computation, the noise and threshold of the signaling mechanism must be well characterized. In cell-cell signaling single molecules diffuse from one cell to another, and cause a reaction which can change the receiving cell behavior dramatically. Since this happens with just a few molecules, diffusing from one cell to another, it falls within the stochastic regime. We used flow cytometry and fluorescent microscopy to gather single-cell data on the transcriptional regulator portion of the lux system from V. Fischeri, luxR. Two different plasmids were transfected into E. coli, containing the lux promoter coupled to either GFP or GFP-LVA, a degradable form of GFP. The goal was to determine the dependence of activation threshold and noise on the incubation temperature. We found that the saturation threshold was shifted downward dramatically as the temperature was reduced, e.g. at 37°C the saturation threshold is a 100M [AII], but at 30°C the saturation threshold is only 10M. The noise was low in the saturation areas, but high in the switching area. There is a slight noise dependence on temperature, but not as dramatic as the observed threshold adjustment. When the degradation sequence in added to GFP, we found it reduced the leakage signal when the system is off. This is especially useful for synchronizing, as it will prevent background signal from climbing before the desired on switch. Cell-cell signaling of this kind is important for use in synthetic biology, as a mechanism for synchronizing behavior or logic in all bacterial cells of a population. Our quantification of the noise inherent in this bacteria system, allows us to use this signal in bacterial circuits. In addition the temperature information gives us the ability to easily shift the threshold dependent on the desired result.

Functional Genomics during the Initial Onset of Coral/Algal Symbiosis

C. E. Schnitzler, V. M. Wei; Zoology, Oregon State University, Corvallis, OR
The mutualism between corals and their intracellular dinoflagellate algae represents a highly specific partnership of two eukaryotic organisms. Very little is known about the molecular and cellular mechanisms controlling the successful establishment of a stable relationship in the early stages of coral/alggal symbiosis. The planula larva of the solitary scleractinian coral Fungia scutaria and its dinoflagellate symbiont Symbiodinium sp. represents an ideal model for studying the onset of coral/alggal symbiosis due to the predictable availability of gametes, and the ability to raise non-symbiotic larvae and establish the symbiosis experimentally. The goal of this study is to identify genes differentially expressed in F. scutaria larvae during the initiation of symbiosis with its algal symbiont. Symbiotic larvae will be compared to non-symbiotic larvae using a blind cDNA microarray. The array was constructed with cDNA libraries from symbiotic larvae. Modification of the algal cell surface by enzymatic digestion with trypsin (cleaves at Arg and Lys) or N-glycosidase (cleaves N-linked glycoproteins) significantly reduced infection success, and implicated algal cell surface glycans in recognition. Using flow cytometry, FITC-lectin binding identified α-mannose/α-glucose and α-galactose residues as potential recognition ligands on the algal cell surface. Finally, inhibition of these cell surface glycans by lectins significantly reduced infection of F. scutaria larvae by the algae. We found that the expression of these surface glycans helps promote infection of F. scutaria larvae.

T-cell Receptor Signaling Model Presents Multiple Activation Levels and Switching Mechanisms

J. M. Burk1, L. Willc,1 M. L. Kemp,1 D. A. Lauffenburger2; 1Biological Engineering, Massachusetts Institute of Technology, Cambridge, MA, 2Biology, Massachusetts Institute of Technology, Cambridge, MA
A properly functioning immune system requires ligand-appropriate T-cell responses. We theorize that T-cell responses (viral, self, and partial) to antigens are biologically controlled by two parameters: receptor-to-peptide ratio (ρ) and specific peptide affinity (α). We derived a mass-action ODE model describing this signaling process using minimal rate constant fitting. The model
is experimentally-verified from data found in literature. Simulations varying $\mu$ and $\kappa$ suggest the theoretical existence of multiple quasi-stable states corresponding with appropriate immune responses, implying possible switching mechanisms controlling T-cell receptor activation. Moreover, we show in model simulations that the presence of self peptide on antigen presenting cells increases the sensitivity of T-cell receptor detection of foreign peptides.

1728 Measurement of the Field Potential in Individual Cardiomyocytes by Multi-electrode Array with Agarose Microchambers

T. Kaneko,1,2 K. Kojima,1 Y. Sugio,1 I. Suzuki,1 K. Yassuda,1 Department of Biomedical Information, Institute of Biomaterials and Bioengineering, Tokyo Medical and Dental University, Tokyo, Japan; 2Precursory Research for Embryonic Science and Technology, Japan Science and Technology Agency, Saitama, Japan

Extracellular recordings of electrical activity with multi-electrode array (MEA) enable non-invasive long-term monitoring of the cell activation. We tried to develop the agarose microchamber (AMC) on the MEA for control of the cell position and the connecting pattern. Then the individual-cell-based electrophysiological measurement system, combining MEA with AMC, has been developed for non-invasive long-term analysis of the cell network activity. We have applied cardiomycocytes to this AMC/MEA system for the analysis of the cell communication. The advantages of this AMC/MEA system are that it allows control of the cell positions on the electrodes and numbers for cultivation using agarose microchambers and control of the flexible connecting pattern of the cell-cell interaction through photothermal etching with a 1480 nm infrared laser. Using the AMC/MEA system, the field potential of the individual spontaneous beating cardiomyocytes arranged on the electrodes in the agarose microchambers was recorded. We have found that the field could be detected reproducibly in field potentials recorded on the same electrode within a single preparation. In two cardiomyocytes synchronization, the field potential of each cardiomyocyte was recorded simultaneously on the neighboring electrodes. The distance of each electrode is 50 μm and the delay time of electrical activity between two cardiomyocytes is 1 ms, and consequently the conduction velocity is 50 mm/s. These results provide a basis for the future analysis of the community effect for the number, kind, and patterning of the cell in the networks.

1729 Microengineered Substrates Reveal E-cadherin-mediated Regulation of Cell Polarity

R. A. Desai, L. Gao, C. S. Chen; Bioengineering, University of Pennsylvania, Philadelphia, PA

Cell polarity is orchestrated by a variety of extracellular cues and guides events such as chemotaxis, mitosis and wound healing. In scratch wound assays of cell monolayers, it has been demonstrated that the microtubule organizing centers (MTOCs) of wound edge cells orient toward the open wound. Several studies implicate the formation of new cell-extracellular matrix (ECM) adhesions as cells spread into the wound as the origin of this polarizing signal. Here we sought to investigate the role of cell-cell adhesions in the process of cell polarization. To eliminate the dynamic events of spreading and new adhesion following scratch wounding, we cultured cells onto large patterned islands of ECM such that groups of cells attached and formed a discrete monolayer on each island. As such, cells at the edge of the monolayer retain asymmetric cell-cell contacts, but do not experience dynamic spreading or new adhesion events associated with a wound scratch. Using this system, we observed normal rat kidney epithelial cells along monolayer edges polarized such that their MTOCs were located between the nucleus and the edge, suggesting that the MTOC may move to an equilibrium position farthest from cell-cell interactions in the absence of changes in cell spreading and cell-ECM adhesion. We then examined whether cell-cell contacts were sufficient to drive this orientation, by using microengineered substrates to generate pairs of cells with specified interfacial geometry between them. Indeed, a limited area of cell-cell contact was sufficient to induce the MTOC to orient on the opposite side of the nucleus from the cell-cell contact. Furthermore, expressing a dominant-negative E-cadherin using an adenoviral vector completely abolished this bias in MTOC location. These findings suggest a role for E-cadherin-mediated cell-cell adhesion in providing signals that drive the polarized cell structure seen during chemotaxis and wound healing.

1730 Human Phagocyte Activity Is Inhibited by SIRP-CD47

R. Tsai, S. Subrahmanyan, D. Fischer; University of Pennsylvania, Philadelphia, PA

The integrin-associated protein (IAP) or CD47, which is found in many tissues, inhibits phagocytic activity of many cell types. CD47 is a ligand for the transmembrane signaling protein, SIRPα, present on macrophages and neutrophils, and it is postulated that CD47 is a ‘marker of self’ through its interaction with SIRPα by signaling an inhibition of phagocytosis. Past studies using mouse knockouts have raised many questions, including whether other proteins are involved. To begin addressing such questions with a reductionist approach, we have coupled CD47 to synthetic particles for studies of phagocytosis. These modified particles were first shown to bind to the extracellular domain of SIRPα in mice. In tests of phagocytosis with opsonized particles and a mouse-derived macrophage cell line, mouse CD47/particle dramatically reduce phagocytosis. The CD47-particle was further explored in human phagocytes where we demonstrate that negative E-cadherin using an adenoviral vector completely abolished this bias in MTOC location. These findings suggest a role for E-cadherin-mediated cell-cell adhesion in providing signals that drive the polarized cell structure seen during chemotaxis and wound healing.

1731 RKIKK Motif in the Intracellular Domain Is Critical for Spatial and Dynamic Organization of ICAM-1: Functional Implication for the Leukocyte Adhesion and Transmigration

H. Oh, S. Lee, Y. Kim, H. Wee, C. Jun; Department of Life Science, GIST, Gwangju, Republic of Korea

No direct evidence has been reported that the spatial organization of ICAM-1 on the cell surface is linked to its physiological function in terms of leukocyte adhesion and transendothelial migration (TEM). Here we observed that ICAM-1 by itself directly regulates de novo elongation of microvilli and is thereby clustered on the microvilli. However, truncation of intracellular domain resulted in uniform cell surface distribution of ICAM-1. Mutation analysis revealed that the C-terminal 21 amino acids are dispensable, whereas a segment of 5 amino acids NRKIKK in the NH-terminal third of intracellular domain is required for the proper localization and dynamic distribution of ICAM-1, and the association with F-actin, ezrin, and moesin. Importantly, deletion of the 507RKIKK511 did not reduce firm adhesion, but significantly delayed LFA-1-dependent ring-shaped membrane projection and subsequent TEM. Collectively, these findings demonstrate that 507RKIKK511 is an essential motif for the micrervillous ICAM-1 presentation and further suggest a novel regulatory role for ICAM-1 topography in leukocyte TEM.

1732 Sustained Thy-1 Engagement of avß3 Integrin Stimulates Astrocyte Migration

N. Munoz,1 D. Munoz,1 A. F. G. Quest,1 K. Barridge,1 L. Leyton1; FonDAP Center for Molecular Studies of the Cell, Facultad de Medicina, Universidad de Chile, Santiago, Chile, 1Cell & Developmental Biology, University of North Carolina at Chapel Hill, Chapel Hill, NC

Astrocytes, the most numerous glial cells in the central nervous system contribute to a fibroblast-like morphology when exposed to blood borne factors upon brain injury. These so called ‘reactive astrocytes’ also proliferate and migrate to the damaged site to form the glial scar, which constitutes a major impediment to neuronal regeneration. Such morphological changes observed in astrocytes in vivo may be related to those triggered in vitro by Thy-1, an abundant antigen expressed on the surface of T lymphocytes. Here we hypothesized that Thy-1 interaction with avß3 integrin in astrocytes provoking dramatic changes in cell shape and increased cell adhesion. Thus, in this study we hypothesized that sustained Thy-1 engagement of avß3 integrin stimulates astrocyte migration. An astrocyte monolayer was scratched with a pipette tip and migration into the cell-free zone was monitored after treating the cells with soluble Thy-1-Fe-Protein A complexes. Thy-1, but not a control Fe-protein, induced the formation of filopodia, lamellipodia and also migration of astrocytes into the wounded area. Moreover, according to results obtained with MTS proliferation and Trypan blue exclusion assays, this finding was not due to cell proliferation. Our data indicate that binding of Thy-1 to avß3 integrin initially stimulates cell adhesion and changes in cell shape, followed by cell migration in a sequence similar to that described for astrogliosis.

1733 The C. elegans LICAM, LAD-2, Functions in Axon Pathfinding

W. Wang,1 T. Cheever,1 V. Schwarz,2 K. Opperman,1 H. Hutter,1 L. Chen1; GCD, University of Minnesota, Minneapolis, MN, 2Developmental Biology, Simon Fraser University, Burnaby, BC, Canada

LICAMs are highly conserved adhesion molecules that are involved in the immune system and in neural development. LICAM homologues in C. elegans, LAD-1, SAX-7 and LAD-2, also play key roles in the immune and nervous systems. Like other LICAM family members, LAD-2 has a short divergent cytoplasmic tail that lacks any recognizable motif, including the ankyrin-binding motif that is present in LICAMs. In C. elegans, the gene sax-7 is ubiquitously expressed, but transcriptional promoter analysis revealed that sax-7 is not expressed in the nervous system. Our data indicate that binding of Thy-1 to avß3 integrin initially stimulates cell adhesion and changes in cell shape, followed by cell migration in a sequence similar to that described for astrogliosis.
cases where apoptosis is blocked, extrusion could enable a carcinoma to exit its primary site within an epithelium, facilitating its metastasis to another site.

Contact the actin and myosin ring. This suggests a model whereby the plus ends of microtubules in the cells neighboring a dying cell contact and locally activate contraction in the basal portion of tissue lymphoma 1) in the signaling from PKC to the IκB activity.

We present results that activation of CaMKII regulates the interactions between the key scaffolding proteins CARMA1, BCL10 (B cell leukemia 10) and MALT1 (mucosa-associated lymphoid tissue lymphoma 1) in the signaling from PKC to the IκB kinase at the T cell immunological synapse. Our results support a model by which Ca2+ signals, through CaMKII activation of NF-κB, can be integrated at the T cell immunological synapse.

Microtubules Regulate the Polarized Contraction of Actin and Myosin That Drives Apical Extrusion of Apoptotic Cells

J. Rosenberg, G. Slattum, L. Cramer, K. McGee; 1Oncological Sciences, Huntsman Cancer Institute, Salt Lake City, UT, 2Cell Biology, LMCB University College London, London, United Kingdom, 3Division of Cell Biology, Institute of Ophthalmology, UCL, London, United Kingdom

We have previously found that to maintain the barrier function of an epithelial monolayer, cells within the epithelium extrude their dying cells. During extrusion, a dying cell signals its live neighbors that react by forming an actin and myosin ring that contracts to squeeze the apoptotic cell out. Apoptotic cells typically get extruded apically (into the lumen), but can also exit basally (to the mesenchyme/blood). As the eventual fate of an apoptotic cell depends on where it gets extruded, we want to determine what dictates the direction of apoptotic cell extrusion. We find that the extrusion polarity is driven not by where the actin/myosin extruding ring forms but rather by the direction that it contracts. Furthermore, we find that microtubules spatially regulate ring contraction. Disrupting microtubules with nocodazole blocks contraction and extrusion of most cells. By contrast, interfering with microtubule dynamics by taxol addition reverses the direction of extrusion. Disruption with either drug does not change the inherent polarity of the cells within the monolayer; rather, it disrupts the number of microtubule plus ends that contact the actin and myosin ring. This suggests a model whereby the plus ends of microtubules in the cells neighboring a dying cell contact and locally activate contraction in the basal portion of the actin/myosin ring; basal contraction then drives extrusion apically. These results may also have implications for tumor cells where cell death is blocked. Since extrusion can still occur in cases where apoptosis is blocked, extrusion could enable a carcinoma to exit its primary site within an epithelium, facilitating its metastasis to another site.

Up-regulation of Semaphorin 3A by EGF in Cultured Human Corneal Fibroblasts

J. Ko, T. Nishida; Ophthalmology, Yamaguchi University Graduate School of Medicine, Yamaguchi Ube, Japan

Semaphorins are a family of glycoproteins that play an important role in repulsive axon guidance during embryogenesis. Semaphorin 3A (Sema3A), one of the most well-characterized members of this family, also up-regulates the expression of cell adhesion molecules and regulates cell-cell and cell-extracellular matrix interactions as well as cell motility in fibroblasts. Fibroblasts in the corneal stroma are surrounded by collagen fibers and are responsible for maintenance of transparency of the cornea. Epidermal growth factor (EGF) stimulates collagen synthesis by corneal fibroblasts and thereby contributes to maintenance and repair of the extracellular matrix of the corneal stroma. We have now investigated the effect of EGF on Sema3A expression in cultured human corneal fibroblasts. Reverse transcription and polymerase chain reaction analysis revealed that human recombinant EGF increased the amount of Sema3A mRNA in these cells in a concentration-dependent manner up to 50 ng/ml. At higher concentrations (100 ng/ml), however, EGF induced down-regulation of Sema3A mRNA. The maximal increase in the abundance of Sema3A mRNA induced by EGF 50ng/ml was apparent at 12 h. Immunoblot analysis showed that EGF also increased the amount of Sema3A protein in corneal fibroblasts in a concentration-dependent manner up to 10 ng/ml. An inhibitor of the tyrosine kinase activity of the EGF receptor, PD153035 (10 µg/ml), blocked the up-regulation of both Sema3A mRNA and protein by EGF. These findings indicate that EGF acts at its specific receptor to regulate the expression of Sema3A in cornal fibroblasts. This effect of EGF may play an important role in maintenance of corneal structure and repair of corneal damage.

Increased Basal Insulin Secretion from Isolated MIN6B1 Cells: A Consequence of Elevated Cytosolic Calcium

F. Jaques, A. Tomas, J. Jirginger, P.A. Halban; Medecine Genetic and Development, Medical Center Geneva, Geneva, Switzerland

Objective: Cell-connection is essential for proper function of islet-beta-cells. We showed previously that dispersed MIN6B1 cells are poorly responsive to glucose vs. confluent cells. The aim here was to understand why basal secretion is elevated in dispersed. Methods: After 48h in culture, cells were preincubated for 2h in KR-buffer at 2.8mM glucose and then incubated for 1h each at 2.8mM and 16.7mM glucose. In order to decrease intracellular calcium, a 10min period in KR-buffer without calcium supplemented with 0.1mM EGTA was performed at the beginning of the preincubation. Results: When cells were confluent (with extensive cell-cell interactions), basal secretion was low (0.45% content/h) and was stimulated 22-fold with 16.7mM glucose. Dispersed cells without cell-cell interaction showed only weak glucose-stimulation of insulin secretion (1.76fold that was due to greatly elevated basal secretion (3.8% content/h) and to a decrease in glucose stimulated insulin secretion (6.5% vs. 9.8%, dispersed vs. confluent cells). The use of various secretagogues showed that dispersed cells were not able to be stimulated by secretagogues that need a change in intracellular calcium level to allow exocytosis but were able to respond to secretagogues acting by a mechanism independent of changes in cytosolic calcium. Using confocal microscopy, we show that cytoskeleton organization in dispersed cells is disorganized as compared to confluent cells that exhibit a well polymerized cytoskeleton in basal conditions that remodels after glucose stimulation. Finally we show that decreasing intracellular calcium before the secretion test is enough to decrease the basal secretion of dispersed cells to that of confluent cells (0.87% vs. 0.73%, dispersed vs. confluent cells) and allow them to respond to glucose. Conclusions: Dispersed cells appear unable to regulate normally cytosolic calcium levels under basal conditions. This could be rectified by short-term (10min) privation of calcium in order to decrease cytosolic calcium in dispersed cells.

Integrin-dependent Actomyosin Contraction Regulates the Loss of E-cadherin-mediated Adhesion during Epithelial Cell Scattering

J. de Rooij, E. Spanjaard, A. Sonnenberg; Cell Biology, The Netherlands Cancer Institute, Amsterdam, The Netherlands

We are studying the role of the mitogen-activating protein kinases (MAPK) in the integrin-mediated actomyosin-contracting process. The MAPK-activating and -promoting growth factor that induces the loss of cell-cell junctions in MDCK cells, surprisingly did not downregulate the ability of E-cadherin to engage in the homotypic interaction that mediates cell-cell adhesion. Instead, HGF induced an increase in actomyosin-myosin dependent tension on cell-cell junctions, which was needed for their efficient breakdown as confirmed by the use of compliant substrates on which cells fail to produce tension. In addition, surfaces coated with ECM components that promote the reorganization of actomyosin showed more rapid and extensive cell-scattering in response to HGF compared to ECM components that did not induce cell-scattering. We can show that actomyosin contraction is critically involved in the breakdown of E-cadherin-mediated cell-cell junctions in response to HGF and that the observed crosstalk between integrins and cadherins depends on integrin-mediated regulation of actomyosin contraction in these cells. Apart from its apparent regulation by increased tension, a loss of tension also results in a destabilization of E-cadherin mediated adhesion. This implies that, like integrin-mediated focal adhesions, cadherin-mediated adhesions junctions are governed by a tight regime of cytoskeletal tension. The alteration of normal cellular tension, for instance during tumor progression, may thus result in the deregulation of junctional integrity. Currently, we are investigating which of the proteins present in the cadherin adhesion complex are responsible for the regulation by cytoskeletal tension. De Rooij J, Kerstens A, Danuser G, Schwartz MA, Waterman-Storm CR. Integrin-dependent acto-myosin contraction regulates epithelial cell scattering. J Cell Biol. 2005 Oct 10;171(1):153-64.
Phosphorylation as a readout, we are identifying upstream signaling pathways and kinase(s) that presumably act through PKC or a PKC-dependent kinase to directly modify p120 activity. Dephosphorylated by PKC activation. In contrast, S873 is not phosphorylated under basal cell conditions but becomes heavily phosphorylated upon phorbol ester treatment. Using S873 to report the generation and characterization of a novel monoclonal antibody to p120 serine 873 (S873), a C-terminal phosphorylation site. The antibody is p120-, phospho- and site-specific and thereby affects cell morphology, motility, proliferation, and ultimately tumor progression. The majority of p120 signaling events are controlled by an N-terminal 300 amino acid segment of p120-catenin (p120) which regulates cell-cell adhesion through its interaction with the cytoplasmic tail of cadherins. In addition to its link with cell adhesion, p120 modulates Rho-GTPase activities, thereby affecting cell morphology, motility, proliferation, and ultimately tumor progression. The majority of p20 signaling events are controlled by an N-terminal 300 amino acid segment of p20 termed the "regulatory domain". This region contains all but two of the known tyrosine (Y) and serine/threonine (S/T) phosphorylation sites and serves as the binding site for several tyrosine kinases and phosphatases. We have identified the major p120 Y and S/T phosphorylation sites and have generated phospho-specific monoclonal antibodies to several of them. Here, we next examined the effect of p120 loss on MDCK cell growth in soft agar, an assay generally used to predict tumorigenicity in vivo. Surprisingly, while morphological transformation by p120 depletion eliminated the adherens junction proteins E-cadherin, beta-catenin, and alpha-catenin (as reported in other cell lines), but cell-cell junctions were retained, possibly because desmosome and tight junction proteins were not affected. RhoA activity was constitutively elevated, resulting in enhanced formation of actin stress fibers. We next examined the effect of p20 loss on MDCK cell growth in soft agar, an assay generally used to predict tumorigenicity in vivo. Surprisingly, while morphological transformation by dominant active (DA)-Rac1 or v-Src was not obviously affected in p20-depleted cells grown in two-dimensional culture, Rac1- and v-Src-induced, but not H-Ras-induced, growth in soft agar was completely blocked in the absence of p20. Moreover, this effect was efficiently restored by selective inhibition of ROCK. Thus, RhoA activation in p20-depleted cells appears to block Rac1- or Src-induced growth in agarose via a ROCK dependent pathway. The data show that p20 plays an essential role in Rac1- and Src-mediated anchorage-independent growth by negatively regulating RhoA activity.
The Role of Serine/threonine Phosphorylation of P120: Does It Alter E-cadherin Dynamics at the Plasma Membrane?
Y. Fukumoto, Eppley Cancer Center, University of Nebraska Medical Center, Omaha, NE
p120-catenin is a membrane associated protein that regulates E-cadherin at the plasma membrane and was first identified as a substrate for oncogenic Src and receptor tyrosine kinases. In contrast to its well-studied transient tyrosine phosphorylation in response to growth factor stimuli, its relatively constitutive serine/threonine phosphorylation is less well understood. In this study we examined the function of serine/threonine phosphorylation of p120 in cadherin activity using cadherin-deficient MIAPaCa-2 and p120-deficient S2013 pancreatic cancer cells. Forced expression of cadherins in MIAPaCa-2 cells converted the otherwise dispersed cells into epithelial-like cells, localized p120 to sites of cell-cell contact, and induced p120 phosphorylation. Triple alanine mutant constructs of cadherins that couple p120 to the cadherin complex blocked p120 phosphorylation. Detergent extraction showed abundant phosphorylation of p120 in the insoluble fraction, and immunofluorescence confirmed membrane localization of phosphorylated p120. Modified E-cadherin constructs incapable of traveling to the plasma membrane did not induce serine/threonine phosphorylation of p120. However, an E-cadherin cytoplasmic domain that was artificially targeted to the plasma membrane did induce serine/threonine phosphorylation of p120. These data suggest that serine/threonine phosphorylation of p120 occurs independent of signals from cadherin-cadherin dimerization and independent of trafficking through the ER/Golgi. Forced expression of various p120 isoforms in S2013 cells influenced E-cadherin dynamics. Calcium switch and detergent solubility assays indicated that p120 isoform 3A stabilized E-cadherin at the plasma membrane relative to isoform 4A. Since the major phosphorylation domain of p120 is included in isoform 3A but not in isoform 4A these data suggest that serine/threonine phosphorylation of p120 influences the stability of the E-cadherin complex at sites of cell-cell contact.

Regulation of Junctional Integrity by Receptor Protein Tyrosine Phosphatase DEP-1
J. L. Salle, K. Burridge; Cell and Developmental Biology, University of North Carolina Chapel Hill, Chapel Hill, NC
Decreased endothelial cell barrier function and the subsequent increase in leukocyte transmendothelial migration have been associated with several chronic inflammatory disease states, such as asthma, multiple sclerosis, and atherosclerosis. An increase in tyrosine phosphorylation of junctional proteins correlates with a decrease in junctional integrity. Tyrosine phosphorylation of any protein reflects the balance between protein tyrosine kinases (PTKs) and protein tyrosine phosphatases (PTPs). DEP-1, a receptor PTP, is expressed in a variety of cells and has been found to localize to adherens junctions. DEP-1 binds p120ctn, γ-catenin (plakoglobin) and β-catenin in vitro in a phosphorylation-dependent manner. This localization pattern raises the possibility that DEP-1 regulates cell-cell adhesion. We have explored this possibility by DEP-1 expression via shRNA constructs. Depression of DEP-1 levels causes a reduction in electrical resistance across cell monolayers, suggesting that DEP-1 is important for the maintenance of junctional integrity. In addition, reduction of DEP-1 enhances phosphorylation of p120ctn during EGTA-induced junctional disassembly. Current work is aimed at testing the hypothesis that DEP-1 may be involved in the remodeling of cell-cell junctions during processes such as diapedesis. Supported by Department of Defense BCRP Predoctoral Traineeship Award BC50198 and NIH grant HL45100.

The Role of Alpha-catenin in Invadopodial Assembly in Human Breast Cancer
S. Mandal, Biochemistry, University of Nebraska Medical Center, Omaha, NE
Tumor formation and invasion are significant human health problems. Cell-cell and cell-matrix interactions are important for cellular migration and invasion. During malignant transformation, cells must co-ordinate changes in cell-cell and cell-matrix interactions. Migratory cells display dynamic plasma membranes and form adhesive structures, including invadopodia and podosomes, on their bottom surfaces that interact with the extracellular matrix. Invadopodia facilitate invasion by forming foci for increased extracellular protease digestion. We are interested in how the adherens junction plaque protein alpha-catenin co-ordinates cell-cell adhesion with the activity of invadopodia. Our preliminary data show that re-expression of alpha-catenin in the alpha-catenin null MDA-MB-468 human breast cancer cell line leads to disassembly of invadopodia. We also show that phosphorylation on ERK is dramatically reduced in alpha-catenin expressing MDA-MB-468 cells as compared to the parental cells. This suggests that cross-talk exist between the cadherin/ catenin adhesion complex and ERK signaling. However, the pathways that mediate crosstalk between ERK signaling and invadopodial assembly are not yet understood. Our long-term goal is to understand the role of alpha-catenin in ERK signaling and how this influences the assembly of invadopodia.

Allosteric Regulation of Alpha-catenin and Its Role in Cell-Cell Adhesion and Cytoskeletal Reorganization
J. Benjamin, W. Nelson; Biological Sciences, Stanford University, Stanford, CA
The adherens junction is dependent upon homophilic binding between cadherins from opposing cells and is mediated intracellularly through binding to β-catenin, which in turn binds α-catenin. While it was previously believed that cadherins are directly linked to the actin-cytoskeleton through α-catenin, recent data from our lab show that α-catenin cannot simultaneously bind the cadherin-β-catenin complex and actin filaments in vitro. This mutually exclusive binding is explained by allosteric regulation of α-catenin; monomer preferentially binds the cadherin-β-catenin complex whereas the homodimer binds actin filaments. While the in vitro data are compelling, the existence of a monomer-dimer transition and its effects on actin have not been demonstrated in vivo. One focus of our studies will be to perturb the localization of α-catenin, such as concentrating α-catenin at the membrane independent of cell-cell adhesion. To do this, we added a myristylation/ palmitoylation tag to the α-catenin binding domain of β-catenin. When transiently transfected into MDCK cells, the β-catenin fragment localizes to the plasma membrane. This construct has no effect on expression or localization of endogenous E-cadherin yet it is able to recruit and increase the amounts of endogenous α-catenin at the plasma membrane as compared to untransfected controls. Transfected cells will be tested for changes in actin organization and cellular dynamics to determine if increased concentration of α-catenin is sufficient for its dimerization. These data will allow us to determine the relative importance of α-catenin dimerization on the establishment and maturation of cell-cell adhesion.

Myosin VI Supports E-cadherin Adhesion and Integrity of the Zonula Adherens in Mammalian Epithelial Cells
M. P. Maddugoda, A. Shewan, A. S. Yap; Institute for Molecular Bioscience, University of Queensland, St Lucia, QLD, Australia
Adhesive cell-cell interactions are dynamic processes that determine tissue patterning and integrity during development and in post-embryonic life. The cell-cell adhesion receptor E-cadherin critically supports such morphogenetic events. In recent years it has become increasingly clear that a complex set of cytoplasmic components are involved in the stringent regulation of E-cadherin activity. Specifically, many components have been identified that regulate the functional interaction between E-cadherin and the actin cytoskeleton. Recently, Myosin VI was identified as an actin-based motor protein that affects E-cadherin-based morphogenesis in Drosophila (Geisbrecht 2002); its potential impact on cadherin activity in mammalian systems has not, to date, been identified. Here we report an association between Myosin VI and E-cadherin at mammalian epithelial cell-cell contacts. Myosin VI was recruited to cadherin adhesions in an E-cadherin-dependent fashion. Characteristically, this was a relatively late event in the biogenesis of confluent epithelial monolayers, that coincided with the formation of cohesive, linear contacts and the apparent formation of the zonula adherens. Depletion of Myosin VI by RNAi disrupted the morphological integrity of cell-cell contacts, perturbed the perijunctional actin cytoskeleton and significantly reduced cadherin surface adhesion. Cell-matrix adhesiveness, however, was not affected. The disruption of cohesive cell-cell contacts was also accompanied by perturbed integrity of tight junctions and desmosomes. Our findings then identify Myosin VI as a key cytoplasmic determinant that is recruited by E-cadherin adhesion to support the biogenesis of the apical junctional complex in epithelia.

Involvement of TRPV4 in the Formation of Cell-Cell Junctions in Skin
T. Fukami-Tominaga, T. Sotabe, S. Yonemura, M. Mizuno, M. Suzuki, M. Tominaga; 1Section of Cell Signaling, National Institute for Physiological Sciences, Okazaki, Japan, 2RIKEN Center for Developmental Biology, Kobe, Japan, 3Jichi Medical School, Minamikawachi, Japan
Barrier function of the skin is essential for terrestrial life to protect against both infection from environment and dehydration from inside. Keratinocytes in epidermis continuously proliferate and are stratified, generating the cornified cell layer to provide the hydrophobic barrier. In addition to cornified cell layer, tight junctions caused by maturation of cell-cell adhesion (adherence junction) also form a significant barrier. Differentiation and formation of these junctions need an increase in intracellular Ca2+, followed by reorganization of actin cytoskeleton. However, the molecular mechanism of Ca2+ signaling responsible for the keratinocyte differentiation remains poorly understood. TRPV4 is a Ca2+-permeable ion channel belonging to the transient receptor signal pathways that mediate crosstalk between ERK signaling and invadopodial assembly are not yet understood. Our long-term goal is to understand the role of alpha-catenin in ERK signaling and how this influences the assembly of invadopodia.
potential (TRP) ion channel super family and activated by various stimuli including warm temperatures (~33°C), and known to be expressed in skin keratinocytes. Because cytoplasmic region of TRPV4 was found to bind β-catenin in keratinocytes which is important for maturation of stratification, we examined the role of TRPV4 in the differentiation process of keratinocytes and barrier function by comparing TRPV4-deficient and wild type mice. Impaired barrier function together with thickened cornified layer was observed in TRPV4-deficient mice both in vitro and in vivo levels. Reorganization of actin cytoskeleton and formation of cell-cell junction in TRPV4-deficient keratinocytes was delayed and immature compared to that in wild type ones. Furthermore, increase in cytosolic Ca++ at 33°C upon high extracellular Ca++ was significantly higher in wild-type keratinocytes than in TRPV4-deficient ones. And the increase was inhibited by disruption of actin filaments in wild-type, but not in TRPV4-deficient keratinocytes. We propose that interaction of TRPV4 with β-catenin plays an important role for actin polarization by enhancing tightness of cell-cell adhesion upon Ca++ entry through the channel.

Regulation of Phosphoinositides in Cell-Cell Adhesion
M. K. Iijima, M. Anai, T. Kodama, Y. Shibasaki; Laboratory for Systems Biology and Medicine, RCAST, The University of Tokyo, Tokyo, Japan
Cell-cell adhesion is essential for cell growth, morphogenesis, and development. Actin rearrangement is required for cell-cell adhesion and is regulated by phosphoinositides such as PtdIns(4,5)P2 (PIP2). Rho family small GTPases have been implicated in cell-cell adhesion and a constitutively active Rac (V12Rac) enhanced this process. However, the mechanisms and downstream effectors remain to be elucidated. We have shown that overexpressed phosphoinositides 5-kinase (PIP5K) γ, a PIP2 synthesizing enzyme, was localized in cell-cell adhesion in A431 epidermoid cells. In this report, we investigated the involvement of other isoforms of PIP5K in cell-cell adhesion. To this end, we have made isoform specific monoclonal antibodies against PIP5Ks and studied endogenous as well as exogenous PIP5Ks. By immunoprecipitation and Western blotting, each antibody detected band(s) with expected size. PIP5K was concentrated in cell-cell adhesion in addition to ruffling in Hela cells. V12Rac increased the accumulation of PIP5K at cell contact sites. PH domain of PLCγ connected to GFP (PH-PLCγ), an indicator for PIP2, and polymerized actin concentrated in contact sites. Our results are consistent with the model that PIP5K increased PIP2 and regulated actin polymerization at cell adhesion. But Rac did not coimmunoprecipitate with PIP5K, suggesting that Rac and PIP5K did not associate directly. PIP5Kγ has been known to be involved in cell-substratum adhesion. These results suggest that phosphoinositides mediated actin dynamics is important both for cell-cell adhesion and cell-substratum adhesion.

Vitamin C Transport in Sertoli Cells: Functional Evidence for the Presence of Facilitative Hexose Transporters (GLUTs) and Sodium-dependent Vitamin C Transporters (SVCTs)
C. Angulo, M. A. Castro, R. Maldonado, A. J. Yahez, J. C. Sileve, J. C. Vera, I. I. Concha, Bioquimica, Universidad Austral de Chile, Valdivia, Chile, Fisiopatologia, Universidad de Concepcion, Concepcion, Chile
A central question for a better understanding of testicular function is how germ cells obtain vitamin C, considering that the hemato-testicular barrier limits the direct access of molecules from the plasma into the adenlular compartment of the seminiferous tubule. In this study we analyzed the molecular identity of the transporters involved in the transport of vitamin C in isolated Sertoli cells and 42GPAA Sertoli cell line. WT1 was used as Sertoli cells specific marker to further validate the use of 42GPAA cell line as a model system. The kinetic assays revealed that both, ascorbic acid transporters (GLUTs) and sodium-dependent vitamin C transporters (SVCTs), are functionally active in these cells. This data is consistent with the concept that Sertoli cells have the ability to take up vitamin C, a finding that may be of importance to the physiology of the germ cells. Participation of Astrocytes in the Inhibition of Neuronal Glucose Uptake by Ascorbic Acid
M. A. Castro, C. Angulo, I. I. Concha, F. Nuñal; Biochemistry, Universidad Austral de Chile, Valdivia, Chile, Cell Biology, Universidad de Concepcion, Concepcion, Chile
Ascorbic acid (AA) is highly concentrated in the Central Nervous System due to sodium-dependent vitamin C transporters in cerebral cells. We have previously demonstrated that an increase in neuronal intracellular AA inhibits glucose utilization in neurons under synaptic glutamatergic activity. Because L-glutatmate is able to stimulate AA efflux from astrocytes, we postulate that astrocytes could play a fundamental role on neuronal glucose inhibition. We show here that L-glutamate stimulates 1H-AA exportation from astrocytes and exported AA inhibited 1H-deoxyglucose (1H-DG) uptake in neurons. The effect, elicited by L-glutamate, was concentration and time dependent. Finally, we observed that 1H-DG transport inhibition was dependent upon AA concentration used in each experiment and on neuronal AA uptake. Therefore, AA exportation from astrocytes to neurons stimulated by L-glutamate and inhibition of neuronal DOG uptake could represent a key element in a metabolic modulation on neurons under glutamatergic synaptic activity. (FONDECYT 1060115, PhD thesis support grant CONICYT 2003)

Membrane Proteins Alkylated by Sulphur Mustard
N. M. Sayer, A. C. Green, J. Jenner, C. D. Lindsay; Biomedical Sciences, Defense Science and Technology Laboratory, Salisbury, United Kingdom
Although much research has been carried out on the vesicant and lung damaging agent Sulphur Mustard (HD) since its first use in World War I little is known about the mechanisms of action underlying its toxic effects. It is known that HD and related compounds have the ability to alkylate and cross-link biomolecules however the exact nature of the cellular target's that initiate HD-induced inflammation and blistering remain unknown. To understand the mechanisms of action of HD in binding to the skin and causing vesication we have investigated the interactions occurring between HD and cellular proteins. In this study we describe the labelling of cultured keratinocyte cell membrane proteins by HD and a related vesicant with the aim of identifying proteins important in HD pathology. Membrane fractions were prepared and analysed by Western blotting to confirm the distribution of sub-cellular fractions. These membrane fractions were incubated with 1H-C and the labelled proteins separated and detected using 1D and 2D electrophoresis and fluorography. Current studies show 1H-C labelling of a number of membrane proteins. Comparison of these results with those of 14C-hemi-HD, a compound with lower vesicant potential shows differences in labelling of a number of cell membrane proteins, especially those of higher molecular weight. These differences will be used to identify proteins alkylated selectively by HD and HD-related compounds with vesicant properties, using mass spectroscopy. Knowledge of these target proteins will benefit our understanding of the vesication process. © Crown Copyright 2006

Multiple Regulatory Roles of Non-T Cell Activation Linker (NTAL/LAB) in Mast Cell Signaling
P. Draber, L. Draberova, G. M. Shaik, P. Volna, M. Tumova, P. Lebduska, P. Heneberg, J. Korb; Signal Transduction, Institute of Molecular Genetics, Prague, Czech Republic
The transmembrane adaptor NTAL [non-T cell activation linker, also called linker for activation of B cells (LAB)] assembles multiple proteins involved in immunoreceptor signaling. Previously, human mast cells with a decreased NTAL expression, by small interfering RNA, were shown to exhibit reduced Fce receptor I (FceRI)-mediated degranulation, whereas bone marrow derived mast cells cultured from NTAL-/- mice exhibited enhanced degranulation, compared to wild-type mice. To understand the effect of NTAL on mast cell signaling, we compared the FceRI-mediated activation events in rat basophilic leukemia 2H3 cells with enhanced or reduced NTAL expression. Overexpression of NTAL inhibited FceRI-induced tyrosine phosphorylation of the FceRI subunits, Syk kinase, LAT and Gab2 adaptor. Downstream events such as calcium mobilization and degranulation were also impaired. On the other hand, reduced expression of NTAL (by RNA interference) had no effect on phosphorylation of FceRI subunits, Syk and LAT, but it did inhibit calcium mobilization and secretory responses. The amount of cellular NTAL directly correlated with the uptake of extracellular calcium in thapsigargin-stimulated cells. Interestingly, thapsigargin did not induce enhanced NTAL tyrosine phosphorylation, suggesting a novel function of NTAL in immunoreceptor signaling. Formation of signaling assemblies on the plasma membrane, containing phosphatases and other signaling molecules, was also affected by enhanced or reduced expression of NTAL. These results suggest that NTAL regulates the FceRI-mediated activation events at multiple steps and by different mechanisms.

Transmembrane Domains of the Sln1 Osmosensor Regulate Signaling
G. D. Tchou, M. C. Gastin; Biochemistry & Cell Biology, Rice University, Houston, TX
The ability to sense and adapt to changes in external osmotic pressure is an essential feature of cellular survival, particularly in yeast and other microorganisms. In Saccharomyces cerevisiae, the transmembrane osmosensor Sln1p is thought to act as the primary regulator of the osmotic stress response. During constant osmotic conditions, Sln1p participates in a multistep phosphorelay system that inhibits the HOG (high osmolarity glycerol) pathway and positively regulates genes involved in cell wall biogenesis and cell cycle progression. Exposure to increased...
external osmolarity inactivates Sln1p, leading to rapid phosphorylation of Hog1p and transcription of osmoadaptation genes. Putative osmosensors homologous to Sln1p are found in many bacteria, fungi, and plants, but the mechanism by which these proteins detect and respond to changes in external osmolarity is largely unknown. Previous work has indicated that the two transmembrane domains (TMDs) of Sln1p are important for osmotic signaling. In order to determine how the TMDs might be functioning in the Sln1p-mediated osmotic stress transduction mechanism, we targeted two potential dimerization regions within the TMDs for mutation. Interestingly, while replacement of TMD1 with sequences from topologically similar membrane proteins resulted in the loss of Osm1p stability within the two TMDs increased the activity of the receptor. These results suggest that helix-helix interactions between the Sln1p TMDs may play a central role in its osmotic signaling mechanisms.

The Functional Regulation of Extracellular Calcium Sensing Receptor by Caveolin in Mouse Mesangial Cells
S. Cha, 1 J. Kwak, 1 J. Kwak, 1, 2Department of Pharmacology and Toxicology, Inha University, Incheon, Republic of Korea, 1Department of Physiology and Biophysics, Inha University, Incheon, Republic of Korea
The extracellular calcium sensing receptor (CaSR) belongs to the type III family of G-protein-coupled receptors, a family that comprises the metabotropic glutamate receptor. The CaSR plays an important role in calcium homeostasis in various cell types. In this study, we examined the expression of the CaSR in the mouse mesangial cells (MMC). Reverse transcriptase-polymerase chain reaction (RT-PCR) was performed with CaSR-specific primers, and this was followed by nucleotide sequencing of the amplified product; this process identified the CaSR transcript in the MMCs. Moreover, CaSR protein was present in the MMCs as assessed by Western blot and immunocytochemical analysis using a polyclonal antibody specific for the CaSR. Functionally, [Ca2+]o-induced increment of the intracellular calcium concentration ([Ca2+]i) in dose-dependent manner. This [Ca2+]o increment by [Ca2+]o was attenuated by the pretreatment with a phospholipase C inhibitor (U73122) and also by a pretreatment with a CaSR antagonist (NPS 2390). The similar results also obtained in IP3 accumulation by [Ca2+]o. To investigate the physiological effect of the CaSR, the effect of the [Ca2+]o on cell proliferation was studied. The increased [Ca2+]o (up to 10 mM) produced a significant increase in the cell numbers. This mitogenic effect of [Ca2+]o was inhibited by the co-treatment with a CaSR antagonist. In addition, CaSR bind to caveolin and CaSR function in [Ca2+]o increment was significantly inhibited by the treatment with caveolin antisense oligodeoxynucleotide. From these results, the [Ca2+]o-induced [Ca2+]i elevation in the MMC is coupled with the extracellular calcium sensing receptor. Furthermore, [Ca2+]o produces a mitogenic effect in MMCs and upregulated by caveolin in normal physiological condition.

Caveolins Bind to Renal Organic Anion Transporter 1 and Regulate Organic Anion Uptake
J. Kwak, 1 C. Su, 1 S. Cha, 1, 2Pharmacology and Toxicology, Inha University, Incheon, Republic of Korea, 3Physiology and Biophysics, Inha University, Incheon, Republic of Korea
The rat organic anion transporter 1 (rOAT1) has recently been identified as the first member of the organic anion transporter family. The mechanisms that regulate rOAT1 function remain to be elucidated. rOAT1 contributes to the transport of a number of organic anions across the basolateral membrane. However, the role of rOAT1 in the intracellular calcium signaling remains unclear. To address the relationship of these two proteins, we investigated the protein-protein interaction between rOAT1 and Cav-1 or -2. The rOAT1 mRNA and protein expression were observed in the rat kidney, and the expressions of Cav-1 or -2 mRNA and protein were also detected in the kidney. Confocal microscopy of the immuno-cytochemistry experiments using primary cultured renal proximal tubular cells showed that OAT1 and Cav-1 or -2 were co-localized at the plasma membrane, respectively. This finding was confirmed by Western blot analysis using isolated caveolae-enriched membrane fractions from the rat kidney and immuno-precipitation experimentation. When rOAT1’s synthesized cRNA of rOAT1 along with the antisense oligodeoxynucleotide of Xenopus Cav-1 or -2 were co-injected into Xenopus oocytes, the [3H] aminoohippuric acid uptake was significantly decreased. These findings suggest that rOAT1 and caveolin-1 or -2 share a cellular expression in the plasma membrane and Cav-1 and -2 regulate the organic anionic compound uptake via rOAT1 under normal physiological conditions.

1759
Molecular Identification and Functional Characterization of a Novel Organic Anion Transporter OATN1
T. Hira, 1 E. Babu, 1 X. He, 1 T. Ishikawa, 1 T. Soga, 1 N. Anzai, 1 H. Endou, 1 Y. Kana, 1 Pharmacology and Toxicology, Kyorin University School of Medicine, Tokyo, Japan, 3Research and Development, Human Metabolome Technologies, Inc., Yamagata, Japan, 2Institute for Advanced Biosciences, Keio University, Kanagawa, Japan
The kidney plays the important roles in the removal of harmful endogenous compounds and xenobiotics from the body and the reabsorption of the essential endogenous compounds. SLC22 organic ion transporter family is responsible for these organic ions transport across the epithelial cells in the renal proximal tubules. This family is composed of 3 subfamilies: organic anion transporter (OAT), organic cation transporter (OCT) and organic cation/wortmannin transporter (OCTN) subfamily. Recently, we identified a novel SLC22 family member, OATN1 (golv type organic anion transporter 1) from the genome database. OATN1 shows ~36% identity to other OAT members at amino acid level. Proximal tubule cell lines (S2 cells) stably expressing OATN1 were used for the functional study. OATN1 mediated transport of nicotinic acid, salicylic acid and prostaglandin D2. In contrast, OATN1 does not transport the typical substrates for OATs (para-aminobenzoate, estrone, estrone sulfate, taurocholate), OCTs (tetraethyl ammonium, choline) and OCTNs (carnitine). OATN1 mRNA was detected only in kidney. Immunohistochemical study showed that OATN1 protein was localized at the apical membrane of renal proximal tubules. Since the substrate selectivity and structure of OATN1 are different from those of other OAT family members in spite of the same localization, we speculate that OATN1 should denote a member of a new SLC22 subfamily and have a different physiological role in renal proximal tubules.

1760
Cell Migration and Signaling Specificity Is Determined by Ralc’s Phosphatidyserine Recognition Motif
C. V. Finkielstein, 1 M. Overduin, 2 D. G. S. Capelluto 3; 1Biological Sciences, Virginia Polytechnic Institute and State University, Blacksburg, VA, 2School of Medicine, CR-UK Institute for Cancer Studies - University of Birmingham, Birmingham, United Kingdom, 3Chemistry, Virginia Polytechnic Institute and State University, Blacksburg, VA
The Rho guanine triphosphatases (GTPases) control cell shape and motility and are frequently overexpressed during malignant growth. These proteins act as molecular switches cycling between active GTP- and inactive GDP-bound forms. Despite being membrane-anchored via their isoprenylated C-termini, Rho GTPases rapidly translocate between membrane and cytosolic compartments. Here, we show that the Rho GTPase Rac1 preferentially interacts with phosphatidyserine (PS)-containing bilayers through its polybasic motif (PBM). Rac1 isoprenylation contributes to membrane binding but is not critical for PS recognition. The similar protein Cdc42 (cell division cycle 42), however, only associates with PS when prenylated. Conversely, other Rho GTPases such as Rac2, Rac3 and RhoA do not bind to PS even when they are prenylated. Cell stimulation with PS induces translocation of Rac1 towards the plasma membrane and stimulates GTP loading, membrane ruffling and filopodia formation. This stimulation also promotes Cdc42 activation and phosphorylation of mitogen-activated protein kinase through Rac1/PS signaling. Consequently, the PBM specifically directs Rac1 to effect cytoskeletal rearrangement and cell migration by selective membrane phospholipid targeting.

1761
Characterization of the DHHC Protein Acyltransferase (PAT) Erf2/Erf4 That Palmitoylates Yeast Ras Protein
K. Ishizuka, L. Zhao, C. Budde, G. Ganeshan, H. Guan, T. Berg, D. A. Mitchell, R. J. Deschenes; Biochemistry, Medical College of Wisconsin, Milwaukee, WI
Palmitoylation is an important posttranslational modification of conserved polar residues with functional and regulatory roles for many proteins. Recently, our lab has identified protein acyl transferases (PATs) for yeast and mammalian Ras protein palmitoylation. In yeast, it is composed of Erf2 and Erf4, which colocalizes on the endoplasmic reticulum (ER) membrane. Both subunits are required for the Ras PAT activity, but the function of individual subunit is unclear. Erf2 contains four putative transmembrane domains (TMDs) and a conserved zf-DHHC (zinc-finger Asp-His-Cys) cysteine-rich domain, which is characteristic of the PAT family. On the other hand, Erf4 has no recognizable motif. To better understand the mechanism of palmitoylation by Erf2/Erf4, we began by determining the topology of Erf2. Analysis of Erf2 amino acid sequence predicted that N- and C-terminus and the loop between TMD 2 and 3, which contains the zf-DHHC domain, are in the cytoplasmic side of the ER membrane. The prediction was tested experimentally by inserting invertase Sac2, which is used as the reporter for the lumenal exposure indicated by glycosylation, into various positions. The results were consistent with the prediction. In addition, the association of Erf4 with Erf2 and/or the membrane has been investigated. Transcriptional mutants of Erf2 and Erf4 were constructed to determine the domain required for the Erf2-Erf4 interaction. Our co-immunoprecipitation results show that the region of Erf2 including a zf-DHHC domain is required for the association of Erf2 and Erf4. Detailed study of Erf2/Erf4 complex serves as a model for the growing list of zf-DHHC proteins that have been found in eukaryotes examined to date.
A Proteome-scale Screen Identifies Novel Phosphoinositide Binding Proteins

S. Lee, 1 M. Kerr, 1 R. Sim, 1 K. A. A. Galbraith, 2 S. Madharavanu, a C. E. Kennedy, b L. C. Cantley, 2 S. J. Field, 1 Endocrinology, University of California San Diego, La Jolla, CA, 2 Division of Signal Transduction and Department of Systems Biology, Beth Israel-Deaconess Medical Center and Harvard Medical School, Boston, MA

Proteins that bind phosphoinositides are critical regulators of membrane trafficking, cell proliferation, apoptosis, and metabolism. Although the number of proteins that are known to bind phosphoinositides has increased dramatically over the past several years, many more are likely to exist. We have devised a systematic and comprehensive approach to identify phosphoinositide binding proteins. We have used a high-throughput assay to screen ~4800 unique proteins (so far) for their ability to bind each of the phosphoinositides. The screen has identified many proteins that bind phosphoinositides. We will present data identifying a novel protein that we demonstrate binds Phosphoinositide 4P both in vitro and in vivo. This protein localizes to the Golgi due to its affinity for Phosphoinositide 4P. Further characterization of this protein will be presented.

Immunohistochemical Studies on the Isolation of Protein 4.1R during Erythropoiesis

W. Nunomura, a M. Hibiuchi, b H. Kato, c Y. Gao, c K. Sawada, a N. Mohandas, a Y. Takakawa a a Biochemistry, Tokyo Womens Medical University, Tokyo, Japan, b Internal Medicine III, Akita University, Akita, Japan, c Red Cell Physiology, NYBC, New York, NY

Two major isoform of protein 4.1R, 135kDa type (4.1R 135) and 80kDa type (4.1R 80) are expressed in erythroblast and in erythrocyte, respectively. Only one difference between these molecules is 4.1R 135 having additional 209 amino acids, named head-piece (HP) at the NH2 termini of 4.1R 80. Based on the in vitro binding assay, we suggested that the Ca2+ regulates the 4.1R 135 binding to membrane proteins through the calmodulin binding to HP. In the present study, we studied on the immunohistochemical localization of 4.1R isoform during the erythropoiesis. [Material and Methods] Isolation and culture of CD34 + cells and immunocytochemical methods were described in previous paper (Blood 2006 107:1366). We prepared the affinity purified rabbit antibodies to HP and to 4.1R. The antibodies to glycoporin A (GPA) and glycoporin C (GPC) were purchased from Sigma. The cell lysate was fractioned by ProteoExtract™ kit (CALBIOCHEM). To examine the effects of Ca2+ on the 4.1R distribution, the cells at D7 (7 days culture after the isolation) cultured in the presence of 5mM EGTA for 40 min. [Results] A. Immunocytochemistry: At D5, the 4.1R 135 broadly distributed in the cells. At D7, the 4.1R 135 localized in the cytoplasm and at the peripheral membrane. At D12, the 4.1R 135 was stained like a dot in the cytoplasm. The GPA and GPC localized at the peripheral membrane after D7. In the EGA treated cells, the 4.1R 135 was strongly stained at the peripheral membrane. B. Immunoblot: The immunoblot detected 4.1R 135 and 4.1R 80 in the membrane fraction at D7. At D12, the 4.1R 80 was more strongly detected in the membrane fraction. However, the band for 4.1R 135 was hardly seen in each fraction. [Conclusion] The localization of 4.1R isoform at peripheral membrane may change during the erythropoiesis. The Ca2+ may regulate the distribution of the 4.1R isoform.

Protein 4.1R Isolom in Blood Cells of Zebrafish (Danio rerio): Analysis of Membrane Binding Properties

W. Nunnoru a, Y. Takakaw a, K. Murata a a Biochemistry, Tokyo Womens Medical University, Tokyo, Japan, a Animal Science, California University at Davis, Davis, CA

Introduction: We have reported that the binding profiles of N-terminal 30kDa (so-called FERM, 4.1-ezrin-radixin-moesin) domain of zebrafish protein 4.1R (ZF4.1R) with human Band3, Glycoporin C (GPC) and p55. A complex of Ca2+ and calmodulin (CaM) did not regulate the 4.1R interactions with these membrane proteins (45 ASCB Meeting Abstract #2608 (2005)). In this study, we found novel isoform of 4.1R containing part of 30kDa domain named BL42 in the blood cells and studied on its binding to membrane proteins of zebrafish and CalMs. [Materials and Methods] Expression of recombinant proteins, BL42, ZF4.1R and GPC (GPCcyt) as a GST-fusion protein and purification of CalMs were performed according to previous reports (JBC 2000 275, 24540). The RNA was isolated from the blood cells with RNA isolation kit (STRATAGENE). RT-PCR was performed with ritanumMTM One-step RT-PCR™ kit (CLONTECH) following the industry instruction. Rabbit antibodies to 4.1R, GPA and p55 of zebrafish were prepared in our laboratory. Protein-protein interaction was measured using IAsys system based on the resonant mirror detection method. [Results] (1) BL42 contains 197 residues of N-terminal and 122 residues of C-terminal of 4.1R. (2) GPC, p55 and 4.1R were detected immunocytochemically in the red cells, (3) The K(D) values of BL42 binding to GPC was ~10 -7 M; (4) The K(D) value for BL42 binding to CalM was ~10 -11 M in the presence and the absence of Ca2+; (5) Ca2+-CalM did not reduce the binding affinity for BL42 to GPCcyt. [Conclusion] Our results suggest that BL42 binding to membrane proteins is not affected by Ca2+-CalM in erythrocytes regardless of Ca2+ level. [Foot Note] The authors WN and KM contributed in equivalent to this study. This study was supported in part by Grant-in-Aid for Scientific Research from the Ministry of Education Culture, Sport, Science and Technology of Japan (#15570123 for NW).

Tissue-specific Alternately Spliced Protein 4.1R Isoforms in the Heart and Blood of the Zebrafish, Danio rerio

K. Murata a, D. Chu a, E. Shimada a, G. Chen a, W. Nunomura a a Animal Science, California University at Davis, Davis, CA, a Environmental Toxicology and Nutrition, Bodega Marine Laboratory, University of California at Davis, Bodega Bay & Davis, CA, a Biochemistry, Tokyo Women’s Medical University, Tokyo, Japan

Introduction: Protein 4.1R (4.1R) has been identified as the major component of the erythrocyte membrane cytoskeleton involved in maintaining the erythrocyte shape and controlling membrane mechanical properties. We have demonstrated the existence of the 4.1R isoform in zebrafish using immunological analysis (ASCB Meeting Abstract #2608, 2005). Particularly in heart tissue, different isoforms are localized in the ventricle and atrium respectively. [Objectives & Methods] To identify the 4.1R isoforms, several CDNs were isolated using RT-PCR. [Results] Full length CDNA encoding zebrafish p4.1R (ZF4.1R) (NM_175084) is composed of putative functional domains that correspond to the human 4.1R N-terminal 30kDa FERM (four-one, ezrin, radixin, moesin) domain, a spectrin and actin binding domain (SABD) and a C-terminal domain (CTD), two unique domains (UD) and an amino acid repeated domain. Five DNA fragments from the blood samples and four from heart sample were amplified. Blood3 encoded the entire FERM domain plus truncated UD and CTD. The Blood4 encoded the FERM domain missing the Ca2+-insensitive calmodulin (CaM) binding site, truncated SABD and CTD missing the p55 binding site. Blood5 encoded a truncated FERM domain missing both CaM binding sites, truncated SABD and truncated CTD. Of note, the Heart3 encoded only truncated UD and whole SABD and CTD. [Conclusions] In the erythrocyte, three unique clones were obtained and their gene products may compensate each other for maintaining the cell shape and its physiological function. The Heart3 gene product may be involved in stabilizing cardiomyoctye structure in the atrium. This suggests that the hetero dimer of spectrin is important in stabilizing the plasma membrane and only SABD in the human 4.1R molecule is essential to bind with hetero dimer of spectrin. These results supported our hypothesis that in the zebrafish, each tissue-specific alternatively spliced gene product of 4.1R will have different functions in different tissues.

Apoptosis and Blood-Testis Barrier during the First Spermatogenic Wave in the Puberlal Rat

J. Cavicchia, 1 A. Morales, 2 F. Mohamed 2 Cuyo Medical School, Institute of Histology and Embryology (IHEM), Mendoza, Argentina, 1 Universidad Nacional de San Luis, Facultad de Quimica, Bioquimica y Farmacia, San Luis, Argentina

In previous works we have found in several animal species that the classically called blood-testis barrier (BTB) or more properly termed Sertoli cell barrier develops in close proximity to zygotene-pachytene spermatocytes. This barrier isolates all developing germ cells from this stage on. It is interesting the exploration of the initial assembling of the BTB during puberty because of a massive physiological apoptosis in the first meiotic cells. Fragments of testsis from 14 to 20 day-old rats were fixed in buffered glutaraldehyde followed by conventional transmission electron microscope techniques. Lanthanum hydroxide was used as an intercellular tracer. TUNEL assay was undertaken in paraffin embedded sections to confirm apoptotic death by light microscopy. When the germ cell line reaches the zygotene-pachytene spermatocyte level and the BTB was not established yet, these cells undergo apoptosis. After the BTB becomes competent, the solid cords turn into the seminiferous tubules and the spermatogenic process continues only with sporadic apoptotic death. The interruption of the sperm cells destined to be isolated in the adluminal compartment prior to BTB assembling may lead to germ cell apoptosis diminishing the efficiency of the first round of spermatogenesis. These events emphasize the importance of a competent BTB in maintaining the progress of spermatogenesis during puberty.

A Novel Serine Palmitoyltransferase Enzyme Isolated from the Emiliania huxleyi

G. Han,1 L. Yan,1 K. Gable,2 W. Wilson,3 J. Harmon,1 T. Dunn3;1 Biochemistry, Uniformed Services University of the Health Sciences, Bethesda, MD, 2Microbiology and Immunology, Uniformed Services University of the Health Sciences, Bethesda, MD, 3Plymouth Marine Laboratory, Plymouth, United Kingdom

Serine palmitoyltransferase (SPT), the committed enzyme of sphingolipid synthesis, is a member of the subfamily of pyridoxal 5'-phosphate (PLP) utilizing enzymes known as the α-oxoamine synthases. Most enzymes in this family, including the prokaryotic SPT protein, are soluble homodimers. In contrast, eukaryotic SPT is an ER-associated heterodimer comprised of the Lcb1p and Lcb2p subunits. Previous studies indicated that there is a single active site at the interface of the heterodimer with critical PLP-binding residues residing in both subunits. The stability of the Lcb2p subunit is dependent on Lcb1p. Furthermore, optimal activity of the yeast Lcb2p-Lcb1p heterodimeric enzyme requires the 80-aa Tsc3p protein. However, the basis of stabilization of Lcb2p by Lcb1p and the role of Tsc3p are not well understood. Remarkably, the recently sequenced genome (Wilson et al. (2005) Science 309, 1090-1092) of E. huxleyi (a virus which infects the marine algae Emiliania huxleyi) revealed the presence of a gene predicted to encode a fusion protein containing of an Lcb2p-like domain fused to an Lcb1p-like domain, hereafter called v-SPT. This v-SPT fusion protein was expressed in yeast and was found to complement the lethality of yeast Δlcb1Δlcb2Δ double mutant. Analysis of the sphingoid base profiles from the v-SPT-repressed Δlcb1Δlcb2Δ yeast mutant raised the possibility that the v-SPT preferentially utilizes myristoyl-CoA (C14) rather than palmitoyl-CoA (C16). This was confirmed in enzymatic assays of the v-SPT. Based on the studies of the v-SPT enzyme, we have constructed and undertaken the expression of yeast Lcb2p-Lcb1p and Lcb1p-Lcb2p fusion proteins. The study of these fusion proteins and their interactions with the yeast Lcb1p, Lcb2p and Tsc3p proteins is providing important insights into the structure and activity of the SPT enzyme, as well as into the role of the Tsc3p protein.

Proteomics for Functional Complexes: Rapid and Direct Access to Intracellular Protein Clusters
C. Lin, Fundamental Science, Pacific Northwest National Lab, Richland, WA

To preserve and regulate biological/physiological functions, intracellular proteins often cluster into biologically active complexes comprised of numerous subunits. Identification of all subunits within complexes is important in understanding the mechanisms and structural requirements of biochemical processes. Membrane-bound proteins are often known to be integral parts of biological-active complexes. Isolation and purification of these proteins are usually tedious and inefficient. In order to minimize dissociation between subunits, and lose of some unknown subunits in many complexes, we have developed a co-fractionation strategy to localize and separate complexes under native states, followed by direct MS/MS analysis of the digested protein fractions. For demonstration, clones of recombinant His-tag ATP synthase were expressed in Shewanella oneidensis MR-1. Membrane proteins were solubilized and separated under native conditions, and separated in order of ionic strength on a Mono Q column. Fractions collected were trypsin digested and forwarded to LC MS/MS (Thermo-Finnigan LCQ). Results of the peptide analysis (Sequest) revealed that not only were ATP synthase subunits eluted in identical fractions, but also proteins within other complexes co-eluted in fractions of different ionic strengths, suggesting the presence of a cluster protein pattern. In parallel, we could detect in-gel ATP hydrolysis activity at the molecular size of the synthase complex (> 450 kD) when membrane fractions were subjected to electrophoresis in native conditions. Two dimensional electrophoresis images of the dissociation-free subunits ranging from 20 kD to 60 kD. We suggest that co-fractionation and electrophoretic separation of membrane proteins in conjunction with powerful mass-spectrometric analysis is a valid and rapid way to gain insight about intracellular protein complexes.

Truncation of Connexin43 Protein Changes Number and Size of Cardiac Gap Junctions
K. Maass1, S. E. Chase1, K. Willecke2;1 Pharmacology, SUNY Upstate Medical University, Syracuse, NY, 2Genetik, Universitaet Bonn, Bonn, Germany

INTRODUCTION: Recent in vitro studies have shown that the carboxy terminal region of the gap junction protein connexin43 (Cx43) acts as a regulatory domain, influencing the interactions with other proteins as well as channel gating. To analyze the functional role of Cx43CT on cardiac gap junctions, mice expressing a mutant isoform lacking most of the Cx43CT (Cx43K258stop) in place of wild type Cx43 have been used in this study. RESULTS: Western blot analysis of whole-cell lysates of adult ventricular tissue revealed a 75% reduction in total Cx43K258stop protein compared to controls. Yet Triton solubility experiments indicated that the mutated protein was more prevalent in the Triton-insoluble fraction when compared to wild-type. Only 14.6% (±3.5%) of Cx43 protein was found in the Triton-insoluble fraction in controls (n=4), whereas 49.2% (±3.7%) of Cx43K258stop protein was detected in the Triton-insoluble fraction (n=3). This seems consistent with previous in vitro data showing a prolonged half-life of truncated Cx43. Co-immunofluorescence analysis of the cardiac intercalated discs further showed a segregation of Cx43K258stop gap junction plaques from adherens junctions or desmosomal proteins. Accordingly, only the wild-type Cx43 protein, but not the truncated mutant (Cx43K258stop), could be co-immunoprecipitated with antibodies against proteins of the mechanical cell junctions or the scaffolding protein ZO1. Both immunofluorescence and TEM analysis revealed a significant reduction in the number of gap junctions in Cx43K258stop hearts (TEM per 100 μm2: 0.14 vs 0.03; n=5 vs. n=3 in controls) while the average size of individual gap junctions was increased and showed a higher scattering (TEM 0.78 μm ±0.11 vs 0.5 μm ±0.02 in controls). TEM analysis further revealed that the overall area covered by gap junctions in Cx43K258stop cardiomyocytes was decreased to 40.8% of the area detectable in controls. CONCLUSION: Cx43CT is essential for regulating stability, localization and size of cardiac gap junctions in vivo.

Site-Directed Mutations Improve High-Level Production and Homogeneous Purification of an Affinity-Tagged Chimeric Human Vitamin K 2,3-Epoxide Reductase- Green Fluorescent Protein Construct (hVKORC1-EGFP) in Pichia pastoris for Structure/Function Analysis
C. G. Bevans,1 H. Tran,2 W. Haase,3 M. Huenberg,2 A. Schauhausen,3 S. Rost,3 A. Fregin,4 C. R. Mueller,2 C. Reinhardt5;1 Structural Biology Department, Max Planck Institute of Biophysics, Frankfurt/Main, Germany, 2Institute of Human Genetics, Biocenter - University of Wuerzburg, Wuerzburg, Germany, 3Molecular Membrane Biology Department, Max Planck Institute of Biophysics, Frankfurt/Main, Germany, 4Institute of Experimental Hematology and Transfusion Medicine, University Clinic Bonn, Bonn, Germany

We recently reported high-level expression and purification of a protein construct (α-flag-his6-pVKORC1-biotag) including enzymatically functional human vitamin K 2,3-epoxide reductase (hVKORC1) (Mol. Biol. Cell 18512). To achieve more rapid and sensitive detection of the construct during production in P. pastoris and purification, we replaced the C-terminal biotag (biotinylation domain, J. Biol Chem 265(18):10327-10330) with a C-terminal StrepIITag-labeled green fluorescent protein (α-flag-his6-pVKORC1-EGFP). Although this protein exhibited vitamin K epoxide reductase (VKOR) activity similar to wild-type hVKORC1, we found evidence of proteolysis by endogenous Pichia proteases and intracellular localization suggesting potential dimerization as previously reported for EGFP (Science 296:913). Site-directed mutagenesis of four amino acids resulting in the new construct α-flag-his6-pVKORC1-EGFPmut eliminated endogenous proteolysis during purification, eliminated dimerization, and maintained wild-type enzymatic activity and sensitivity to the specific VKOR inhibitor warfarin. Biochemical analysis of potential post-translational modifications revealed that the alpha factor (α) targeting sequence, but not glycosylation of the hVKORC1 domain. A total production level of 6.6 mg/L in shaker flask culture was achieved as assessed by EGFP fluorescence relative to commercially available EGFP standard protein.

hScrib: A Key Protein in Cell Polarity
C. Navarro1, N. Vitale1, S. Audebert1, S. Nola1, J. Borg2;1 Randall Division of Cell and Molecular Biophysics, King's College London, London, United Kingdom, 2Centre de Neurochimie, Unité Propre du Centre National de la Recherche Scientifique 2356, Strasbourg, France

α(ΔhVKORC1) (exhibited vitamin K epoxide reductase (VKOR) activity similar to wild-type hVKORC1, we found evidence of proteolysis by endogenous Pichia proteases and intracellular localization suggesting potential dimerization as previously reported for EGFP (Science 296:913). Site-directed mutagenesis of four amino acids resulting in the new construct α-flag-his6-pVKORC1-EGFPmut eliminated endogenous proteolysis during purification, eliminated dimerization, and maintained wild-type enzymatic activity and sensitivity to the specific VKOR inhibitor warfarin. Biochemical analysis of potential post-translational modifications revealed that the alpha factor (α) targeting sequence, but not glycosylation of the hVKORC1 domain. A total production level of 6.6 mg/L in shaker flask culture was achieved as assessed by EGFP fluorescence relative to commercially available EGFP standard protein. Purification is achieved by two-step affinity chromatography using Ni-NTA resin (binding the N-terminal polyhistidine tag of the protein constructs) followed by streptactin resin (binding the C-terminal StrepIITag) to ensure recovery of only full length protein construct. Thin section electron microscopy of immunogold labeled protein constructs in P. pastoris cells confirmed localization of α-flag-his6-pVKORC1-EGFP and α-flag-his6-pVKORC1-EGFPmut in different subcellular compartments in stacked membranes that can be easily and efficiently separated from most other cellular organelles before solubilizing with detergents, eliminating contaminants including proteases and enzymes that could post-translationally modify the protein constructs. Functional analysis of VKOR enzymatic activity of affinity-purified α-flag-his6-pVKORC1-EGFPmut following various washing protocols before elution suggests lipid, bound protein or cofactors are essential to maintain enzymatic function. Support: National Genome Research Network Cardiovascular Diseases (BMWF-DLR-01GS0424) & Baxter Germany
spectrometry analysis of selected bands. We discovered several new protein complexes associated with Sec6: ZO-2 and betaPIX/GIT1/Pak1. Moreover, we were able to demonstrate that the PDZ domains of Sec6 are essential to mediate these interactions. Furthermore, we uncovered a function for the Sec6/betaPIX/GIT1 complex in regulated exocytosis and in neuronal transmission. Moreover, this complex mediates vesicular recycling of Thyrotropin Receptor (TSHR) in thyroid cells and is required for the signalling capacities of the receptor. Taken together, these results suggest a role of Sec6 in various aspects of cell polarity and receptor signalling.

1773 Homologues of Oysterol-binding Proteins Affect Cdc42p- and Rho1p-mediated Cell Polarization in S. cerevisiae

K. G. Kozmikowski, G. Allaró, S. Dighe, C. Behl, Biology and Cell Biology, University of Virginia, Charlottesville, VA, 1Molecular Biology and Biochemistry, Simon Fraser University, Burnaby, BC, Canada, 2University of Virginia, Charlottesville, VA.

Polarized cell growth requires the establishment of an axis of growth along which secretion can be targeted to a specific site on the cell cortex. Disrupting the ordered progression of these processes causes a failure in polarized growth, leading to cells with aberrant morphologies and impaired function. How polarity establishment and secretion are choreographed is not fully understood, though Rho and Rab GTPase-mediated signaling is required. Superimposed on this regulation are the functions of specific lipids and their cognate binding proteins. In a screen for S. cerevisiae genes that interact with Rho-family RalA homologous to mammalian oxysterol-binding protein (OSBP). Other yeast OSH genes (OSBP homologues) had comparable genetic interactions with CDC42, implicating OSH genes in the regulation of CDC42-dependent polarity establishment. Loss of OSH genes (OSHI-OSH7) disrupted cell polarization. However, many proteins involved in the polarized organization of the actin cytoskeleton localized at the bud site independently of OSH gene function. We found that the OSH gene family promotes cell polarization by maintaining the proper localization of the Rho GTPases Cdc42p and Rho1p, and the Rab GTPase Sec4p. The OSH gene family is also necessary for proper septin ring assembly. Disruption of all OSH gene function caused specific defects in polarized exocytosis (e.g., block of Bgl2p-associated secretion), indicating the Osh proteins are collectively required for a secretory pathway implicated in the maintenance of polarized growth. In contrast to the above results, mcOsy OSH gene expression, especially that of OSH4, antagonized a rho1 growth defect. The OSBP1 and OSBP2 domains of Os4p (and other Oshs) differentially affected CDC42- and RHOA-regulated cell polarization, respectively. We propose that Osh proteins collectively mediate transitions between early and late cell polarization events.

1774 Molecular Mechanisms for a Non-mechanical Role of Intermediate Filaments in Apical Polarization

A. S. Ono, F. A. Wuld, A. H. Langshaw, P. J. Salas, Cell Biology and Anatomy, Univ. of Miami School of Medicine, Miami, FL, Pediatrics, Univ. of Miami School of Medicine, Miami, FL.

Intermediate filaments (IFs) are apically polarized in simple epithelia. Such a polarization precedes that of microtubules and actin filaments. Previous studies indicate that keratin 8 (K8) null mice villus enterocytes, fully depleted in IFs, display a complex apical phenotype that includes disorganization of the microtubular architecture and redistribution of microtubule-organizing centers (MTOCs), as well as deocalization of apical membrane proteins. Likewise, overexpression of K8 in transgenic mice abolishes the formation of the brush border. The present study was performed to gain understanding of the molecular mechanisms underlying those phenotypes. We analyzed binding in vitro and in the yeast-two hybrid model between keratins and components of the apical actin scaffold (ezrin) and the MTOC (GCP6). Various mutants of these proteins were studied to identify the binding sites in each molecule, as well as the possible regulation by signaling pathways. The results confirm the localization of the keratin binding site in GCP6 within the C-terminal domain, the presence of a physiological Cdk-1 phosphorylation site, and point at the localization of the corresponding binding site in K8 and K19. The binding sites for dormant ezrin were also identified. In addition, and as a by-product of these studies, the data from the microtubule nucleation also support a model of microtubules by non-centrosomal MTOCs, with centrosomes inactive in 70 % of Caco-2 cells in interphase. The results are consistent with a non-mechanical role of apical keratins in the assembly of apical cytoskeletal scaffolds, specially during the acquisition of epithelial polarity.

Ganglioside GM1 and GM3 Highlight Distinct Lipid Microdomains within the Apical Plasma Membrane of Polarized Epithelial Cells

P. Janich, D. Corbeil, Tissue Engineering Laboratories, BIOTECH, Technical University of Dresden, Dresden, Germany

The domain of epithelial cells is composed of distinct subdomains such as plasma membrane protrusions (microvilli and cilium) and a non-protruding region. It contains as well a variety of lipid species that have distinct physico-chemical properties. Using the cholesterol-binding protein prominin-1 as a specific marker of plasma membrane protrusions we have previously proposed the coexistence of different cholesterol-based lipid microdomains (lipid rafts) within the apical plasma membrane, which might underlie the generation and maintenance of subdomain structures (Kopf et al., NatCellBiol. 2000). This hypothesis was based in part on detergent extraction experiments where prominin-1 was found to be soluble in Triton X-100 but insoluble in another non-ionic detergent, Lubrol WX. However, concerns about the ability of this latter detergent to selectively solubilize membrane proteins and thus discriminate between those associated or not with lipid microdomains have been raised. Here we have re-investigated the issue whether the microvillar plasma membrane contains a distinct set of lipids compared to the planar, non-protruding portion of the apical domain by analyzing the distribution of prominin-1 and ganglioside GM1 and GM3 by fluorescence microscopy. Interestingly, GM1 was found to co-localize with prominin-1 on microvilli irrespective of the staining procedures and fixation methods. On the other hand, the major ganglioside of MDCK cells, GM3, was segregated from prominin-1/GM1-positive microdomains suggesting its localization in the planar region. Regarding the cilium overlapping fluorescent signals of GM1 and prominin-1 were observed. Remarkably, GM3 immuno-reactivity was also observed in the cilium. Taken together our data corroborate the hypothesis that the microvillar plasma membrane subdomains are composed of a lipid microdomain that differs from that found in the non-protruding region, and reveal surprisingly that two plasma membrane protrusions with different structural bases (actin for the microvillus and tubulin for the cilium) are composed of distinct types of lipids.

Species-specific Interactions among β-subunit of the Na+K+-ATPase

V. M. Castro Villella, M. Hidalgo, M. Roldán, R. Fiorentino, E. Del Oso Agustín, R. G. Contreras, M. Cereijido, L. Shoshani; Physiology, CINVESTAV-IPN, Mexico City, Mexico

Due to its peculiar polarized expression, Na+K+-ATPase is responsible for the ionic balance of the cell, as well as for the transcellular movements of biologically important substances. We have previously shown that this polarisation is due to specific adhesion between the β-subunits of two Na+K+-ATPases present in neighboring cells (Shoshani, L. et al. Mol. Biol. Cell 16: 1071-1081, 2005). This interaction is a highly specific one. Thus MDCK cells never express Na+K+-ATPase at contacts with CHO cells, except when these express β1-subunit (i.e. same animal origin than MDCK cells). In the present work we pursue the study of this β1-β1 interaction. Using a mammalian two hybrid assay, we observe that the β1-β1 interaction is a direct one, so that an intermediate molecule may not be required. The high specificity of this interaction is revealed by the fact that transfecting CHO cells with β1-subunit from the rat kidney (CHO-β1a) which has a 97% homology with the dog one, does not achieve the correct polarized distribution of the pump. This is confirmed by studies with NRK-E52 which naturally express rat β1-subunit. However, when these NRK-E52 cells are transfected with dog β1-subunit (NRK-β1b), MDCK cells do express their Na+K+-ATPase in the correct polarized position. Taken together, our results indicate that epithelial cells like MDCK express Na+K+-ATPase in its borders contacting another (i.e. at the lateral membrane), because this is the only position where the β-subunits of their Na+K+-ATPases can interact with each other.

Sec5 and Exo84 Mediate Distinct Aspects of RalA/Exocyst-dependent Cell Polarization

K. E. Gokay, D. J. Sturgill, C. Yeaman; Anatomy & Cell Biology, University of Iowa, Iowa City, IA

Spatial regulation of the secretory machinery and the cytoskeleton is essential for development of cell polarity. Yet mechanisms linking polarized exocytosis and cytoskeletal remodeling are incompletely understood. Here, we show that polarized growth of invasive cell protrusions in prostate tumor cells is dependent on the Exocyst, an octameric complex involved in tethering secretion, indicating the Osh proteins are collectively required for a secretory pathway implicated in the maintenance of polarized growth. In contrast to the above results, multicopy OSH gene expression, especially that of OSH4, antagonized a rho1 growth defect. The OSBP1 and OSBP2 domains of Os4p (and other Oshs) differentially affected CDC42- and RHO1-regulated cell polarization, respectively. We propose that Osh proteins collectively mediate transitions between early and late cell polarization events.

2006 ASCB Annual Meeting Abstracts
RaLα to limit lamellipodium growth. These results suggest that RaLα-binding to different Exocyst subunits orchestrates activation and inactivation of actin regulatory factors necessary for maintaining cell polarity and persistent migration.

1778 Fission Yeast Type I Myosin Regulates Sterol-rich Membrane Organization through the TH1 Tail Domain
M. A. Ellis, F. Chang; Microbiology, Columbia University, New York, NY

The rod-shaped fission yeast Schizosaccharomyces pombe exhibits distinct membrane domains enriched in sterols at growing cell tips and at the medial region of the cell during cytokinesis. We are interested in how these membrane domains are generated and localized. Our lab recently identified myosin type I (myo1p) as a protein needed for membrane organization (Takeda and Chang, Current Biology 2005). Deletion of myo1p results in loss of distinct sterol-rich domains, while myo1p over-expression causes the formation of ectopic membrane domains. Here, we examine what domains of myo1p are needed for this function, focusing our attention on the polybasic TH1 domain. A myo1 mutant lacking the TH1 domain does not rescue the membrane defects in a myo1-deletion mutant. Overexpression of the TH1 domain alone, but not other tail domains of myo1, partially rescues sterol-rich membrane organization and morphology defects in a myo1 deletion background. Overexpression of the TH1 domain can also cause ectopic sterol-rich membrane formation in wild-type cells. In other myosin type I, the tail domain has been shown to interact with acidic phospholipids such as PI2P. We are currently testing if the TH1 domain of myo1p can bind and cluster membrane components to organize a membrane domain in vitro and in vivo.

1779 Lateral Distribution of Proteins and Lipids within Plasma Membrane Is Triggered by Membrane Potential
G. Grossmann,1 M. Opekavara,2 J. Malinsky,1 I. Weig-Meckl,1 W. Tanner,1 Lehrstuhl für Zellbiologie und Pflanzenphysiologie, Universität Regensburg, Regensburg, Germany, 2Laboratory of Cell Reproduction, Institute of Microbiology CAS, Prague, Czech Republic, 3Department of Microscopy, Institute of Experimental Medicine CAS, Prague, Czech Republic

Two non-overlapping lateral raft-based membrane compartments (RMC) within the yeast plasma membrane have recently been described. The first one (RMC P) is occupied by the H- ATPase, Pma1p (Malinka K et al., Mol Biol Cell 18:4427-36, 2003). The other (RMC C) houses Sar1p, and the proton symporters Can1p, Fur4p (Malinka K et al., J Cell Sci 117:6031-41, 2004), and HUP1, the heterologously expressed hoxose/H+ symporter from Chlorella (Grossmann G et al., Eukaryot Cell 5:945-53, 2006). Here we present evidence that ergosterol, the main lipid constituent of the yeast plasma membrane, together with another H+-symporter, tryptophan permease Tat2p, accumulate within RMC C. We also document that the composition of RMC C depends on the membrane potential. After plasma membrane depolarization, H+-symporters (Can1p, Fur4p, HUP1, Tat2p) together with ergosterol leave RMC C within minutes in a reversible manner, whereas Sar1p is not affected. Depolarization in RMC P is not affected either. Depolarized cells are considerably less sensitive to detants, possibly due to the more disorder structure of their plasma membrane. The reported results provide direct evidence for the dynamic character of yeast plasma membrane compartmentation. Financial support of DFG (Schwerpunkt 1108) and of Fonds der Chemischen Industrie is acknowledged. M.O. was also supported from LC545 and GA CR (204/06/0009), and J.M. from AS CR (AV0Z 5039512) and GA CR (304/05/0374).

1780 Transbilayer Distribution of Sphingomyelin Studied by Freeze-fracture Immunoelectron Microscopy
M. Murate, K. Ishii, T. Kobayashi; Sphingolipid Functions Laboratory, RIKEN, Wako, Japan

Little is known about the transbilayer distribution of lipids in biomembranes. The combination of freeze-fracture replica technique with immunocytochemical labelling (Fujimoto et al. J. Cell Sci. 109, 2453 (1996)) is a promising method to directly examine lateral membrane lipid distribution in both model- and biomembranes under electron microscope. In this study, we examined the lateral and transbilayer distribution of sphingomyelin-rich membrane domains in red blood cells and human skin fibroblast. We have employed the sphingomyelin-specific toxin, lysenin, as a probe (Kiyokawa et al. J. Biol. Chem. 280, 24072 (2005)). In red blood cells, sphingomyelin was distributed exclusively in the outer leaflet of the membrane. Interestingly, in human red blood cells, sphingomyelin is 12-15 % of total phospholipids sphingomyelin-rich domain whose radius was around 30 nm was observed. In contrast, in sheep erythrocytes (sphingomyelin comprises 40-50 % of total phospholipids), sphingomyelin was randomly distributed. Unlike red blood cells, sphingomyelin was distributed both in the outer and the inner leaflet of the plasma membrane from human skin fibroblasts, although majority of the lipid was in the outer leaflet. On the outer leaflet, sphingomyelin formed domains with 30 nm radius. Interestingly, sphingomyelin forms distinct clusters in the inner leaflet of the plasma membrane. Our results thus indicate that sphingomyelin exists both in the inner and outer leaflet of the plasma membranes in fibroblasts but not in red blood cells.

1781 Clustering of Raft-associated Proteins in the External Membrane Leaflet Modules Internal Leaflet H-Ras Diffusion and Signaling
S. Eisenberg,1 D. E. Shvartsman,2 M. Ehrlich,3 Y. J. Hemi,1 Neurobiochemistry, Tel Aviv University, Tel Aviv, Israel

One of the least-explored aspects of cholesterol-enriched (rafts) in cells is the coupling between such domains in the external and internal monolayers and its potential to modulate transbilayer signal transduction. Here, we employed FRAP to study the effects of antibody-mediated patching of influenza hemagglutinin (HA) proteins (raft-resident wild-type HA and glycosylphosphatidylinositol-anchored HA, or the nonraft mutant HA(2A520)) on the lateral diffusion of internal-leaflet raft and nonraft Ras isoforms (H-Ras and K-Ras, respectively). Our studies demonstrate that clustering outer-leaflet or transmembrane raft-associated HA proteins (but not their nonraft mutants) retards the lateral diffusion of H-Ras (but not K-Ras), suggesting stabilized interactions of H-Ras with the clusters of raft-associated HA proteins. These modulations were paralleled by specific effects on the activity of H-Ras, but not of the nonraft K-Ras. Thus, clustering raft-associated HA proteins facilitated the early step whereby H-Ras is converted to an activated, GTP-loaded state, but inhibited the ensuing step of downstream signaling via the Mec/Erk pathway. We propose a model for the modulation of transbilayer signaling by clustering of raft proteins, where external clustering (antibody or ligand-mediated) enhances the association of internal-leaflet raft proteins with the stabilized clusters, promoting either enhancement or inhibition of signaling.

1782 Competitive Recruitment to the Mga5/Galectin Lattice and Caveolin Raft Domains Regulates EGFR Signaling and Tumor Growth
P. Lajoie,1 E. A. Parttridge,2 G. Guay,1 S. Nim,2 J. G. Goetz,1 J. Pawling,2 A. Lagana,4 J. W. Dennis,2 I. R. Nabi1

1Cellular and Physiological Sciences, University of British Columbia, Vancouver, BC, Canada, 2Mount Sinai Hospital, Samuel Lunenfeld Research Institute, Toronto, ON, Canada, 3Pathologie et Biologie Cellulaire, Université de Montréal, Montréal, PQ, Canada, 4Biotechnology Research Institute, National Research Council of Canada, Montreal, PQ, Canada

Goïgi N-acetylgalactosaminyltransferase V (Mga5) generates galectin-binding β1,6GlcNAc-branched N-glycans on receptors that promote surface residency and cytokine responsiveness. Cav1 levels in tumors from PyMT transgenic mice correlate inversely with tumor growth rates in Mga5- mice but not Mga5- littermates, suggesting that downregulation of Cav1 relieves growth restrictions imposed by Mga5 deficiency. Cav1 is a broad-specificity negative regulator of cytokine signaling and lipid raft endocytosis, and a putative tumor suppressor. Reduced Cav1 expression in Mga5- mammary tumor cells restores sensitivity to EGF, but not sensitivity to TGF-β, epithelial-mesenchymal transition, or fibronectin fibrillogenesis, that are all rescued by Mga5 expression in Mga5- cells. Cav1 inhibited raft-dependent endocytosis and diffusion of cell surface GM1-bound cholera toxin. Galectin binding promotes surface residency of EGF in a dynamic microdomain-specific available for ligand activation that is dominant to Cav1-dependent sequestration and negative regulation. These results support Cav1 as a conditional tumor suppressor, whose loss is advantageous when β1,6GlcNAc branched N-glycans are below a threshold for optimal lattice formation. Supported by the Canadian Institutes of Health Research (CIHR)

1783 Association of Caveolin-1 with Gap Junctions in Chicken Lens Fiber Cells
S. Biyas1, C. Zhou,1 W. Peng,1 W. Lo2,3

1Anatomy & Neurobiology, Morehouse School of Medicine, Atlanta, GA, 2Ophthalmology, Emory University, Atlanta, GA

Caveolin-1 is a signature protein of caveolar lipid rafts in many cell types. Our preliminary study showed that a large amount of Cav-1 was found in lens fiber cells of various species studied. Since caveolae are rarely observed in lens fiber cells, we wanted to determine what non-caveolar domains are associated with Cav-1 in fiber cells of chicken embryonic and adult lenses. Immunoblotting analysis showed that Cav-1 has a molecular weight of ~24 kDa containing and β forms in fiber cells. Immunofluorescence study revealed that Cav-1 was expressed early in the lens pit and lens vesicle during lens formation at E2.4. Although Cav-1 was also labeled in the anterior epithelium, the elongating posterior epithelial cells (i.e., nuclear fiber cells) exhibited a significant dotted labeling pattern along cell membranes at E5.7. At E8-20, and in the adult lens, the unique dotted pattern of Cav-1 labeling was more prominent in middle cortical fiber cells.

2006 ASCB Annual Meeting Abstracts

328
as they underwent the maturation process from superficial to deep cortical regions of the lens. We hypothesize that Cav-1 is associated with gap junctions because both Cav-1 and connexins show similar dotted labeling pattern in the specialized ball-and-socket interlocking domains as well as flat membrane of fiber cells. Double immunofluorescence labeling showed that Cav-1 was partially co-labeled with Cx43 and Cx36 in fiber cells, suggesting that Cav-1 may be selectively associated with different gap junction populations in the lens. By using freeze-fracture immunogold labeling (FRIL) for high resolution localization, Cav-1 was indeed localized in many, but not all, gap junctions of the ball-and-socket domains and flat membrane examined. Since Cav-1 is in close proximity to the heterogeneous distribution of cholesterol in fiber gap junctions, it is currently under investigation with filipin cytochemistry in conjunction with freeze-fracture TEM and FRIL. Supported by NEI/NIH grant EY05314.

1784 Correlating Membrane Nanostructure with IgE Receptor Crosslinking in Mast Cells: An Ultrafast Dynamics Approach
A. M. Davey,1, E. D. Sheets,2,3 and A. A. Heikal2,3; 1Department of Chemistry, The Pennsylvania State University, University Park, PA; 2The Huck Institutes of the Life Sciences, University Park, PA; 3Department of Bioengineering, The Pennsylvania State University, University Park, PA

Cholesterol-rich microdomains (or “lipid rafts”) within the plasma membrane have been hypothesized to exist in a liquid-ordered phase and play important roles in cell signaling. However, these microdomains are difficult to examine using conventional imaging in living cells under physiological conditions. Here, we exploit the exquisite sensitivity of excited-state dynamics and anisotropy to probe the correlation between IgE crosslinking and the nanostructure of lipid microdomains in suspended RBL mast cells. Our experimental approaches encompass integrated biophotonic techniques such as confocal microscopy, two-photon fluorescence lifetime imaging (FLIM), and fluorescence polarization anisotropy for imaging the dynamics of the lipid marker, dil-C18, and Alexa 488-labeled IgE. Extensive crosslinking of the high affinity receptor for IgE (FcRII) triggers co-redistribution of molecules associated with cholesterol-rich microdomains (e.g., saturated lipids [the lipid analog dil-C18] and lipid-anchored proteins) with crosslinked FcRII in well-defined patches. Upon IgE-FcRII crosslinking, we observe an enhanced fluorescence lifetime with reduced segmental mobility of both probes, which indicates a restrictive and highly ordered membrane environment within these patches. Our results support the hypothesis that FcRII moves into more ordered membrane domains for further signaling and establishes excited-state dynamics imaging as an effective approach for probing local membrane heterogeneity and nanostructure. Currently, we are investigating the structure-function relationships between the plasma membrane of adherent mast cells and fluorescently labeled signaling molecules during IgE stimulation under physiological conditions.

1785 Immobilization of the Type XIV Myosin in Toxoplasma Membranes Is Cholesterol-dependent
T. M. Johnson, Z. Rajfur, K. Jacobson, C. Beckers; Cell and Developmental Biology, University of North Carolina at Chapel Hill, Chapel Hill, NC

Toxoplasma gondii is an intracellular protozoan parasite of animal cells that can cause severe disease or death in fetuses and immunocompromised individuals. Movement of the parasite within the infected animal as well as actual host cell penetration is believed to be facilitated by the interaction of F-actin, associated with a cell surface adhesin of the parasite, and myosin-A, a type XIV myosin. Myosin-A is found in a complex, called the glideosome, with three additional subunits: a myosin light chain (MLC1) and two accessory proteins, GAP45 and GAP50. The latter is an integral membrane glycoprotein that is required for the movement of the inner membrane complex (IMC), a membrane system underlying the parasite plasma membrane. In order for net movement to be produced by this motility system it is critical that the glideosome is firmly anchored within the plane of the IMC. Using FRAP analysis of YFP-tagged GAP50 we demonstrate here that this is indeed the case. While YFP-tagged cytoplasmic proteins or proteins associated with the IMC through acylation demonstrate a rapid recovery after photobleaching, we could not detect recovery of photobleached GAP50-YFP, suggesting that this protein is immobilized within the plane of the IMC membrane. This immobilization is not due to the interaction of GAP50 with other IMC proteins as judged by failure to detect these by chemical cross-linking or co-immunoprecipitation. The use of different detergent extraction approaches reveals that the glideosome, as well as the whole IMC membrane, is solubilized by Triton X-100 in a temperature-dependent fashion. We find that the IMC contains a significant proportion of cholesterol and that an redistribution of the glideosome is sensitive to depletion of cholesterol. These findings suggest that the glideosome is found in a cholesterol-rich membrane fraction that may constitute a large portion of the IMC.

1786 The Involvement of Lipid Microdomains in the Activation of Sperm from the Nematode Caenorhabditis elegans
J. J. Fraire-Zamora, C. C. Castillo, A. Cortez, H. Miyata, R. A. Cardullo; Biology, UC Riverside, Riverside, CA

In the nematode Caenorhabditis elegans fertilization takes place in the spermatheca of hermaphrodites. Subsequent to ovulation, or following ejaculation from a male inside the hermaphroditic uterus, the round and sessile spermatids undergo spermiogenesis resulting in the extension of a pseudopod and the initiation of motility. Although nematode sperm lack both a flagellum and an acrosomal vesicle, it has been hypothesized that these cells must undergo similar physiological changes to acquire motility and the ability to fertilize an egg. We are particularly interested in the recruitment and activation of signaling molecules with lipid microdomains (lipid rafts) in the plasma membranes of nematode gametes as these have been implicated in sperm from other taxa, most notably deuterostome lineages. In C. elegans, the current genetic model for spermiogenesis suggests a physical interaction of both membrane and cytoplasmic proteins to form a multi-component complex. Specifically, novel proteins involved in spermatic activation and the acquisition of motility (SPE-6, SPE-8, SPE-12, SPE-19, SPE-27 and SPE-29) are thought to play a central role in the signal transduction pathways that represses or triggers spermiogenesis. Using large-scale isolation methods and in vitro activators, we have demonstrated that caveolin is found in the plasma membrane of spermatids. The presence of caveolin in the plasma membrane suggests the involvement of lipid microdomains in spermiatic activation.

1787 Coordinated Volume and Lateral Cell Surface Reduction Are Linked with Isochoric Lumen Initiation in MDCK Three-Dimensional Cell Culture
A. Velgodszky, A. Ferrari, R. Korschewski; Institute of Biochemistry, ETH Zurich, Zurich, Switzerland

Epithelial cells embedded in collagen matrices can proliferate and differentiate into cysts, lumen-enveloping growth arrested monolayers of polarized cells. Despite the fact that lumen formation is an essential and conserved process during metazoan ontogeny, the cellular mechanisms causing the formation of a lumen and thus a novel cell free compartment and apical surface are unresolved. Therefore we investigated the conditions upon which lumens between epithelial cells are generated. Lumens in the MDCK model system were always initiated in aggregates containing 2 to 10 cells. Solid aggregates of more than 10 cells had no residual probability to initiate a lumen. Lumen initiation, where the lumen was smaller than a single cell volume, occurred in a solid aggregate and was followed by cell proliferation and lumen enlargement. Formation of initial lumens was isochoric as it occurred without changes in the total aggregate volume. The reasons for this were reductions of volume and specifically of the cell-cell contact surface of individual cells in the aggregates. The increases of cells in the aggregate did not change during lumen initiation. Thus, we exclude some possibilities to form a lumen and demonstrate that predominantly the reduction of the cell-cell contact surface and cell volume are linked with lumen initiation. We conclude that the novel apical surface was formed at cost of the cell-cell contact surface and that initial lumen filling involves membrane trafficking. Thus neither apoptosis nor exclusively lipase pumping caused lumen initiation indicating the presence of a discrete trafficking dependent step in lumen formation during cystogenesis.

1788 Suppression of dru2Δ Cold-Sensitive Growth and Ergosterol Localization Defects by kes1Δ
B. Muthusamy, T. R. Graham; Biological Sciences, Vanderbilt University, Nashville, TN

Dru2p is a lipid binding protein, its relation with the heterogeneous distribution of cholesterol in fiber gap junctions is currently under investigation with filipin cytochemistry in conjunction with freeze-fracture TEM and FRIL. Supported by NEI/NIH grant EY05314.

CD21 Expression in B-cells Inhibits Uptake of αCD19 Immunconjugate Therapy of Lymphomas

G. S. Ingle, 1 P. Chan, 1 J. P. Stephan, 1 J. Elliott, 3 C. Nelson, 1 M. Kljavin, 1 L. Giere, 4 W. Chang, 5 S. J. Scales 1; 1Molecular Biology, Genentech, Inc., South San Francisco, CA, 2Assay and Automation Technology, Genentech, Inc., South San Francisco, CA, 3Pathology, Genentech, Inc., South San Francisco, CA, 4Protein Chemistry, Genentech, Inc., South San Francisco, CA, 5Translational Oncology, Genentech, Inc., South San Francisco, CA

CD19 and CD21 function as co-receptors to enhance signaling through the B cell receptor in response to antigen. CD19 and CD21 are also expressed in various B-cell cancers including Non-Hodgkin’s lymphoma, diffuse large B-cell lymphoma, and follicular lymphoma. An ideal immunconjugate for therapy of such lymphomas could comprise a B-cell specific antibody conjugated to a cytotoxic drug such that the drug would only be released inside the B-cells rather than non-specifically into the circulation, but this requires that the immunconjugate be sufficiently internalized to be efficacious. We therefore performed internalization experiments using immunofluorescence and FACS in various B-cell lines to evaluate the suitability of antibodies to CD19 and CD21 for immunconjugation. We found that αCD19 antibodies do not significantly internalize, which could explain the lack of efficacy of certain αCD19 conjugates in clinical trials. We observed that αCD21 antibodies are efficiently internalized, which could explain the efficacy of αCD21 conjugates in clinical trials. We also observed that αCD19 antibodies are efficiently internalized, which could explain the efficacy of αCD21 conjugates in clinical trials. We also observed that αCD21 antibodies are efficiently internalized, which could explain the efficacy of αCD21 conjugates in clinical trials. We also observed that αCD21 antibodies are efficiently internalized, which could explain the efficacy of αCD21 conjugates in clinical trials. Ligand-dependent Cellular Trafficking of Lactoferrin Receptor

V. Lopez, S. L. Kelleher, B. Lonnerdal; Nutrition, UC Davis, Davis, CA

Lactoferrin (Lf) is an iron-binding protein secreted by macrophages to modulate diverse cellular functions. We have previously demonstrated that Lf binds to its receptor in human placenta cells; however, downstream effects of ligand stimulation on lactoferrin receptor (LfR) have not been investigated. We hypothesized that Fe-saturated-(holo) Lf and Fe-saturated-(apo) Lf, which have profoundly different conformations, will elicit different cellular events resulting from their interaction with LfR. BeWo cells were treated with holo-Lf or apo-Lf. For siRNA, mastoparan and cycloheximide studies, 125I- apo- and holo-Lf uptake was measured. Plasma membrane proteins were biotinylated and LfR abundance was assessed by SDS-PAGE. Biotinylated apo- and holo-Lf, Lamp1, a lysosomal marker, and LfR localization were visualized with confocal microscopy. Knockdown of LfR protein significantly decreased 125I-apo-Lf uptake and 125I-holo-Lf to a lesser extent compared to controls. Mastoparan significantly decreased 125I- apo- and holo-Lf uptake compared to controls. Cell surface abundance of LfR protein significantly increased in the presence of apo-Lf, while holo-Lf had no effect. Cycloheximide significantly increased 125I- apo-Lf uptake after 3 h, compared to cells without cycloheximide. However, 125I-holo-Lf uptake was significantly decreased with cycloheximide compared to untreated cells. After 20 min, LfR co-localized with Lamp1 when stimulated with holo-Lf and to a lesser extent with apo-Lf. At 1 h, LfR co-localized with biotinylated apo- and holo-Lf and by 2 h biotinylated apo-Lf co-localized with the nucleus whereas biotinylated holo-Lf was absent. In summary, LfR mediated apo-Lf uptake, potentially due to intracellular degradation by the lysosomal compartment, whereas apo-Lf was transported to the nucleus. Our data suggest that internalization of apo- and holo-Lf was clathrin-dependent and changes in plasma membrane abundance were ligand-dependent. De novo LfR protein synthesis was a requisite for holo-Lf uptake, potentially due to intracellular degradation by the lysosomal compartment, whereas apo-Lf was transported to the nucleus. Our data suggest that internalization of apo- and holo-Lf mediates subsequent LfR compartmentalization, which in turn may elicit different cellular responses. Supported by NIH HD43240.

Ferritin Induces Degradation of the Transferin Receptor

L. Horonchik, M. Westling-Resnick; Genetics and Complex Diseases, Harvard School of Public Health, Boston, MA

Previous studies from our laboratory identified “ferritinian” (NCI #306711) as an inhibitor of transferrin (Tf) mediated iron uptake [Brown et al. (2004) Chem Biol 11: 407-416]. To further characterize the drug’s mechanism of action, rates of Tf uptake and recycling were studied in HeLa and HEK293T cells. Neither trafficking pathway was influenced by ferritinian, but [125]Tf and [55Fe]-Tf binding experiments showed that the number of cell surface Tf receptors was significantly reduced after 4 h incubation with the drug. Western blot analysis revealed this effect was due to a time- and dose-dependent loss in receptor protein levels and that the presence of the ligand holo-Tf protected against ferritinian-induced Tf receptor degradation. Immunofluorescence microscopy experiments showed a corresponding decrease in Alexa-red Tf uptake after pre-treatment with ferritinian, while internalization of FITC-dextran and D-glucosamine was unaffected, confirming that endocytosis was not disrupted by the drug and supporting its specificity of action towards the Tf receptor. Ligand-independent Tf receptor degradation induced by ferritinian was blocked by inhibitors of both proteosomal (MG132, epoxomicin) and lysosomal (bafilomycin A1, leupeptin, chymostatin) function. Filipin also interfered with ferritinian-induced Tf receptor degradation, suggesting that a clathrin-independent pathway is involved. The properties associated with ferritinian inhibition of iron uptake point to a ligand-independent pathway for receptor down-regulation and degradation that could potentially be exploited to therapeutically limit iron acquisition by cancer cells.

Differential Endocytic Sorting of Myelin Proteins

C. Winterstein, A. Handwerk, W. Moebius, K. Nave; Biology, Molecular Cell Biology, Johannes Gutenberg-University, Mainz, Germany, 3Max-Planck-Institute for Experimental Medicine, Goettingen, Germany

Myelin is a sophisticated compartmentalised membrane system produced by oligodendroglial cells, which is reminiscent of the segmented membrane domains of polarised cells. Development and maintenance of the myelin sheath requires coordination of protein and lipid synthesis and directed trafficking towards the axon. To unravel membrane trafficking mechanisms we have established assay systems to resolve vesicular transport pathways of myelin components. Using confocal microscopy and subcellular fractionation, we separated oligodendroglial membrane compartments and made use of SNAREs as markers to map oligodendroglial trafficking pathways. Since the major myelin protein PLP appears to be enriched in a lysosome-like compartment, we hypothesised that endocytosis plays a role in the sorting of myelin components. Cell-surface biotinylation and antibody uptake assays performed with oligodendroglial cells demonstrate that myelin proteins are indeed subject to endocytosis. Interestingly, the endocytic route followed by PLP seems to be distinct from that of other myelin proteins, such as MAG and MOG. We have dissected these endocytic pathways and are addressing whether re-association of endocytosed PLP and other myelin components to the plasma membrane (myelin) occurs.

1797

GIPC Is Recruited by APPL to Peripheral TrkA Endosomes and Regulates TrkA Trafficking and Signaling

T. Varsano, M. Dong, L. Niesman, H. Gacula, X. Lou, T. Ma, J. R. Testa, J. R. Yates, M. G. Faragher; Cellular and Molecular Medicine, University of California San Diego, La Jolla, CA, 2Human Genetics Program, Fox Chase Cancer Center, Philadelphia, PA, 3Department of Cell Biology, Scripps Research Institute, La Jolla, CA

GIPC is a PDZ protein located on peripheral endosomes. Previously we showed that it binds to the juxtamembrane region of the TrkA NGF receptor and that overexpression of GIPC interferes with NSF gating (Lou et al. MBC 12: 615, 2001). To shed light on the mechanism by which GIPC affects TrkA signaling we used IPs and mass spec to identify additional GIPC-binding proteins. We found that endogenous GIPC binds to the C-terminus of APPL, a Rab5 binding protein, which is a marker for signaling endosomes. When TrkA is activated, GIPC and APPL translocate from the cytoplasm and bind to incoming, endocytic vesicles carrying TrkA concentrated at the tips of the cell processes. GIPC, but not APPL, dissociates from these peripheral endosomes prior to, or during their trafficking from the juxtanuclear region where they acquire EEAP. GIPC’s interaction with APPL is essential for recruitment of GIPC to peripheral endosomes and for TrkA signaling, because a GIPC PDZ domain mutant that cannot bind APPL, or APPL knockdown with siRNA inhibits NGF-induced GIPC recruitment, MAP kinase activation and neurite outgrowth. GIPC is also required for efficient endocytosis and trafficking of TrkA because depletion of GIPC slows down endocytosis and trafficking of TrkA and APPL to early EEAP endosomes in the juxtanuclear region. We establish that GIPC, following its recruitment to TrkA by APPL, is required for efficient trafficking of TrkA and APPL to early endosomes and for optimal TrkA signaling from peripheral endosomes. The ability of GIPC to form homodimers and bind to APPL, TrkA, and several additional receptors (TrkB, IGF, TGFβIII, dopamine D2, LH and β1Adrenergic receptors) suggests that GIPC might play a similar role in the assembly of protein complexes required for endocytosis and signal transduction of other receptors.

1799

A Screen of Rab GTPases Reveals Different Endocytic Pathways of Human Adenovirus Type 2 and Type 35

M. Gastadelli, N. Linka, B. T. Amstutz, F. DiGenmaro, M. Havenga, K. Boucke, U. F. Greber; 2Department of Zoology, University of Zurich, Zurich, Switzerland, 2Crucell Holland BV, Leiden, The Netherlands

Human Adenoviruses (Ads) are nonenveloped DNA viruses causing respiratory or gastrointestinal diseases. The species B adenovirus serotype Ad35 and the species C serotypes Ad2 and Ad5 interact with different cellular receptors. Hematopoietic cells are largely refractory to species C Ad infection due to low levels of the attachment receptor CAR. In epithelial cells, Ad2 and Ad5 attach to CAR by virtue of protruding fiber proteins, and bind integrins with the proximal penton base proteins stimulating clathrin-mediated viral uptake, and accessory macrophagocytosis. In contrast, the fibers of Ad35 attach to the membrane cofactor CD46. CD46 attachment leads to endocytosis of Ad35 into both epithelial and hematopoietic cells, independent of dynamin 2, a large GTPase involved in the regulation of clathrin-mediated endocytosis, caveolar endocytosis and phagocytosis. In epithelial cells, Ad35 endocytosis was blocked by amiloride and protein kinase C inhibitors, which inhibit macrophagocytosis. Endocytic vesicles containing Ad35 acquired lysobisphosphatidic acid and lysosomal associated membrane protein 1 (Lamp1) which are markers of late endosomes and lysosomes. In contrast, vesicles containing Ad2 and Ad5 were deficient of early and late endosomal markers. An infectious virus entry screen of Rab GTPases revealed that the infection of HeLa cells was independent of Rab5, which is implicated in the regulation of membrane traffic from the plasma membrane to early endosomes. One particular Rab protein was found to regulate the entry of both species B and C Ads, indicating that there is at least one common trafficking knoll of clathrin-dependent endocytosis and macrophagocytosis. These results allow us to explore the mechanistic links between different endocytic trafficking routes in the context of viral infections.

The Intracellular Fate of Campylobacter jejuni

R. O. Watson, J. E. Galan; Yale University-School of Medicine, Section of Microbial Pathogenesis, New Haven, CT

Campylobacter jejuni is the leading cause of bacterial food-borne illness in the United States and one of the most common causes of diarrhea worldwide. Both in vivo and in vitro studies have demonstrated that C. jejuni invades intestinal epithelial cells. Although C. jejuni internalization is believed to be important in campylobacter pathogenesis, little is known about the intracellular fate of C. jejuni.
Cytostome/cytopharynx. The described lipid raft/caveolae profiles of mammal cells. In this work we have demonstrated the occurrence in electron microscopy and immunofluorescence microscopy. Expression of clathrin and flotillin in (LIT with 10% inactivated fetal calf serum). Five-day-old culture parasites were submitted to protein and lipid extraction. The protein extract was used in Western blotting and dot blotting.

The EGF family member ErbB2 is overexpressed in 25-30% of human breast cancers. While ErbB2 is normally highly concentrated on the cell surface, the antibiotic geldanamycin (GA)

Clathrin-independent Endocytosis of ErbB2 in SKBr3 Cells

N. Porat-Shliom,1 Y. Kloog,2 J. Donaldson1; 1NHLBI/LCB, National Institutes of Health, Bethesda, MD, 2Neurobiochemistry, Tel-Aviv University, Tel-Aviv, Israel

pathway is inhibited by amiloride that characterizes it as macropinocytic in nature. These observations, plus the fact that CD94/4/NKG2A endocytosis functions independently of dynamin affect the cell surface levels or internalization of CD94/NKG2A, suggesting an involvement of a non-clathrin dependent endocytic pathway. Nystatin treatment had no effect on its endocytosis.

CD94/NKG2A receptors are internalized into early EEA-1+ and Rab5+ endosomes, but failed to co-localize with transferrin receptor, Rab-4, -7, or -11. We then investigated if any of the CD94/NKG2A, but does reduce cell surface expression, suggesting that the actin cytoskeleton is required for CD94/NKG2A exocytosis but not endocytosis. Immunostaining revealed that the CD94/NKG2A protein containing the translocation and the catalytic domain of DT but an alternative receptor binding domain causes the same phenotype. These large Rab5 positive vesicles are early endosomes as demonstrated by the colocalization with the Rab5 effector EEA1. It was shown that a Rab5 mutant, S34N, inhibits fusion between early endosomes and its overexpression induces the accumulations of very small endosomes. After treatment of GFP-Rab5-S34N positive cells with DT, only small punctate endosomes were present demonstrating that large endosomes induced by DT are excessively fused. Ammonium chloride and bafilomycinA, a specific inhibitor of the vacuolar proton ATPase, increases the endosomal pH in cells and blocks DT translocation. We demonstrate that in Rab5 positive endosomes, ammonium chloride and bafilomycinA block the toxin effect on endosome fusion. In HeLa cells, nocardazole blocks the transport from ECV to late endosomes but it doesn’t change the morphology of the Rab5 positive endosome treated with DT. We can conclude that the DT translocation domain promotes endosome fusion following membrane insertion and may be coupled with toxin entry into the cytosol.

A Novel Clathrin- and Lipid Raft Independent Macropinocytic Pathway for Internalization of the CD94/NKG2A Inhibitory Receptor in Natural Killer Cells

M. Masilamani, M. E. Prieto, F. Ilorrego, J. E. Coligan; Receptor Cell Biology Section, Laboratory of Allergic Diseases, NIAID, NIH, Rockville, MD

An adequate immune response must be tightly regulated to avoid poor responses on one hand or excessive inflammation leading to autoimmunity on the other. This is achieved through a balance of activating and inhibitory signals that control immune cell function. Natural Killer (NK) cells are poised to kill any cell that they encounter without prior sensitization. CD94/NKG2A is an inhibitory receptor expressed by NK cells that recognizes HLA-E expressed by normal cells, but often downregulated on diseased cells. CD94/NKG2A expression needs to be constantly maintained, as any ligand-induced downregulation of CD94/NKG2A would permit activation receptor(s) induced killing of normal bystander cells. The mechanism by which CD94/NKG2A continuously recycles to and from the cell surface maintains steady state levels as has been described. We show that latrunculin A does not affect the internalization of cell surface CD94/NKG2A, but does reduce cell surface expression, suggesting that the actin cytoskeleton is required for CD94/NKG2A exocytosis but not endocytosis. Immunostaining revealed that the CD94/NKG2A protein is internalized into early EEA-1+ and Rab5+ endosomes, but failed to co-localize with early EEA-1, Rab-4, -7, or -11. We then investigated if any of the known endocytic pathways are involved in the internalization of CD94/NKG2A. Hypertonic treatment of cells with sucrose and expression of dominant negative dynamin K44A mutant did not affect the cell surface levels or internalization of CD94/NKG2A, suggesting an involvement of a non-clathrin dependent endocytic pathway. Nystatin treatment had no effect on its endocytosis suggesting that lipid raft dependent pathways are not likely involved. The CD94/NKG2A vesicles co-localized with endocytosed dextran indicating involvement of a pinocytic pathway. This pathway is inhibited by amiloride that characterizes it as macropinocytic in nature. These observations, plus the fact that CD94/NKG2A endocytosis functions independently of dynamin indicate that CD94/NKG2A utilizes a previously described endocytic pathway.

H-Ras Traffics through and Regulates Clathrin-independent Endocytosis

N. Porat-Shliom,1 Y. Kloog,2 J. Donaldson1; 1NHLBI/LCB, National Institutes of Health, Bethesda, MD, 2Neurobiochemistry, Tel-Aviv University, Tel-Aviv, Israel

Despite their high sequence homology and their ability to bind and activate the same down stream effectors in vitro, the biological outputs in vivo of Ras proteins are distinct. Accumulating data indicates that these differences are a result of diverse post translational modifications of Ras isoforms, and differential localization within the cell that serve as platforms for different down stream effector activation. For example, H-Ras, but not K-Ras, was shown to activate Raf1 from endosomes in the clathrin-dependent pathway. However little is known about the role of the clathrin-independent pathway in H-Ras trafficking and signaling. The clathrin-independent pathway includes the internalization of distinct cargo proteins such as the Major Histocompatibility Complex I (MHC). Clathrin-independent derived cargo enters in distinct endosomes that then fuse with early endosomes that contain clathrin-dependent derived cargo, e.g., transferrin. In HeLa cells, at this stage, cargo might be targeted for degradation or recycled back to the plasma membrane via the characteristic recycling tubular endosomes. We sought to identify whether H-Ras use the clathrin-independent pathway as an additional platform for trafficking and signaling. Using immunofluorescence and localization studies, we demonstrate that H-Ras co-localizes with the clathrin-independent pathway markers, Arf6 and MHC1. Furthermore, we were able to show that the dominant active mutant of H-Ras (G12V) stimulates the clathrin-independent pathway and increases the levels of MHC1 internalization, while it has no effect on transferrin internalization. These results establish the clathrin-independent pathway as a route for H-Ras trafficking not only as a cargo molecule but also as a potential regulator. Since signaling molecules such as Src and Erk are also present on these endosomes, our next goal is to examine whether this pathway could provide an additional unique platform for Ras signaling.

Clathrin-independent Endocytosis of ErbB2 in SKBr3 Cells

D. J. Barr, A. G. Ostermeyer-Fay, D. A. Brown, Biophysics and Cell Biology, SUNY Stony Brook, Stony Brook, NY

The EGFR family member ErbB2 is overexpressed in 25-30% of human breast cancers. While ErbB2 is normally highly concentrated on the cell surface, the antibiotic geldanamycin (GA) triggers internalization and downregulation of the receptor. It is known that GA treatment of cancer cells overexpressing ErbB2 leads to transport to early endosomes and multi-vesicular bodies. However, the initial internalization pathway remains uncharacterized. In the present study we examined GA-induced internalization and trafficking of ErbB2 in SKBr3 human breast cancer cells. We found that GA-induced ErbB2 internalization was not blocked by dominant negative forms of dynamin or eps15. Further, internalization was not inhibited by the clathrin
inhibitor chlorpromazine, and ErbB2 did not colocalize with transferrin during initial internalization. Internalization was blocked by filipin treatment, and the receptor colocalized with cholera toxin beta subunit and GPI-anchored proteins after 5 minutes of internalization. The receptor did not accumulate in enlarged endosomes induced by constitutively active ARF6. Taken together, these results suggest ErbB2 was internalized by a non-clathrin mediated pathway. After 30 minutes of internalization, ErbB2 colocalized with markers of early and late endosomes and lysosomes, confirming earlier reports. In summary, we showed that in GA-treated cells, ErbB2 is internalized by a clathrin-independent mechanism, but soon merges with the classical endocytic pathway.

Active Arf6 Recruits ARNO/cytohesin GEFs to the PM through an Interaction with Their PH Domains Leading to Sequential Arf Activation
L. A. Cohen,1 P. Varani,1 A. Houda,2 T. Balla,2 J. Donaldson,1 Laboratory of Cell Biology, NIH/NHLBI, NIH, Bethesda, MD, 1Endocrinology and Reproduction Research Branch, NICHD, NIH, Bethesda, MD
ARNO is a guanine nucleotide exchange factor (GEF) for the Arf family of small GTP binding proteins. Although in biochemical assays ARNO prefers Arf1 as a substrate over Arf6, its localization in cells suggests an interaction with Arf6 at the plasma membrane (PM). In this study we examined the relationship between ARNO and its potential substrates Arf1 and Arf6. In HeLa cells, ARNO activation of Arf6 was twice as efficient as activation of Arf6. By contrast, an unambiguous exchange factor for Arf6, EFA6, was two times more effective at activating Arf6 than Arf1. These results suggest that ARNO prefers Arf6 as a substrate when expressed in HeLa cells. On the other hand, co-expression of Arf6 and ARNO in HeLa cells led to a dramatic recruitment of ARNO onto the PM and endocytic structures. Curiously, the Q67L (GTP locked) mutant of Arf6 was also capable of recruiting ARNO onto cellular membranes, whereas ARNO’s substrate mimic, the T27N (GDP bound) mutant, could not. Remarkably, ARNO co-immunoprecipitated with Arf6-GTP, and this binding was mediated not by the sec7 domain, but through the PH domain of ARNO. The interaction with Arf6 is conserved in other ARNO/cytohesin family members, and requires both inositol phospholipids and GTP. There is ample evidence for involvement of "Golgi-associated" Arfs at the PM as we and others have observed that expression of ARNO and Arf1 in COS-7 cells induces membrane ruffles and marcupinosomes where both proteins are transiently associated. Hence, this study reveals a novel downstream effector for Arf6-GTP, which is the recruitment of ARNO family GEFs capable of activating cytosolic Arfs such as Arf1 in a sequential cascade at the PM.

The Arf6 GEF BRAG2 Regulates Cell Adhesion by Controlling Endocytosis of β1 Integrins
J. L. Dunphy,1 P. Melancon,1 J. E. Casanova1; 1Cell Biology, University of Virginia, Charlottesville, VA, 1Cell Biology, University of Alberta, Edmonton, AB, Canada
Accumulating evidence indicates that Arf6 regulates post-endocytic trafficking of a subset of membrane proteins, including β1 integrins. Integrins have been reported to enter an Arf6-positive endosomal compartment that is morphologically and functionally distinct from early endosomes, and dominant negative Arf6 mutants impairs recycling of these proteins to the plasma membrane, suggesting that this process requires active Arf6. BRAG2 is a recently described guanine nucleotide exchange factor (GEF) with specificity for Arf6 in vitro. We have identified a second, longer isoform of BRAG2 (BRAG2b), which like BRAG2a is ubiquitously expressed. Both isoforms activate Arf6 in vivo, as determined using a pulldown assay for Arf6-GTP. To determine the role of BRAG2 in Arf6 function, we performed an RNAi analysis using sh1 integrin trafficking as a readout. Knockdown of Arf6 itself led to a 30% reduction in surface expression of β1 integrin and impaired both attachment and spreading of cells on fibronectin. Surprisingly, knockdown of BRAG2a and BRAG2b resulted in a 50% increase in surface β1 and a corresponding enhancement of both attachment and spreading. This effect was specific for integrin, as surface levels of transferrin receptor remained unchanged, and was also specific for BRAG2, as knockdown of a different Arf6 GEF, ARNO, had no impact on adhesion. Intriguingly, BRAG2b contains a functional clathrin box near its N-terminus, suggesting that it interacts directly with the clathrin endocytic machinery. Together these results indicate that Arf6 regulates both integrin internalization and recycling and that BRAG2 selectively regulates the endocytic step.

1808
Regulation of CXC4 Receptor Trafficking and Signaling by ARF6
C. C. Moore, J. L. Benovic; 1Biochemistry and Molecular Biology, Kimmel Cancer Center, Thomas Jefferson University, Philadelphia, PA
CXCR4, a chemokine G protein-coupled receptor essential for neuronal, cardiovascular, and hematopoietic cell migration towards stromal-derived factor (SDF), has recently emerged as a critical player during cancer cell migration. This receptor is involved in the vigorous pursuit of factors that regulate the CXCR4-SDF axis. We demonstrate here that ARF6 regulates cell surface levels of CXCR4 following SDF stimulation, as measured by an ELISA assay. Expression in HEK293 cells of either wild-type ARF6 or a GTPase-deficient ARF6 mutant (Q67L) inhibits CXCR4 receptor internalization, whereas a GDP/GTP exchange-deficient ARF6 mutant (T27N) promotes CXCR4 internalization. Consistent with these data, agonist-dependent CXCR4 internalization is altered following modulation of endogenous ARF6 by EFA6, an ARF6-selective guanine nucleotide exchange factor (GEF), or by ACAP1, an ARF6-selective GTPase activating protein (GAP). In addition to regulating CXCR4 receptor trafficking at the cell surface, ARF6 regulates SDF-promoted MAPK signaling at the membrane, in both HEK293 and MDA-MB-361 cells, a metastatic breast cancer cell line. These data demonstrate ARF6 regulation of the CXCR4-SDF axis, and thus may have implications on dysregulated CXCR4 trafficking and signaling during cancer metastasis.

Cholesterol Controls Own Endocytosis through Rab11
M. Takahashi,1 M. Fukuda,2 A. Otta,3 T. Koyabashii; 1Molecular Membrane Biology Lab., RIKEN, Saitama, Japan, 1Spinophilin Functions Lab., RIKEN, Saitama, Japan, 2Research Center, Tohoku University, Miyagi, Japan, 3Department of Biotechnology, University of Tokyo, Tokyo, Japan
The endocytic pathway of cholesterol is not well understood. Recently we have shown that fluorescent poly(ethylene glycol)-derivatized cholesterol (PEG-Chol) is preferentially partitions to cholesterol-rich membrane domains (Sato et al. J. Biol. Chem. 279, 23790 (2004)). Membrane impermanent nature of PEG-Chol made it possible to follow the endocytic route of cholesterol-rich domains of the plasma membrane in living cells. In this study, we examined the internalization of PEG-Chol in subconfluent and confluent Chinese hamster ovary (CHO) cells. In subconfluent cells, PEG-Chol was accumulated to the recycling endosomes whereas in confluent cells the fluorescence was observed in the early endosomes. Endocytosis of fluorescent sphingomyelin but not lactosylceramide was similarly affected, suggesting that the endocytosis of a limited number of cargos are affected by cell confluency. Our biochemical and histochemical analysis showed the dramatic increase of cellular cholesterol in confluent cells. The crucial role of cellular cholesterol in cell-confluency dependent endocytosis was confirmed by the observation that the fluorescent sphingomyelin was transported to the recycling endosomes when cell surface cholesterol was depleted in confluent cells. In order to understand the mechanistic network(s) of cell confluency- and cholesterol-dependent endocytosis, we examined intracellular distribution of small GTPases. Our results indicate that rab11 but not rab4, altered intracellular localization in a cell confluency-associated manner and this alteration was dependent on cell cholesterol. In addition, the expression of a constitutive active mutant of rab11 changed the endocytic route of PEG-Chol from early to recycling endosomes. These results thus suggest that cholesterol controls endocytic routes of certain cargos including cholesterol itself through rab11.

EHD1 Regulates LDL Internalization and Cholesterol Homeostasis
N. Nalavsky,1 J. Rahajeng,1 D. Rapaport,2 M. Horowitz,2 B. G. Coon,3 R. C. Aguilar,3 P. L. Sorgen,1 S. Caplan1; 1University of Nebraska Medical CenterDept. of Biochemistry and Molecular Biology, University of Nebraska Medical Center, Omaha, NE, 2Dept. of Cell Research and Immunology, Tel Aviv University, Ramat Aviv, Israel, 3Department of Biological Sciences, Purdue University, West Lafayette, IN
Endocytic transport is a key mechanism for controlling the subcellular distribution of free cholesterol and the endocytic recycling compartment (ERC) is an important organelle that stores cholesterol and regulates its transport. Rab11, which regulates transport via the ERC, regulates the exit of cholesterol from this organelle. EHD1, a member of the C-terminal EH-domain family of proteins that regulates recycling and coordinates transport via the Rab11 pathway, has also been reported to play a role in free cholesterol transport through the ERC. To directly assess the role of EHD1 on cholesterol homeostasis and cellular distribution, we utilized mouse embryonic fibroblasts derived from EHD1 knockout mice (MEF +/-). Surprisingly, these cells displayed reduced levels of cellular free and esterified cholesterol, an effect that could be rescued by overexpression of wild-type EHD1. To understand the reduction in intracellular cholesterol in the absence of EHD1, we turned our focus to low density lipoprotein (LDL) and its receptor, LDLR, a major source of cellular cholesterol intake. We observed higher levels of LDLR on the plasma membrane of MEF +/- cells, yet LDL itself was internalized at a slower rate in these cells. Furthermore, in cells lacking EHD1, lipopid droplets appeared greatly reduced in size, suggesting that less esterified cholesterol and triglycerides were present in lipid droplets. Two-hybrid binding assays and NMR spectroscopy suggest that the EH-domain of EHD1 interacts

333
with Epsin, a well-characterized component of the endocytic pathway that contains NPF motifs and regulates receptor internalization. Our data indicates that EHDI affects cholesterol homeostasis and lipid droplet biogenesis by controlling internalization of LDL receptor, possibly through interactions with NPF-containing endocytic regulators such as Epsin.

1811
Rab8-dependent Recycling Promotes Endosomal Cholesterol Removal in Normal and Sphingolipidosis Cells
M. D. Linder, 1 R. Uronen, 1 M. Hölttä-Vuori, 2 P. van der Sluijs, 2 J. Peränen, 3 E. Ikonen 1; 1Institute of Biomedicine, University of Helsinki, Helsinki, Finland, 2Department of Cell Biology, University Medical Center Utrecht, Utrecht, The Netherlands, 3Institute of Biotechnology, University of Helsinki, Helsinki, Finland

The mechanisms by which low-density lipoprotein (LDL)-cholesterol exits the endocytic pathways are not well understood. The process is defective in Niemann-Pick type C (NPC) disease in which cholesterol and sphingolipids accumulate in late endosomal compartments. This is accompanied by defective cholesterol esterification in the endosomal reticulum and impaired ATP-binding cassette transporter A1 (ABCA1)-dependent cholesterol efflux. We show here that overexpression of the recycling/exocytic Rab GTPase Rab8 rescued the late endosomal cholesterol deposition and sphingolipid mistrafickling in NPC fibroblasts. Rab8 redistributed cholesterol from late endosomes to the cell periphery and stimulated cholesterol efflux to the ABCA1-ligand apolipoprotein A-I (apoA-I) without increasing cholesterol esterification. Depletion of Rab8 from wild-type fibroblasts resulted in cholesterol deposition within late and recycling endosomal compartments. This cholesterol accumulation was accompanied by impaired traffic of LDL-cholesterol from endocytic compartments to apoA-I, and could not be bypassed by liver X receptor activation. Our findings establish Rab8 as a key component of the regulatory machinery that leads to ABCA1-dependent removal of cholesterol from endocytic circuits.

1812
Multiple Degradation Pathways for Misfolded Mutants of the Yeast Plasma Membrane ATPase, Pma1
Y. Liu, S. Sirazade, A. Chang; Molecular, Cellular, and Developmental Biology, University of Michigan, Ann Arbor, MI

To understand protein sorting and quality control in the secretory pathway, we have analyzed intracellular trafficking of the yeast plasma membrane ATPase, Pma1. Pma1 is ideal for such studies because it is a very abundant polytopic membrane protein, and its localization and activity at the plasma membrane are essential for cell viability and growth. We have tested whether the cytoplasmic amino and carboxy terminal domains of Pma1 carry sorting information. As the sole copy of Pma1, mutants truncated at either N- or C-termini are targeted at least partially to the plasma membrane and have catalytic activity to sustain cell viability. In addition, the mutants are detected to be degradation pathways. Strikingly, N- and C-terminal Pma1 mutants are differentially recognized for degradation at distinct cellular locales. C-terminal mutants are recognized for destruction by ER-associated degradation. By contrast, N-terminal mutants escape detection by ERAD entirely, and undergo endoplasmic degradation after apparently normal cell surface targeting. Both N- and C-terminal mutants are conformationally abnormal, as revealed by increased sensitivity to trypsin cleavage, but are able to assemble to form oligomers. We propose that different quality control mechanisms may assess discrete domains of Pma1 rather than a global conformational state.

1813
Overcoming the KDEL Sequence and Escaping the ER: A Lumenal Golgi Complex Protein
A. N. Perry, 1 Z. Wang, 2 D. Russel, 2 Z. Cabarova, 2 P. E. Scherer, 3 E. L. Snapp 2; 1Syracuse University, Syracuse, NY, 2Anatomy and Structural Biology, Albert Einstein College of Medicine, Bronx, NY

Cellular proteins localize to specific organelles through a combination of targeting sequences and their corresponding receptors. For example, proteins with the lumenal endoplasmic reticulum (ER) retrieval sequence, KDEL, interact with the KDEL receptor in post ER compartments to be returned with the KDEL receptor to the ER. Here, we report a lumenal protein with a KDEL sequence that is inefficiently retrieved to the ER and exhibits a predominantly Golgi complex localization pattern. We used immunofluorescence and GFP-fused constructs to characterize protein localization. The steady-state distribution the protein is not due to protein overexpression or saturation of the KDEL receptor machinery. A co-expressed ER-RFP-KDEL protein does not escape the ER. Truncation and chimera experiments reveal that trafficking of the protein to the Golgi complex is mediated by a previously uncharacterized sorting sequence. The sequence is recognized by several cell types, consistent with a general machinery that overrides the KDEL sequence and creates a steady-state Golgi complex localization pattern for lumenal proteins.

Our results may help explain how a number of resident lumenal ER proteins escape into the secretory pathway and suggest that escape is a regulated event.

1814
Transition of Galactosyltransferase 1 from Trans-Golgi Cisterna to the Trans Golgi Network (and Back) Is Signal Mediated
B. Schaub, B. Berger, E. Berger, J. Rohrer; Physiology, University of Zurich, Zurich, Switzerland

The Golgi apparatus (GA) is the organelle where complex glycan formation takes place. In addition, it is a major sorting site for proteins destined for various sub-cellular compartments or for secretion. Here we investigate β1,4-galactosyltransferase 1 (galT) and α2,6-sialyltransferase 1 (siaT), two trans-Golgi glycosyltransferases, with respect to their different pathways in monensin treated cells. Upon addition of monensin galT dissociates from siaT and the GA and accumulates in swollen vesicles derived from the trans-Golgi network (TGN), as shown by co-localization with TGN46, a specific TGN marker. We analyzed various chimeric constructs of galT and siaT with confocal fluorescence microscopy and time lapse video-microscopy as well as Optiprep density gradient fractionation. We show that the first 13 amino acids of the cytoplasmic tail of galT are necessary and sufficient for its localization to swollen vesicles induced by monensin. We also show that the monensin sensitivity resulting from these 13 amino acids can be conferred to siaT, which leads to the rapid accumulation of the galT-siaT chimera in swollen vesicles upon monensin treatment. Based on these data we suggest that cycling between the trans-Golgi cisterna and the trans-Golgi network of galT is signal mediated.

1815
Identification of Go Palmitoyl Acyl Transferase
R. Tsutsui, 1 Y. Fukata, 1 M. Fukata 1; Laboratory of Genomics and Proteomics, National Institute for Longevity Sciences, Aichi, Japan

Palmitoylation is the post-translational lipid modification of proteins and regulates subcellular trafficking and function of proteins. Several a subunits of trimeric G proteins (Gα) including Gαi, Gαq and Gαs are palmitoylated and their membrane localization and functions are dynamically regulated by this reversible palmitoylation. However, the responsible enzymes for palmitoylation of Gα (G-PAT) remain unclear. Here we report the enzymes that promote Gα palmitoylation in vivo. HEK293 cells were co-transfected with the cDNA for Gα and twenty-three cDNA clones encoding DHHC palmitoyl transferase family members. Only DHHC3 and 7 enhanced the incorporation of [3H]palmitate into Gαq and Gαs. We also found that DHHC3, 7, 8 and 21 enhanced Gαq palmitoylation. Mutations at cysteine residues 9 and 10 of Gαq abolished the increased palmitoylation by DHHC3 and 7. Overexpression of DHHC3 or 7 relocated Gαs and Gαq to the peri-nuclear region, suggesting that DHHC-3 and 7 regulate subcellular localization of Gαs and Gαq through palmitoylation. Time-lapse imaging revealed that treatment with 2-bromomalpinolate, an inhibitor of thioacylation, dispersed Gαq from the plasma membrane to cytoplasm, indicating that palmitate on Gαq dynamically turns over. These observations suggest that several DHHC proteins are physiological G-PATs, regulating Gα subcellular localization and functions.

1816
Activity-dependent Regulation of PSD-95 Palmitoylation by P-PAT
J. Noritake, 1,2 Y. Fukata, 1 M. Fukata 1; Laboratory of Genomics and Proteomics, National Institute for Longevity Sciences, National Center for Geriatrics and Gerontology, Obu, Japan, 2Department of Cell Pharmacology, Nagoya University Graduate School of Medicine, Nagoya, Japan

PSD-95 palmitoylation is the posttranslational lipid modification of proteins and regulates the membrane targeting and function of proteins. Palmitoylation is unique in that it is reversible and dynamically regulated by specific extracellular signals. Several studies have reported that proteins containing a DHHC cysteine-rich domain mediate palmitoyl acyl transferase activity in yeast. We recently isolated 23 mammalian DHHC proteins and found that a subset of DHHC proteins, P-PAT subfamily, regulate synaptic function through PSD-95 palmitoylation. However, the regulatory mechanism of PSD-95 palmitoylation by P-PAT remains to be clarified. Here, we monitored palmitoylation level of endogenous PSD-95 in cultured hippocampal neurons by several methods including acyl-biotin-exchange and metabolic labeling with [3H]palmitate. Treatment with 2-bromomalpinolate, an inhibitor of palmitoylation, reduced PSD-95 palmitoylation, but not Gαq palmitoylation, suggesting that PSD-95 palmitoylation dynamically turns over in neurons. We also found that inhibition of glutamate receptor activity by kynuretate, APV or CNQX robustly enhanced PSD-95 palmitoylation. This enhancement was significantly blocked by the dominant negative form of P-PAT, suggesting that P-PAT activity is negatively regulated downstream of glutamate receptors. Also, PSD-95 dynamics examined by TIRF (Total Internal Reflection Fluorescence) imaging will be discussed.
The Cdc50p-Drs2p Putative Aminophospholipid Translocase and the Arf GAP Gcs1p Are Involved in Vesicle Formation in the Retrieval Pathway from Yeast Early Endosomes to the TGN

H. Sakane,1 T. Yamamoto,2 K. Tanaka2; 1Institute for Genetic Medicine, Hokkaido University, Sapporo, Japan, 2Institute for Genetic Medicine and Life Science, Hokkaido University, Sapporo, Japan

Drs2p, the catalytic subunit of the Cdc50p-Drs2p putative aminophospholipid translocase, has been implicated in conjunction with the Arf1 signaling pathway in the formation of clathrin-coated vesicles (CCVs) from the TGN. Herein, we explore another vesicle transport pathway in which Cdc50p-Drs2p is involved, we searched for Arf regulator genes whose mutations were synthetically lethal with cdc50Δ, and identified the Arf GAP gene Gcs1. Most of the examined transport pathways in the Cdc50p-depleted gcs1Δ mutant were nearly normal, including endocytosis to vacuoles, carbonylase Y sorting, and the processing and secretion of invertase. In contrast, this mutant exhibited severe defects in the early endosome-to-TGN transport pathway; proteins that are transported via this pathway, such as the v-SNARE Snc1p, the t-SNARE Tlg1p, and the clathrin synthase III subunit Chs3p, accumulated in TGN-independent aberrant membrane structures. Electron microscopy and immunolabeling revealed that the Cdc50p-depleted gcs1Δ mutant accumulated large abnormal double-membrane structures containing Snc1p. We extended our analyses to clathrin adaptors and found that the Cdc50p-depleted gcs1Δ gga2Δ mutant and the gcs1Δ apl2Δ (the β1 subunit of AP-1) mutant exhibited growth defects and intracellular accumulation of Snc1p-containing membranes. These data suggest that Gga1pGga2p and AP-1 were also involved in the early endosome-to-TGN transport pathway. Interestingly, Ap4lp-GFP, the γ subunit of AP-1, was mislocalized in the Cdc50p-depleted gcs1Δ mutant, suggesting that Cdc50p-Drs2p and Gcs1p are involved in the AP-1 recruitment to endosomal membranes. Our results suggest that Cdc50p-Drs2p plays an important role in the Arf1p-mediated formation of CCVs via AP-1 for retrieval from early endosomes to the TGN.

Endocytic Recycling in Yeast Is Regulated by Putative Phospholipid Translocases and the Ypt31p32p-Rcy1p Pathway

N. Furuta, K. Fujimura-Kamada, T. Yamamoto, K. Saito, K. Tanaka; Institute for Genetic Medicine, Hokkaido University, Sapporo, Japan

Most cell types display an asymmetric distribution of phospholipids across the plasma membrane bilayer. The regulation of this asymmetry is believed to require the action of phospholipid translocases (PLTs). In budding yeast, putative PLTs are encoded by the DRS2 gene family of type 4 P-type ATPases. The homologous proteins Cdc50p, Lem3p, and Cre1p are potential non-catalytic subunits of Drs2p, Dnr1p, and Dnt2p, and Dnt3p, respectively, and these putative putative PLTs share an essential function for cell growth. To explore the cellular function(s) in which PLTs are involved, we constructed and dissected the cdc50-30 lem3Δ cre1Δ temperature-sensitive mutant (cdc50-30 mutant). The temperature-sensitive growth of the cdc50-30 mutant was suppressed by overexpression of YPT31/32, two genes that encode Rab family small GTases that are involved in both the exocytic and endocytic recycling pathways. In the cdc50-30 mutant, the recycled exocytic v-SNARE Snc1p intracellularly accumulated in an aberrant structure, whereas it was predominantly localized to the plasma membrane in the wild-type. Additionally, TGN/early endosome t-SNARE Tlg1p accumulated in a similar structure. This aberrant compartment is probably derived from early endosomes, since the accumulated Snc1p colocalized with the endocytic tracer FM4-64 after a short incubation. Furthermore, abnormal membranous structures containing Snc1p were observed in the cdc50-30 mutant by electron microscopy. In contrast, the cdc50-30 mutant did not exhibit defects in the exocytic pathways. Genetic studies suggested that the YPT31/32 effectors RCT1 and CDC50 function in the same signaling pathway, and simultaneous overexpression of CDC50 and DRS2 restored growth as well as the plasma membrane localization of Gfp-Snc1p in the rct1Δ mutant. In addition, Rcy1p coimmunoprecipitated with the Cdc50p-Drs2p complex. We propose that the Ypt31p32p-Rcy1p pathway regulates putative PLTs to promote formation of vesicles destined for the TGN from early endosomes.

Synaptophysin I Selectively Specifies the Exocytic Pathway of Synaptobrevin2/VAMP2

D. Bononomi,1 L. Rusconi,1 C. Colombo,1 F. Benfenati,2 F. Valorta1; 1Department of Neuroscience, San Raffele Scientific Institute and "Vita-Salute" University, Milan, Italy, 2Department of Neuroscience, The Italian Institute of Technology and Department of Experimental Medicine, Genova, Italy, 3The Italian Institute of Technology, Research Unit of Molecular Neuroscience, Milan, Italy

Biogenesis and recycling of synaptic vesicles are accompanied by sorting processes that preserve the molecular composition of both the vesicles and the compartments from which these organelles are generated. However, the mechanisms underlying selective protein sorting during synaptic vesicle assembly remain elusive. In this study we address the targeting of synaptobrevin2/VAMP2, a critical component of the synaptic vesicle fusion machinery, in a heterotypic context where its sorting is not confounded by the presence of other neuron-specific molecules. Ectopically-expressed synaptophysin 1 controls the intracelluar distribution of VAMP2 with no detectable effects on the targeting of other membrane proteins, including exogenous synaptotagmin I and markers of the endosomal recycling pathway. Along the secretory pathway synaptophysin I ret總是 VAMP2 to vesicles exhibiting a low propensity for constitutive exocytosis. These results indicate that interfacial interactions between the sorting determinants of synaptic vesicle proteins can operate independently of a neuronal context and implicate the association of VAMP2 with synaptophysin I in the specification of the pathway of synaptic vesicle biogenesis.

Identification of a Novel Protein Trafficking Regulator in Saccharomyces cerevisiae

L. Tu, D. K. Banfield, Biology, Hong Kong University of Science and Technology, Hong Kong

We identified VPS754 as a multi-copy suppressor of the lethality associated with the loss of SFT1— which encodes an essential Golgi SNARE protein in Saccharomyces cerevisiae. Although Vps74p is a non-essential yeast protein it shares ~40% amino acid sequence identity with two mammalian Golgi phosphoproteins: GM3x3alpha/GDP34 and GM3x3beta/GDP34 and recognizable homologues have been identified in many eukaryotes - with the exception of plants. We have determined that Vps74p contains both cytoplasmic and Golgi-membrane associated pools and that it binds to the Golgi coat protein complex COP (companion) as well as to certain SNAREs. In addition, null mutants of VPS74 are sensitive to calcitran white, indicating that the cell walls of these cells are defective. Consistent with this, processing of the GPI-anchored protein Gas1p, which is required for proper cell wall assembly and morphogenesis, was altered in vps74 deletion cells. We have established that the Gas1p processing defect observed in vps74 deletion cells is attributable to the mislocalization and rapid degradation of a subset of mannose transferases. Our current data suggests that one of the roles of Vps74p may therefore be to function as a protein sorting receptor for COP1. Acknowledgements This work was supported by grants from the Hong Kong Research Grants Council to DKB (HKSUST440/02M and HKSUST607/05M).

The Role of Protein Acylation in Cell-Surface Transport of Multi-spanning Membrane Proteins

K. K. Y. Lam,1 M. Davey1, N. G. Davis,1 E. Combea1; 1centre for Molecular Medicine and Therapeutics, Department of Medical Genetics, University of British Columbia, Vancouver, BC, Canada

Many cell surface proteins, such as ion channels, transporters, and receptors, are trafficked from intracellular storage to the plasma membrane in response to specific extracellular cues. This process of regulated trafficking is crucial to cellular function, but it is not well characterized. A number of multi-spanning membrane proteins in the yeast Saccharomyces cerevisiae undergo regulated trafficking, thus providing models to study the underlying mechanisms. These proteins include several amino acid permeases (AAPs) and the chitin synthase Chs3p, which are transported to the cell surface in response to external nutrient conditions and cell stress, respectively. We have previously identified Pfa4p as a genome-wide fluorescence screen for mutants that missort Chs3. Pfa4p is a DHHC palmitoyltransferase responsible for modifying Chs3 at the ER and facilitating Chs3 export from this compartment (Lam et al., 2006. J Cell Biol 174: 19). To complete this work we have recently performed aкрыл mutagenesis screen for mutants that affect the trafficking of Chs3. Our current data suggests that one of the roles of Pfa4p may therefore be to function as a protein sorting receptor for COP1. Acknowledgements This work was supported by grants from the Hong Kong Research Grants Council to DKB (HKSUST4105/02M and HKSUST4607/05M).

Moving Transporters into Intracellular Storage: Identifying New Components of the Early Endosome Sorting Machinery in Saccharomyces cerevisiae

Y. Tam, M. Davey, E. Combea; Medical Genetics, University of British Columbia, Vancouver, BC, Canada

Many cell surface proteins, such as ion channels, transporters, and receptors, are trafficked from intracellular storage to the plasma membrane in response to specific extracellular cues. This process of regulated trafficking is crucial to cellular function, but it is not well characterized. A number of multi-spanning membrane proteins in the yeast Saccharomyces cerevisiae undergo regulated trafficking, thus providing models to study the underlying mechanisms. These proteins include several amino acid permeases (AAPs) and the chitin synthase Chs3p, which are transported to the cell surface in response to external nutrient conditions and cell stress, respectively. We have previously identified Pfa4p as a genome-wide fluorescence screen for mutants that missort Chs3. Pfa4p is a DHHC palmitoyltransferase responsible for modifying Chs3 at the ER and facilitating Chs3 export from this compartment (Lam et al., 2006. J Cell Biol 174: 19). To further characterize this lipid modification, the 22 cysteine residues in Chs3 that can serve as potential palmitoylation sites were mutated. Our data suggest that Chs3 is palmitoylated at an internal cysteine. Interestingly, Pfa4p has also recently been shown to modify several AAPs at a C-terminal consensus sequence that is not present on Chs3 (Roth et al., 2006. Cell 125:1003). Moreover, through genome-wide screens of the yeast deletion collection, we find that Pfa4p may influence the cell surface activity of one of these AAPs. A thorough comparison between AAP and Chs3 trafficking may therefore elucidate whether Pfa4p-mediated palmitoylation plays a more general role in regulating the transport of multi-spanning membrane proteins. The similar lipid modifications of AAPs and Chs3 could direct common sorting events that may also be relevant for transporter translocation in higher cells.
In the yeast *Saccharomyces cerevisiae*, the chitin synthase Chs3 is maintained in Golgi/endosome-derived intracellular pool and is transported to the plasma membrane under extracellular stress. Transport of Chs3 to the cell surface requires Chs6. In chs6Δ cells, cell surface translocation of Chs3 can be restored by mutations in the clathrin adaptor complex, AP-1. This suggests that AP-1 normally sorts Chs3 into intracellular compartments. However, how AP-1 regulates Chs3 transport or whether other factors are involved in this process is still unknown. To uncover genes that are specific for the transport of Chs3 between early endosomes and the TGN, we have deleted the CHS6 gene in yeast knockout collections and screened for double deletion mutants that have restored translocation of Chs3 to the plasma membrane, using a novel fluorescence assay. This approach has identified known AP-1 components, endosomal transport factors as well as uncharacterized genes. To delineate functionally related genes that work in the AP-1 and/or other pathways, epistatic miniarray profiling and hierarchical clustering have been performed on the set of top mutants. We have characterized two novel factors, Cby1 (Chs6 bypass suppressor 1), and Cby2, which interact with AP-1 and participate in the AP-1-dependent retrograde transport of Chs3.

An AP-1-interacting Sorting Signal Directs Intracellular Transport of Yeast Chitin Synthase III

T. Starr; University of California, Berkeley, Berkeley, CA

Sorting signals present in proteins that traverse the secretory pathway are essential for the proper localization of these proteins within the cell. The composition and location of these signals within proteins determine act on the signals and thus determine where the proteins are delivered. We identified a sorting signal that is required for the intracellular retrieval of yeast Chitin Synthase III (Chs3p). This signal is similar to signals found in other proteins that are known to interact with clathrin adaptor protein complexes (APs). Tandem affinity purification (TAP) of AP-1 revealed an interaction between AP-1 and Chs3p; mutation of the signal reduces this interaction. To determine the direction in which the sorting signal may transport Chs3p, we made fusions between a region of Chs3p containing the sorting signal and the vacuolar protein alkaline phosphatase (ALP) to make Chs3-ALP. The Chs3-ALP fusion protein is transported to the vacuole and this event is dependent on the specificity of the AP-1-interacting signal. We are currently working towards understanding the role of the compartment(s) of the signal sorting directs Chs3-ALP en route to the vacuole.

1824

Di-leucine Motifs Bind to the Gamma/Sigma1 Hemicomplex of Adaptor Protein-1 (AP-1) and Expose the Yxxφ Binding Site on the Mu1 Subunit

I. Lee, B. Dorney, S. Kornfeld; Internal Medicine, Washington University School of Medicine, St. Louis, MO

The adaptor protein AP-1, a heterotetramer containing γ1/μ1/ε1 subunits, is known to bind cargo proteins via two types of motifs: tyrosine-based Yxxφ and di-leucine-based E(D)XXLL motifs. While it is well established that Yxxφ motifs bind to the μ1 subunit, di-leucine motifs have been reported to bind to μ1, β1, and, based on the yeast-three hybrid technique, to the γ1/ε1 hemicomplex (Janvier et al., JCB, 163:1281-1290, 2003; Coleman, et al., J. Virology, 79:2066-2078, 2005). To approach this issue from a biochemical standpoint, we have expressed each subunit of AP-1 individually as well as the β1/μ1 and γ1/ε1 hemicomplexes in insect cells and used GST-pulldown assays to determine the binding properties of these subunits. We find that the γ1/ε1 hemicomplex binds the di-leucine motifs of several proteins quite strongly, whereas binding to β1 and μ1 is extremely weak by comparison. Under these binding conditions, there was no interaction with GST alone. The binding to γ1/ε1 does not require the hinge or appendage domain of γ1, implicating the trunc region as the site of interaction. Peptide competition experiments indicate that the various di-leucine motifs bind to the same site on γ1/ε1. We have also found that binding of a di-leucine motif-containing peptide to intact cytosolic AP-1 results in enhanced accessibility of the μ1 subunit, as determined by increased sensitivity to tryptic cleavage. This is associated with increased binding of Yxxφ peptides. In the case of CI-MPR cytoplasmic tail, which contains both types of motifs, we found that binding of the Yxxφ motif to the μ1 subunit of cytosolic AP-1 is totally dependent on the presence of the di-leucine motif. We conclude that di-leucine motifs bind the γ1/ε1 hemicomplex of AP-1 and induce a conformation change in the heterotetramer that facilitates binding of Yxxφ motifs to the μ1 subunit.

1825

 Trafficking and Retention of a Plasmodium Falciparum Protein, Pfs16, in the Parasitophorous Vacuole Membrane

S. Eksi, L. Ma, M. T. Mcintosh, D. Elliott, J. Gibbons, K. C. Williamson; 1Biology, Loyola University Chicago, Chicago, IL, 2Medicine, Yale University, New Haven, CT, 3Biological Sciences, University of Illinois at Chicago, Chicago, IL

Red blood cell invasion and parasitophorous vacuole (PV) formation in *Plasmodium falciparum* is critical for the development and pathogenesis of malaria, a continuing global health threat. As the intraerythrocytic parasite grows from 1um to 5um diameter there is a corresponding increase in the size of the PV membrane (PVM). Since mature RBC lack internal organelles and no longer actively synthesize membranes, the production and trafficking of lipids and proteins required for the expansion of the PV is orchestrated by the parasite. Pfs16, a 16kDa integral PV membrane protein was chosen as a model for studying trafficking of material from the parasite across the PV space to the plasma membrane. Pfs16 synthesis begins right after RBC invasion and continues to be expressed on the PVM as P. falciparum develops through the 5 morphologically distinct stages of gametocytogenesis. Green fluorescent protein (GFP) was used as a reporter to test the ability of distinct regions of Pfs16 to direct trafficking to the PV. The combined presence of the 25aa amino-terminal secretory signal and a 42aa region, made up of the predicted 22aa transmembrane domain (TM), Pfs16 aa105-126 and the next 20aa (Pfs16 aa127-146), were sufficient to target expression to the PV. The 20aa tail contains 3 sections with distinct charge profiles. Section 1 is the first 6aa following the TM domain and includes 4 lysines (K). Section 2 is the next 8aa and contains 3 tandem aspartates (D) followed by K-glycine-D. Section 3 is the remaining 6aa which is made up of 3 tandem repeats of KD. Although, wt Pfs16 contains an additional 11 C-terminal aa (Pfs16 aa147-157) including 4 Ds, these aa are not required for PVM targeting. The 44aa PVM targeting region identified by this work provides an important probe for further evaluation of this unique parasite to PVM trafficking pathway.

Traffic of *Salmonella typhi* Cytochalal Distending Toxin within Host Cells

S. Spano, J. E. Galan; Section of Microbial Pathogenesis, Yale University School of Medicine, New Haven, CT

*Salmonella typhi*, the agent of typhoid fever, encodes CdbB, a toxin that induces G2 cell cycle arrest and cellular distortion by infiltrating limited host-cell DNA damage. This toxin is delivered to the host cell by a novel pathway that depends on bacterial internalization into host cells. Expression of the toxin occurs only 2 to 3 hours after S. typhi internalization into the host cell, when the bacterium has reached a highly specialized membrane-bound compartment. In order to be directed to its cellular target CdbB must traffic from the Salmonella-containing vacuole to a subcellular compartment where retro-translocation to the cytosol can occur. The aim of this study is to dissect this novel pathway and identify the molecular mechanisms that govern it. We have been able to detect epitope-tagged CdbB in infected epithelial cells and follow its transport within the host cell by microscopic and biochemical techniques. Secretion of CdbB from the bacterium starts 3 to 5 hours after infection. At this time the toxin is localized on the surface of intracellular bacteria, within the Salmonella-containing vacuole. At later times after infection, the toxin is also detected in small puncta throughout the cell, seemingly emanating from the Salmonella-containing vacuole. We hypothesize that these are intermediate compartments that may transport the toxin to the site of retro-translocation. The number and fluorescent intensity of these structures gradually increase up to 20 hours after infection. The nature and dynamics of these CdbB transport intermediates are currently being investigated.

Expression and Localization of the Mammalian Facilitative Glucose Transporter GLUT12 in Renal Epithelial Cells

A. L. Wilson-O'Brien, L. DeHaan, S. Rogers; 1Medicine St. Vincent's, The University of Melbourne, Melbourne, Australia, 2Department of Genetics, The University of Melbourne, Melbourne, Australia

Glucose homeostasis is a major cause of diabetic complications, including diabetic nephropathy. Our studies have shown GLUT12 expression in the distal tubules of rat fetal and human adult kidney, with subcellular localization to the apical membrane. In addition, renal GLUT12 expression was upregulated in an animal model of diabetic nephropathy. We aimed to elucidate the mechanisms that regulate expression and localization of GLUT12 in the kidney in response to factors associated with diabetic nephropathy. Regulated expression of GLUT12 in response to AngII and TNFα was studied in cultured cell models using real time PCR and Western blotting. Regulated targeting of GLUT12 was studied with fluorescence-tagged constructs, retroviral transfection and confocal microscopy in response to acute and chronic high glucose (25mM). In Human Embryonic Kidney 293T cells, GLUT12 RNA and protein levels remained unchanged after TNFα and AngII treatments. Transfection of renal epithelial Madin Darby Canine Kidney (MDCk) cells with a fluorescence-tagged GLUT12 construct demonstrated a perinuclear localization in basal conditions. Acute treatment with high glucose had no effect on GLUT12 localization. However, chronic high glucose treatment resulted in GLUT12 movement from a perinuclear position to the apical membrane. MDCk polarization was demonstrated by the expression of the ZO1 junctional marker, with apical localization of GLUT12 confirmed by Z-section imaging and co-localization with GLUT3. The functional role of GLUT12 was examined using glucose uptake assays and transwell filters. Our study localizes GLUT12 to the apical

surface of renal epithelial cells in response to chronic elevated glucose. This novel finding suggests a role for GLUT12 in reabsorption of glucose in the late nephron, implicating GLUT12 in the progression of diabetic nephropathy.

1828 Nucleocytoplasmic Shuttling of Leukemia-associated RhoGEF
E. Grabocka, P. B. Wedegaertner; Department of Biochemistry and Molecular Biology, Thomas Jefferson University, Philadelphia, PA
Leukemia-Associated-RhoGEF (LARG), together with PDZ-RhoGEF and p115RhoGEF, also known as RGS-RhoGEFs, function in linking heterotrimeric G-protein signaling to the monomorphic RhoGTPase. As such they are important regulators of several pathways controlling cell growth and differentiation. Here we provide the first evidence that LARG undergoes nucleocytoplasmic shuttling regulated by its dimerization. Thus, deletion of the C-terminus (ΔC), previously demonstrated to be involved in the dimerization of RGS-RhoGEFs, causes LARGΔC, but not PDZ-RhoGEFΔC or p115RhoGEFΔC, to localize to the nucleus as indicated by immunofluorescence and nuclear fractionation assays. FRAP analysis reveals LARGΔC to be actively imported into the nucleus, and nuclear import is Ran dependent. We identify a nuclear localization sequence (NLS), 29PTDKKQ35, necessary for the nuclear targeting of GFP-LARGΔC. The NLS of LARG, however, requires an additional N-terminal stretch of amino acids to target an unrelated protein to the nucleus. Our data suggests that dimerization of LARG blocks the exposure of both nuclear localization and nuclear export sequences (NES). Thus, using the rapamycin inducible FRB/FKBP dimerization system, otherwise nuclear GFP-LARGΔC fused to the FRB or FKBP domains shows a cytosolic localization when expressed in the presence of rapamycin. We identify a predicted coiled-coil region (a.a. 1508-1522) in the extreme C-ter of LARG as a regulator of dimerization and nucleocytoplasmic shuttling. We demonstrate that whereas GFP-LARG is not sensitive to the CRM1 nuclear export pathway inhibitor leptomycin B (LMB), a LARG mutant lacking the coiled-coil region shows a nuclear localization upon LMB treatment. Taken together, our results indicate that LARG may play a signaling role in the nucleus and that nucleocytoplasmic shuttling of LARG may be a mechanism regulating its signaling functions.

1829 Expression Patterns of Lectins in Cardiovascular System
P. Chu, S. Jung, A. Wu, Medicine, Chang Gung Memorial Hospital and University, Taipei, Taiwan, 2Pathology, Chang Gung Memorial Hospital and University, Taipei, Taiwan, 3Glyco-Immunochromepstry Research Laboratory, Chang Gung University, Taipei, Taiwan
Objective: A variety of common cardiovascular disorders are characterized by the changes of lectin, such as P-selectin on the activated endothelium in the reperussed area and L-selectin on the leucocytes have a vital role in mediating the initial steps of this cascade. Lectins or glycoproteins are simply defined as proteins which specifically bind (or crosslink) carbohydrates. The existence of glycoproteins in cardiovascular system has not been demonstrated completely. The purpose of this investigation was to elucidate the expression patterns of lectins in cardiovascular system.
Methods: This study analysis of micro-tissue array composing of 80 patients with cardiac myxoma that were surgically excised. The expression patterns of 21 glycoproteins in cardiomyocytes and vessels were elucidated by immunohistochemical analysis. Results: All heart containing vessels were analyzed detailed. In the membrane of cardiomyocytes, only wheat germ agglutinin (WGA, 95%), Ricinus communis (RCA, 85%), and Cysteine-rich antifungal protein 2B (M2B, 60%) were expressed. There were more lectins expressed in the nucleus of the cardiomyocytes, including RCA, M2B, RCA, ricin, Bandeiraea (Griofinia) simplicifolia lectin-I, isolectin B4, Agaricus bisporus agglutinin, Bandeiraea (Griofinia) simplicifolia lectin-I, isolectin A4, Abra-A, BHG3, Jacalin, and M2B. The existence of glycoprotein in the endothelium is more ubiquity except Vicia villosa B4(4). Conclusion: The characteristics of expression patterns of glycoprotein in cardiovascular system imply the important role of cardiovascular diseases.

1830 Nicotine Decreases Pregnenolone Synthesis and Reduces STAR Import into Mitochondria
H. S. Bose, M. Bose, D. Deb Nath, C. Huang; Physiology, University of Florida, Gainesville, FL
The rate-limiting step in steroidogenesis is the transport of cholesterol from the outer to inner mitochondrial membrane, which is facilitated by steroidogenic acute regulatory protein (STAR). STAR is a 37 kDa cytoplasmic phosphoprotein processed as 32 kDa and mature 30 kDa protein. STAR activity is proportional with its residency time at the outer mitochondrial membrane. Exposure of 1 mM nicotine to the COS-1 cells transfected with STAR/F2 decreased pregnenolone synthesis and reduced expression of 37 kDa and 32 kDa STAR by 50%, and 2.5 mM nicotine ablated STAR expression and activity. Incubation of biosynthetic STAR to isolated mitochondria with 1 mM nicotine reduced pregnenolone from 600 to 285 ng/ml. Mitochondria pretreated with 1 mM nicotine inhibited STAR import and stopped completely with 2.5 mM, but similar doses of nicotine had no effect on the import of signal sequence substituted STAR (SCC/N-62STAR). 355-Star imported onto isolated mitochondria formed one single complex on digitonin extraction. Density gradient ultracentrifugation showed that 37 kDa OMM associated complex was degraded with nicotine but not the imported 30 kDa STAR complex. Fluorescence emission maxima of N-62 STAR at 337.2 ±0.2 was unchanged but the free energy of unfolding 2.46 changed to 3.14 kcal/mol with 1 mM nicotine. Thus we conclude that the transport process of STAR at the OMM is specific and sensitive to environmental factors, like nicotine, resulting interruption in cholesterol fostering into mitochondria, which ultimately decreases pregnenolone synthesis.

1831 Structural Requirements That Determine Tail Anchoring of Myotonic Dystrophy Protein Kinase (DMPK) Isoforms to ER or Mitochondria
R. J. A. Oude Ophuis, J. Fraenen, B. Wieiringa, D. G. Wansink; Cell Biology, Nijmegen Centre for Molecular Life Sciences, Nijmegen, The Netherlands
DMPKs, alternatively spliced isoforms of the gene mutated in myotonic dystrophy type 1, are members of the AGC group of kinases, to which also MRCKs, Rho kinases, and citron kinase belong. DMPK appears to be an evolutionary "recent" protein, occurring only in mammals. Long DMPK isoforms A and C of mouse contain distinct C-terminal tails that anchor the protein selectively to the ER or the mitochondrial outer membrane (MOM), respectively. Human DMPK A and C, although highly homologous, both target to the MOM. We here report on the precise structural requirements that determine DMPK's behaviour as a tail-anchored protein. Deletion mutation analysis, protein tagging and transfection studies in muscle and neuronal cell types revealed that only the tails of DMPK A and mDMPK A are necessary and sufficient for correct membrane targeting. For human and mouse DMPK C, additional presence of a short upstream coiled coil region was required for selective binding. Mutation of single amino acid positions revealed that charged residues (arginines) in close proximity of a putative transmembrane domain in the tail determined MOM or ER selectivity. Interestingly, expression of mDMPK C or mDMPK C, which also bind to the MOM. This effect resides in the tail domain only and is not dependent on kinase activity of the protein. We will report on the delineation of the precise structural and cell-type conditional requirements for selective MOM anchoring and the induction or absence of associated biological effects. Also data on membrane topology determinants for tail anchoring of DMPK will be presented. 1. Groene, P.J. et al. HUMG 9, 605-16 (2000). 2. Wansink, D.G. et al. MCB 23, 5489-501 (2003). 3. van Herpen, R.E. et al. MCB 25, 1402-1404 (2005).

1832 Identification of the Yeast R-SNARE Nyp1p as a Novel Longin Domain-containing Protein
L. Chen, ' W. Wen, ' H. Wu, ' X. Sun, ' M. Zhang, ' D. K. Banfield; ' Biology, Hong Kong University of Science and Technology, Hong Kong, 'Biochemistry, Hong Kong University of Science and Technology, Hong Kong
Using NMR spectroscopy we establish that the N-terminal domain of the yeast vacuolar R-SNARE Nyp1p adopts a longin-like fold similar to those of Sec22p and Ykt6p. Nyp1p is sorted to the limiting membrane of the vacuole via the AP3 adaptin pathway and we show that its longin domain is sufficient to direct transport to this location. In contrast, we found that the longin domains of Sec22p and Ykt6p were not sufficient to direct their localization. A YXXPHI-like adaptin-dependent sorting signal (Y31GTI34) unique to the longin domain of Nyp1p mediates interactions with the AP3 complex in vivo and in vitro. We show that amino acid substitutions to Y31GTI34 (Y31QI34Q) resulted in mislocalization of Nyp1p as well as reduced binding of the mutant protein to the AP3 complex. Also, the longin domain of vacuolar r-SNAREs is dependent upon the Y31GTI34 motif, and Y31 in particular, our finding is consistent with structure-based amino acid substitutions in the mu chain (Apm3p) of yeast AP3 suggest a mechanistically distinct role for this subunit in the recognition of YXXPHI-like sorting signals. It has recently been proposed that the TBC (Tre2/Bub2/Cdc6) domain functions as a GAP (GTPase-activating protein) domain for small GTPase Rab. Because of the large number of Rab proteins in mammals, however, most TBC domains have never been investigated for Rab-GAP activity. In this study we established panels of the GTP-fixed form of 60 different Rabs constructed in pGAD-C1, a yeast two-hybrid bait vector. We also constructed a yeast two-hybrid prey vector (pGIDU-C1) that harbors the cDNA of 40 distinct TBC proteins. Systematic investigation of 2400 combinations of 60 GTP-fixed Rabs and 40 TBC proteins by yeast two-hybrid screening revealed that seven TBC proteins specifically and differentially interact with specific Rabs (e.g., OAT1 interacts with Rab2A; FLJ12085 with Rab5A/B/C; and Evi5-like with Rab10). Measurement of in vitro Rab-GAP activity revealed that OAT1 and Evi5-like actually possess significant Rab2A- and Rab10-GAP activity, respectively, but that FLJ12085 do not display Rab5A-GAP activity at all. These results indicate that specific interaction between TBC protein and Rab would be a useful indicator for screening for the target Rabs of some TBC/Rab-GAP domains, but that there is little correlation between the Rab-binding activity and Rab-GAP activity of other TBC proteins.

**PAT-1 Confers Increased Neutral Lipid Storage Capacity in Cultured Cell Lines**

W. E. Ackerman,1 S. R. Bartholomew,2 E. M. Hlavina,3 T. L. Summerfield,1 J. T. Tansey1, Obstetrics and Gynecology, The Ohio State University, Columbus, OH, Chemistry and Biochemistry, Otterbein College, Columbus, OH

Lipid storage droplets (LSDs) serve an essential cell role in neutral lipid storage and trafficking within most eukaryotic cells. A family of proteins sharing homology in the N-terminal PAT domain has been implicated in the regulation of mammalian LSDs. In addition to the perilipins, adipose differentiation-related protein (ADRP), tail-interacting protein of 47 kDa (TIP-47), and S3, a novel mammalian PAT paralog (termed PAT-1 or myocardial LD protein [MLDP]) has been identified. To explore the function of PAT-1, an epitope-tagged fusion construct of this recently characterized protein (PAT-1-3xFLAG) was ectopically expressed in two cell lines (CHO-K1 and NIH 3T3) lacking endogenous PAT-1 expression. The recombinant protein partitioned with ADRP in the basolateral LD fraction following sucrose gradient centrifugation, and localized to the perimeter of neutral-lipid containing organelles. PAT-1-3xFLAG localized to both ADRP- and TIP-47-encocated vesicles of varying sizes, from microlipid droplets to enlarged LSDs. Unlike ADRP, the expression of PAT-1-3xFLAG was not destabilized by lipid deprivation. Moreover, ADRP was not destabilized in the presence of epitope-tagged PAT-1, suggesting that, unlike perilipin A, PAT-1 does not displace endogenous PAT proteins from LSDs. Finally, stable expression of PAT-1-3xFLAG enhanced the capacity of CHO-K1 cells to accumulate cholesterol and triglycerides following oleic acid supplementation. These results suggest that PAT-1 represents a bona fide LD coat protein that acts in association with ADRP and TIP-47 to confer increased neutral lipid storage capacity in cultured cells.

**Computational Modeling of Gab Family PH Domains**

E. Wywial, S. M. Singh; Biology, Brooklyn College, Brooklyn, NY

The Grb-2 associated binder (Gab) adapter/scaffolding molecules have no enzymatic activity, but they contribute to the localization and/or amplification of signal transduction pathways. The Gab family currently comprises mammalian Gab1, Gab2, Gab3, the Drosophila homolog Daughter of seventimes less, and the Caenorhabditis elegans homolog Suppressor of Clear1- (SoC-1). There are many studies to date that link the Gab family proteins to oncogenic transformation. Gab1 has been implicated in breast, thyroid, and leukemia tumors. Gab2 has been shown to play a role in Bcr-Abl transformation, which causes chronic myelogenous leukemia (CML) and breast cancer. It has been suggested that Gab1 transforming potential may be activated by the loss of its pleckstrin homology (PH) domain, which is the most conserved region within various Gab family members. Many PH domains bind membrane phosphoinositides but the exact role of PH domain is still unknown. However, it is apparent that mutation or deletion of the PH domain has a drastic effect on the functioning of Gab proteins, leading to aberration in signaling cascades and oncogenesis. We have characterized 21 Gab family PH domains by 1) predicting secondary structures; 2) creating homology models using a number of different approaches, i.e. homology modeling, protein threading, multiple sequence and structure alignment, sequence to profile alignment, and loop refinement; 3) generating the electrostatic potential contours; 4) searching for a consensus sequence, which predicts high affinity binding to PI3-Kinasic enzymes. We present the detailed characterization of these PH domains and the analysis of their physical interactions with membrane phosphoinositides. On-line supplementary information is available at http://userhome.brooklyn.cuny.edu/ssingh/gabs/gabs.html

**Halofuginone Is a Small Molecule Regulator of a Novel Transcriptional Complex That Controls Extracellular Matrix Gene Expression**

Y. G. Kamberov,1 R. Mazitschek,2 M. R. Whitman1; Developmental Biology, Harvard Dental School, Boston, MA, Chemical Biology Program, Broad Institute, Cambridge, MA

Halofuginone (HF) is a potent and specific regulator of ECM gene expression and is unique in its therapeutic potential. The basis for HF effects on the ECM is unknown but ultimately results in the transcriptional control of a number of ECM components including Type I collagen (Pines M and Nagler A 1998, Gen. Pharmacol. 30, 445-450). The aim of this study was to identify the molecular mediators of HF function and regulation of the complex by which the compound exerts cell-type specific effects. We have synthesized active and inactive variants of HF, and have used derivitized HF as the basis for a novel polymer based-affinity purification technique to identify the first specific HF binding proteins. We find that HF interacts with a novel complex of nuclear chromatin remodeling factors, and we have mapped the domains necessary for HF association with this complex. Our work with the HF protein complex suggests a new approach to small molecule based regulation of the ECM transcriptional program in vivo. In addition, our affinity purification system provides an improvement over existing approaches for the identification of novel cellular targets of small molecules. Knowing the targets of HF allows the development of more specific and better tailored therapeutics for regulating ECM disorders, and provides a powerful tool for elucidating ECM biology on the sub-cellular level.

**Expression of Membrane Type 2 - Matrix Metalloproteinase during Avian Development**

R. A. Patterson,1 V. Cantemir,2 P. R. Brauer,1 M. V. Reedy1, Department of Biology, Creighton University, Omaha, NE, Department of Biomedical Sciences, Creighton University, Omaha, NE

Matrix metalloproteinases (MMPs) comprise a family of zinc-binding proteolytic enzymes that play essential roles in tissue remodeling, cell proliferation, migration, differentiation, apoptosis, and degradation of the extracellular matrix. Inhibition of MMP activity results in birth defects and developmental anomalies. Membrane Type-MMPs (MT-MMPs) are membrane-bound forms of MMPs that can direct to specific regions on their cell surface to localize proteolytic activity. We used whole mount in situ hybridization to determine the expression pattern of MT2-MMP mRNA during various stages of avian embryonic development (HH stages 9-22). After hybridization, embryos were embedded in tissue freezing medium and sectioned in order to better evaluate the distribution pattern of MT2-MMP-expressing cells. At stages 10-14, MT2-MMP expression was detected in the notochord and in the posterior neural folds prior to fusing to form the neural tube. At stages 11-15, MT2-MMP expression was found in the intermediate mesoderm, tailbud, and in blood islands of the extraembryonic tissue. MT2-MMP expression was also detected in the otic placodes spanning stages 12-22. At stages 17-22, MT2-MMP expression was also found in the pharyngeal arches, ventral myocardium of the developing heart, dorsal limb bud mesoderm, and dermomyotome. These observations suggest that MT2-MMP plays multiple roles in the embryogenesis of several organs. This research was supported by the American
Mechanical Stress Induces Involvement Associated Events in Mammary Epithelial Cells

A. Quaglino, T. B. Tanos, O. A. Coso, E. C. Kordon; IFIBYNE-CONICET, FCCEyN - Universidad de Buenos Aires, Buenos Aires, Argentina

It has been demonstrated that local factors are responsible for the initiation of mammary gland involution after weaning. Results from different groups, including our own, indicate that during this process there is transcription induction of specific genes, as if, c-fos and tnf-a, and activation of different quinases and transcription factors as Erk1/2 and Stat3. It has been speculated that milk-stasis and the consequent stretching of lobular acini could be the earliest stimuli for triggering this process. However, up to now there has been no report indicating whether mechanical stress could exert any effect on mammary epithelial cells. Therefore, our goal was to determine whether mammary cell stretching, could be an early signal that triggers biochemical changes that in turn would lead to epithelial apoptosis. Then, a novel device that applies controlled radial stretching to cells growing in monolayer was designed for mimicking the physical tension generated in the mammary acini when milk efflux is interrupted. Mammary epithelial HC1 cells were seeded on flexible silicone sheets previously coated with collagen. When cells reached confluence, silicone sheets were stretched up to 20% during different times (2min - 4hrs). By semiquantitative and quantitative RT-PCR assays we found that cells exposed to sustained stretching (30 min) showed if, c-fos and tnf-a transcription induction. In addition, by Western blot analysis we found that mechanical stress also induced Erk1/2 serine and Stat3 tyrosine phosphorylation after 5 minutes. In addition, after 1h a strong increase in c-Fos protein levels was detected. Interestingly, stretched cells showed a much higher content of this protein in the cell nuclei than controls, suggesting that mechanical stress not only induced c-Fos expression but also its activation. Therefore, these results are the first direct evidence showing that mammary cell stretching could be relevant in triggering events leading to cell death during post-lactational involution.

Casein Expression in Heterotopic Organs of Lactating Mice

T. Kanazawa, A. Takagai, H. L. Hosick;1 Department of Bioresource Science, Ibaraki University, College of Agriculture, Ibaraki-ken, Japan, 2School of Biological Sciences, Washington State University, Pullman, WA

Casein is accepted to be a milk-specific protein that is synthesized in mammary glands. Messenger RNA for casein is, however, detected in some other tissues of the mouse, including thymus, tongue and pancreas. These findings raise the question of whether casein is expressed specifically in mammary glands. We have therefore surveyed casein in a variety of organs of the mouse at various reproductive stages, by using Western blotting, immunohistochemistry and RT-PCR techniques. Western blotting analysis, using a mouse whole casein-specific antisemur and mouse β-casein-specific monoclonal antibody as probes, revealed casein-related bands in the homogenates from skin of abdominal-, dorsal- and tail-portion, tongue, salivary glands, liver, pancreas, brain, kidney, thymus, uterus, ovary, lung and cardiac tissues of lactating mice, at levels less than that of mammary glands. No casein-related bands were detected in these organs of virgin and expressing in heterotopic organs of mice during lactation, and that casein expression in these heterotopic organs is also mediated through prolactin stimulation. We interpret these findings to indicate that casein is not milk-specific, although the amount of casein expressed in heterotopic tissues is not high as in lactating mammary glands in mice.

Further Analysis of HLA-G and HLA-E Expression in Human Placental Tissue

M. Greimel, M. Siwetz, A. Blaschitz, G. Dohr, H. Hutter; Institute of Cell Biology, Histology and Embryology, Medical University of Graz, Graz, Austria

The human MHC class I genes HLA-G and HLA-E are referred to as non classical or class 1b molecules. They are distinguished from the classical HLA class I molecules by a low allelic polymorphism and they differ by specific patterns of transcription, protein expression and immunotolerant functions. HLA-G and HLA-E proteins may play a central role in the development of tolerance between fetal and maternal tissue at the feto-maternal interface in the human placenta. The aim of this work was to further analyze the expression pattern of HLA-G and HLA-E in human placental tissue during the first trimester of pregnancy. Using a set of specific monoclonal antibodies (HC2A, 4H84, MEM-G1/1, MEM-G9, MEM-E2, and MEM-E/8) and different biochemical and immunohistochemical methods (e.g. Western blotting, single/double immunostaining and immunofluorescence), we detected a strong expression of HLA-G in extravillous cytrophoblast as well as a weaker expression of HLA-E in the same placental cell population. Moreover a strong expression of HLA-G in endothelial cells of blood vessels and endometrial glands of the decidua was detected. The cell specific expression of HLA-G and HLA-E in human placental tissue may suggest an interacting functional role of these proteins with Killer Cell Inhibitory Receptors (KIR) of decidual NK cells which may result in down regulation of the immune response and a successful maintenance of pregnancy.

Parathyroid Hormone-related Protein (PTHRP) Regulates Tumor-Related Genes in Breast Cancer Cells

J. Dittmer, A. Dittmer, M. Vetter, D. Schunke, P. N. Span, F. Sweep, C. Thomssen;1 Clinic for Gynecology, University of Halle, Halle, Germany, 2Department of Chemical Endocrinology, Radboud University Nijmegen Medical Centre, Nijmegen, The Netherlands

PTHRP is expressed by the majority of breast cancer. It is responsible for hypercalcemia of malignancy and is involved in the regulation of biological activities of cancer cells. By interacting with the PTH1 receptor, PTHRP is able to activate protein kinase A and C pathways. PTHRP is also capable of traveling into the nucleus, an activity that is regulated by cdc2. To identify genes that are regulated by PTHRP, we suppressed endogenous PTHRP expression of MDA-MB-231 breast cancer cells by PTHRP-specific siRNA (siPTHRP) and subjected the RNA from these cells to microarray analysis. Three independent experiments were performed and evaluated. Of the genes whose expression was significantly altered relative to control siRNA, some were chosen for further analysis. The expression of more than 200 genes were affected by siPTHRP. Interestingly, siPTHRP interfered with cdc2 activity by increasing its expression and the expression of its activator cdc25B and cdc25B's regulator -Towe. PTHRP peptide 1-34 and forskolin downregulated cdc2 and cdc25B expression suggesting that PTHRP regulates these genes via PTH1R. In primary breast cancer, higher expression of cdc2 and cdc25B was found at low PTHRP levels. siPTHRP downregulated integrin alphait (ITGA6), Kias-1 and plasminogen activator inhibitor-1 (PAI-1). In primary breast cancer, ITGA6 RNA levels were positively correlated with those of PTHRP. siPTHRP inhibited migration and proliferation. These siPTHRP effects could be mimicked by a combination of siRNAs directed against ITGA6, PAI-1 and Kias-1 suggesting that PTHRP may exert its migratory, proliferative and motogenic effects through these genes. The results suggest that, by controlling cdc2 activity, PTHRP may regulate its own nuclear activity. The data also imply, that by interfering with the expression of oncogenes, such as ITGA6 and PAI-1, and tumor suppressor genes, such as KISS-1, PTHRP contributes to the regulation of proliferation and migration of breast cancer cells.

Prostate Tumor Cells Near and Distant from Focally Disrupted Basal Cell Layers Have Different Gene Expression Profiles

Y. Man, X. Liu, J. Mason, S. Prabhakar, B. Wang, X. Zeng, M. Stamatakis, W. Gardner;1 Armed Forces Institute of Pathology and American Registry of Pathology, Washington, DC, 2Laboratory of Molecular Biology, National Cancer Institute, National Institutes of Health, Bethesda, MD, 3Superarray Bioscience Corporation, Frederick, MD

Our previous studies revealed that a subset of pre-invasive breast tumors contained focally disrupted myoepithelial (ME) cell layers that were surrounded by leukocyte infiltration. Compared to adjacent cells within the same tumor, but distant from disruptions, tumor cells overlying these focal disruptions showed a significantly higher frequency of tumor invasion-related genetic alterations. As the prostate basal cell layer is structurally and functionally comparable to the ME cell layer, and that similar focal basal cell layer disruptions and leukocyte infiltration are seen in a subset of pre-invasive prostate tumors, this study attempted to assess whether these two organs would share a similar pattern of genetic alterations. Consecutive sections were prepared from primary breast cancer, and from multiple areas of primary breast cancer. Tumor gene expression profiles were analyzed in a subset of prostate tumors with similar pathology. The data was compared with a panel of prostate gene expression profiles. siRNA were chosen for further analysis. The expression of more than 200 genes were affected by siPTHRP. Interestingly, siPTHRP interfered with cdc2 activity by increasing its expression and the expression of its activator cdc25B and cdc25B's regulator -Towe. PTHRP peptide 1-34 and forskolin downregulated cdc2 and cdc25B expression suggesting that PTHRP regulates these genes via PTH1R. In primary breast cancer, higher expression of cdc2 and cdc25B was found at low PTHRP levels. siPTHRP downregulated integrin alpha3 (ITGA6), Kias-1 and plasminogen activator inhibitor-1 (PAI-1). In primary breast cancer, ITGA6 RNA levels were positively correlated with those of PTHRP. siPTHRP inhibited migration and proliferation. These siPTHRP effects could be mimicked by a combination of siRNAs directed against ITGA6, PAI-1 and Kias-1 suggesting that PTHRP may exert its migratory, proliferative and motogenic effects through these genes. These results suggest that, by controlling cdc2 activity, PTHRP may regulate its own nuclear activity. The data also imply, that by interfering with the expression of oncogenes, such as ITGA6 and PAI-1, and tumor suppressor genes, such as KISS-1, PTHRP contributes to the regulation of proliferation and migration of breast cancer cells.

The Role of the 3UTR in Regulating BMP2 Gene Expression in Lung Cells

S. Jiang, D. T. Fritz, M. B. Rogers; Biochemistry and Molecular Biology, Graduate School of Biomedical Science, UMDNJ-New Jersey Medical School, Newark, NJ

Bone morphogenic protein 2 (BMP2) is an essential growth factor that regulates cell proliferation, apoptosis and differentiation. BMP2 expression is abnormal in various tumors. The BMP2 protein stimulates angiogenesis and promotes lung tumor growth. Mis-regulated BMP2 expression in lung tissue may promote tumor formation. Using northern blots and ELISA, we detected BMP2 mRNA and protein in A549 cells (human lung adenocarcinoma cells) but not in BEAS-2B cells (immortalized human bronchial epithelial cells). This mirrors the finding that BMP2 is over-expressed in lung tumors compared to normal tissues. Mycoplasma infection induced BMP2 in BEAS-2B cells and further induced BMP2 in A549 cells. Additionally, mycoplasma induced a novel transcript in both cells. Chronic mycoplasma infection reduced contact inhibition and increased the proliferation of BEAS-2B cells. Noggin, a BMP2 antagonist, abrogated the increased proliferation. The incidence of mycoplasma infection is elevated in lung cancer patients relative to controls. An influence of mycoplasma on BMP2 expression may influence the onset and progression of lung cancer. We hypothesized that an ultra-conserved sequence in the BMP2 3′ untranslated region contains cis-regulatory elements that regulate BMP2 expression via specific RNA-protein interactions. The ultra-conserved sequence induced gene expression in cells that express BMP2 (A549), but repressed expression in cells that do not express BMP2 (BEAS-2B). RNA oligonucleotide linking experiments and RNase protection assays demonstrated that cell-type specific proteins bound to the BMP2 RNA. Some are Al-rich element binding proteins, well-known factors that regulate RNA stability and translation. RNAs with different alleles of a common human SNP in the ultra-conserved region bound different proteins and decayed differently. We are now using proteomics to identify protein complexes that associate with the ultra-conserved sequence. Understanding the post-transcriptional mechanisms that regulate BMP2 expression is necessary to elucidate why certain cancer cells express BMP2 aberrantly and may lead to novel lung cancer treatments.

Identification of CPEB in Light and dark-adapted Octopus Retinas

S. Kelly, H. Yamamoto, L. J. Robles; Biology, California State University, Dominguez Hills, Carson, CA

CPEBs are trans-acting elements known to bind to the CPE regions located with the 3′ untranslated regions of mRNAs, resulting in the temporal regulation of translational repression and activation of the mRNA in Xenopus (Mendez and Richter, 2001; Stelbins-Boaz et al., 1999; Cao and Richter, 2002). In addition to regulating the mRNA localization of vertebrate and invertebrate maternal mRNAs, CPEB up-regulation is also indicated in translational regulation occurring in hippocampal neurons and mouse synapses, such as the activated synapses in Aplysia (Si et al., 2003). We have previously reported the differential expression and translation of S-crystallin and α-tubulin mRNAs and proteins in light- and dark-adapted octopus retinas. We believe that the increases in S-crystallin and α-tubulin mRNA expression in the light and the subsequent increase of protein synthesis in the dark may result from mRNA masking and unmasking. Here we investigate the presence of a CPEB in light- and dark-adapted octopus retinas. Equal concentrations of total protein isolated from light- and dark-adapted octopus retinas were subjected to SDS-PAGE and western blot analysis, using a CPEB antibody directed against the amino acid residues 545-562 of human CPEB and that also recognizes recombinant mouse CPEB. The detection of bands at ~62 kDa and 28 kDa confirmed the presence of CPEB in light- and dark-adapted retinas, with preliminary analysis revealing higher concentrations of CPEB present in the light-adapted retinas. Increased concentrations of CPEB in light-adapted octopus retinas may be involved in the activation of masked S-crystallin and α-tubulin mRNAs, resulting in increased protein synthesis in dark-adapted octopus retinas. Supported by NIH/NIGMS/MRBS GM08156.

Pathology and Nuclear Abnormalities in Hearts of Transgenic Mice Expressing M371K Lamin A Encoded by an LMNA Mutation Causing Emery-Dreifuss Muscular Dystrophy

Y. Wang,1 A. J. Herron,2 H. J. Worman;1 Departments of Medicine, and Anatomy and Cell Biology, College of Physicians and Surgeons, Columbia University, New York, NY, 2Institute of Comparative Medicine and Department of Pathology, College of Physicians and Surgeons, Columbia University, New York, NY

Mutations in LMNA, which encodes nuclear lamin A and C, cause a broad range of diseases, including autosomal dominant Emery-Dreifuss muscular dystrophy and related disorders with a predominant cardiomyopathy phenotype. While homologous Lmna model “knock-in” and null mice develop cardiac hypertrophy, heterozygous mice do not. Overexpression of lamin A mutants that cause cardiomyopathy in cultured cells induces morphological abnormalities in the nuclear envelope and lamina; however, effects on tissue and organ pathology have not been determined. We used the heart-selective α-myosin heavy chain promoter to drive transgenic mice of human wild type and M371K lamin A, which causes Emery-Dreifuss muscular dystrophy. Mice expressing M371K lamin A were born at approximately 0.07 of the expected frequency and those born typically died at 2 to 7 weeks of age. Histological analysis showed increased eosinophilia and fragmentation of cardiomyobasts, nuclear pyknosis and edema without fibrosis or significant inflammation, indicative of acute or subacute injury. Expressing human wild type lamin A were born at only slightly less than the expected frequency and had normal life spans. Confocal immunofluorescence microscopy demonstrated abnormal nuclear envelopes with intranuclear foci of lamins in cardiac cells expressing M371K lamin A. Electron microscopy revealed extensively convoluted nuclear envelopes, intranuclear inclusions and chromatin clumps in cardiomyocyte nuclei. These results suggest that expression of a lamin A mutant that alters mutations in nuclear morphology can cause tissue and organ damage in mice with a normal complement of wild type lamin.
Role of Transcription Factor NFI in Regulation of Human Osteoblast IGF Binding Protein 5 Gene Expression

L. A. Perez-Casellas, 1,2 G. Gutierrez, 3 D. D. Strong, 1,2 T. A. Linkhart 2,3 Biochemistry and Microbiology, Loma Linda University, Loma Linda, CA; Loma Linda VAMC, Loma Linda, CA

IGF Binding Protein-5 (IGFBP-5) is expressed in many cell types and has complex effects on IGF activities depending on cell type and localization. IGFBP-5 stimulates osteoblast proliferation and differentiation and inhibits osteoblast apoptosis in vitro, while stimulating bone formation in vivo. Glucocorticoids (GCs) inhibit IGFBP-5 expression in normal human osteoblasts (hOBs), suggesting that decreased IGFBP-5 production contributes to GC inhibition of bone formation. We found that GC inhibition of IGFBP-5 gene promoter activity was mediated by a composite response element containing a Nuclear Factor I (NFI) binding site. Four homologous mammalian NFI genes are important in development, but their role in osteoblasts is unknown. To determine whether NFI might regulate IGFBP-5 expression in human osteoblasts, effects on IGFBP-5 transcription were compared by transient transfection with NFI expression vectors and an IGFBP-5 promoter Luciferase reporter in TE-85 osteosarcoma cells. NFI-B and NFI-X stimulated promoter activity 10 fold and 3 fold respectively, but NFI-A and NFI-C were not active. NFI-B increased promoter activity 10 fold in MG-63 osteosarcoma cells, and this induction was inhibited by GC treatment. NFI mRNA levels were determined by quantitative RT-PCR in TE-85, MG-63 and U-2 OS human osteosarcoma cell lines and hOB cultures. NFI-C was most abundant in all cells except MG-63, in which NFI-B was 16 fold higher than NFI-C. NFI-B may thus be the most important activator of IGFBP-5 expression in MG-63 cells. When NFI-B expression was inhibited with specific siRNA oligonucleotides in MG-63 cells, NFI-B mRNA and protein levels were decreased by 55% and 33% respectively, compared to control siRNA. Similar effects of NFI-B knockdown were observed with hOBs. These results suggest an important role for NFI-B in modulating IGFBP-5 expression in human osteoblasts and thus in regulating proliferation, differentiation and apoptosis.

High Throughput/High Content Assay of Lipid Droplets and Perilipin in Human Adipocytes

R. M. Agustin, 1 B. M. Bauer, 2 D. Stricker, 3 N. L. Prigozhina, 1 E. A. Hunter, 1 I. Mikic, 1 S. Callaway, 1 J. H. Price, 2 P. M. McDonough 3 The Burnham Institute for Medical Research, La Jolla, CA, ZenBio, Research Triangle Park, NC, Biological Studies, Vala Sciences Inc, La Jolla, CA

Obesity is an important health problem, particularly, in the US where 30% of adults have a body mass index ≥ 30. Adipogenesis (the formation and differentiation of adipocytes) is therefore of high interest to the biomedical community. We report here the development of automated imaging and analysis techniques to enable high throughput/high content screening of test compounds on lipid droplets and associated proteins. Primary human pre-adipocytes from liposuction procedures, were plated in 96-well plates for 15 days in the presence of rosiglitazone (rosi), a PPARγ agonist which promotes adipogenesis, then fixed and stained for lipids and nuclei. To quantify the number and size of the lipid droplets, an algorithm was developed that identifies circular staining patterns within cell-based images. The number of lipid droplets, as quantified by the algorithms, increased 6-fold, in a dose-dependent manner for cells exposed to rosi (maximal at 1 μM), with a Z’ value of 0.47. Lipid droplet size was also increased by rosi. The dose-response relationship for rosi vs. lipid droplet number was very similar to that obtained for overall triglyceride content, as assayed by traditional techniques. A related algorithm was developed to quantify the association of perilipin with lipid droplets. Perilipin is involved in beta-adrenergic stimulation of lipid droplet metabolism and was visualized in a separate fluorescent channel. For adipocytes cultured in maintenance medium, perilipin was associated with < 5% of the droplets, whereas it increased to 75% for rosi-treated cells. Thus, both lipid droplet formation and the association of proteins with the droplets can be assayed in cultured human adipocytes in a high throughput manner which will enable discovery of drugs that can modify fat deposition and metabolism.
It is known that condensed chromosomes contain higher Ca2+ concentrations while decondensed chromosomes contain lower concentrations, which range 20-32 mM. We have shown recently that the nucleolus of mammalian cells contains numerous vesicular inositol 1,4,5-trisphosphate (IP3)-sensitive Ca2+ stores that consist of the IP3 receptor/Cal2+ channels, Ca2+ storage protein chromatin B, and phospholipids. These Ca2+ store vesicles have an average diameter of ~50 nm. Here we show localization of these IP3-sensitive Ca2+ store vesicles, which were labeled with IP3 receptor and chromatin B, in close association with several round structures that have diameters of ~11 nm. These round structures were labeled with histone H3 and considered to be nucleosomes. Each Ca2+ store vesicle was surrounded by several nucleosomes that appear to be enwrapped by DNA strands. Localization of these vesicles in close proximity with the nucleosomes suggests a close functional coupling between the nucleosomes and the Ca2+ stores, and strongly suggests the Ca2+ stores’ indispensable roles in controlling chromatin structure.

The Role of Smu1 in Splicing Is Conserved through Evolution
K. Sugaya, E. Hongo, Y. Ishihara, H. Tsujii; Radiation Effect Mechanisms Research Group, National Institute of Radiological Sciences, Chiba, Japan

Temperature-sensitive CHO-K1 mutant cell line tsTM18 exhibits chromosomal instability and cell cycle arrest at S and G2 phases with decreased DNA synthesis at the nonpermissive temperature, 33°C. We were severely affected by the depletion of PR-Set7, suggesting that PR-Set7-dependent mono-methylation plays an important role in cell proliferation. We investigated the in vivo function of PR-Set7-dependent methylation by studying the cell cycle in mutant neuroblasts. Neuroblasts are diploid and their cell cycle progression has been well documented. We found that in PR-Set7 mutants, both the mitotic and the S phase indices were reduced, progression through early mitosis was delayed, and cyclin B was downregulated by APC/C proteolysis. In a double mutant of PR-Set7 and mei-41 (the fly ATR ortholog), the abnormalities of cell cycle progression and protein level of cyclin B were restored, indicating that in PR-Set7 the DNA damage checkpoint is activated, and that this activation results in mitotic abnormalities. We also observed abnormal chromosome condensation in PR-Set7 that was enhanced when the checkpoint-arrest was abolished in the double mutant, suggesting that the defect in chromosome condensation is independent of the checkpoint activation. Most histone methyltransferases have generally been considered to be regulators of transcription. However, since the expression of genes involved in the DNA damage checkpoint is normal in PR-Set7, control of gene expression is not involved in activation of the checkpoint. We propose that mono-methylated H4K20 is involved in the maintenance of proper higher order structure of DNA and is consequently essential for chromosome condensation. A function in DNA damage response has been shown for methylated histone H4K20 in S. pombe. Interestingly, the function of mono-methylation of H4K20 in Drosophila is clearly different. Our results suggest that mono-methylation of H4K20 has a more global effect on chromatin structure than described so far.

Aberrant Mono-methylation of Histone H4 Lysine 20 Activates the DNA Damage Checkpoint in Drosophila
A. Sakaguchi, R. Stewart; Molecular Biology and Biochemistry, Waksman Institute, Rutgers University, Piscataway, NJ

PR-Set7 is a histone methyltransferase that specifically mono-methylates histone H4 lysine 20 (H4K20). In Drosophila larvae, tissues with higher rates of cell divisions, such as imaginal discs, are severely affected by the depletion of PR-Set7, suggesting that PR-Set7-dependent mono-methylation plays an important role in cell proliferation. We investigated the in vivo function of PR-Set7-dependent methylation by studying the cell cycle in mutant neuroblasts. Neuroblasts are diploid and their cell cycle progression has been well documented. We found that in PR-Set7 mutants, both the mitotic and the S phase indices were reduced, progression through early mitosis was delayed, and cyclin B was downregulated by APC/C proteolysis. In a double mutant of PR-Set7 and mei-41 (the fly ATR ortholog), the abnormalities of cell cycle progression and protein level of cyclin B were restored, indicating that in PR-Set7 the DNA damage checkpoint is activated, and that this activation results in mitotic abnormalities. We also observed abnormal chromosome condensation in PR-Set7 that was enhanced when the checkpoint-arrest was abolished in the double mutant, suggesting that the defect in chromosome condensation is independent of the checkpoint activation. Most histone methyltransferases have generally been considered to be regulators of transcription. However, since the expression of genes involved in the DNA damage checkpoint is normal in PR-Set7, control of gene expression is not involved in activation of the checkpoint. We propose that mono-methylated H4K20 is involved in the maintenance of proper higher order structure of DNA and is consequently essential for chromosome condensation. A function in DNA damage response has been shown for methylated histone H4K20 in S. pombe. Interestingly, the function of mono-methylation of H4K20 in Drosophila is clearly different. Our results suggest that mono-methylation of H4K20 has a more global effect on chromatin structure than described so far.

The Effect of Overexpression of H1 Variants- H1c and H1e on Global Gene Expression
S. Bhan, W. May, S. Warren, D. B. Sittman; 1Biochemistry, University of Mississippi Medical Center, Jackson, MS, 2Preventive Medicine, University of Mississippi Medical Center, Jackson, MS

Histone H1 is an essential component of chromatin that binds to the linker DNA between nucleosomes and facilitates the formation of a compact chromatin fiber. Multiple nonallelic variants of H1 have been preserved through evolution. Extensive literature suggests that these variants are heterogeneous and may play distinct roles in the organization of chromatin. However, it is not yet clear what unique functional roles these variants serve. Previously, our lab has attempted to identify functional differences between two H1 variants- H1c and H1e, by developing a system for inducible overexpression of these variants in stably transfected 3T3 fibroblasts. Overproduction of individual variants perturbs the normal H1 stoichiometry and can, thus, help to understand their functional significance. In these studies, we found that these variants have differential effects on gene expression. We have studied the effects of these two variants on global gene expression using the same system of inducible overexpression. The effects of these H1 variants on gene expression were studied at two early time points in G1 phase of the cell cycle- 3h and 6h. Expression of numerous genes was found to be affected by either one of the variants of H1. This is suggestive of unique or specific roles of H1 variants. However, there were several genes that were affected by both the type of variants. Interestingly, the expression of these genes was affected similarly by both the variants. This suggests that besides having unique or specific functions, the H1 variants may have common roles in the organization of chromatin. Also, as expected, more number of genes was affected by the variants at the later time point of 6h. Identification of genes affected by H1s can help decipher the functional differences between the H1 variants as well as specific roles played by the class of H1 proteins.

Regulation of Chromatin Structure and Gene Expression by JIL-1 Kinase-mediated Histone H3S10 Phosphorylation in Drosophila
H. Deng, X. Bao, W. Cai, M. J. Blacketer, J. Girton, J. Johansen, K. M. Johansen; Biochemistry, Biophysics & Molecular Biology, Iowa State University, Ames, IA

Epigenetic regulation of gene expression and chromatin structure is an important aspect of both disease and normal development. In order to gain a molecular understanding of these processes we have identified a histone H3S10 kinase, JIL-1, that localizes specifically to gene-active interband regions of polytene chromosomes. We have recently demonstrated that a major function of the JIL-1 histone H3S10 kinase is to prevent H3K9-dimethylation and heterochromatization from occurring on inappropriate euchromatic targets (Zhang et al., Development 133:229, 2006). This is underscored by the finding that JIL-1 loss-of-function lethality is restored by a reduction in histone dimethyl-transfase activity. Furthermore, analysis of hypomorphic JIL-1 alleles shows that loss of JIL-1 activity results in major alterations in chromatin structure and gene expression. These results suggest a model where JIL-1 mediated phosphorylation of histone H3S10 at interphase functions to antagonize heterochromatization by regulating a dynamic balance between repressing and activating factors of gene expression. To directly test the hypothesis that changes in chromatin structure can be caused by the phosphorylation state of histone H3S10 we have used a lac-tethering system to target JIL-1 ectopically to different chromatin environments. The results show that when lac-JIL-1 is tethered to a banded polytene chromosome region the chromatin attains an interband morphology with the band appearing "split in two" and that this "split" is directly correlated with ectopic upregulation of histone H3S10 phosphorylation. Furthermore, we show that neither viability, heterochromatic spreading, nor polytene chromosome morphology is rescued by introduction of a full-length "kinase dead" construct into JIL-1 null animals. Thus, taken together these experiments provide strong support for the hypothesis that chromatin structure and packaging in Drosophila are regulated by JIL-1 kinase-mediated histone H3S10 phosphorylation. (Supported by NIH grant GM62916).

Relationships of Drosophila RECQ5/QE to Cell Cycle Progression and DNA Damage
K. Kowalski, M. Nakayama, K. Nakano, S. Murayama, F. Ito, K. Kato 1, S. Miyazaki 1, S. Kato; Developmental Genetics Group, The National Institute for Basic Biology, Hitachinaka, Japan

Regulation of cell cycle progression is a fundamental process in all eukaryotic organisms. The mammalian cell cycle is regulated by a complex network of proteins that are involved in cell cycle entry, cell proliferation, and maintenance of chromosomal stability. Members of the RecQ family of proteins are regulators of this network and are involved in response to DNA damages. For example, BLM protein is expressed in late S and G2. DNA-damaging agents induce BLM by a p53- and ATM- independent mechanism (Bischof et al (2001) J Cell Biol 153: 367-380). However, little is known about RecQ5, another member of RecQ family. How RecQ5 is involved in cell cycle regulation and in response to DNA damage is still unclear. To investigate the cell cycle regulation of RecQ5, we analyzed the RECQ5/QE protein in Drosophila S2 cells. The amount of RECQ5/QE protein was almost constant during cell and can be induced by irradiation with UV or MMS. The amount of RECQ5/QE protein in S2 cells. These results suggest that RECQ5/QE protein is regulated in response to DNA damages. To elucidate the biological functions of RECQ5/QE in vivo, we have generated transgenic flies that overexpress RECQ5/QE in the developing eye primordia. These flies showed mild roughening of the normally smooth ommatidial lattice. The phenotype of RECQ5/QE overexpression was enhanced by DNA-damaging agents and mei-41 mutation. Overexpression of RECQ5/QE...
perturbed the cell cycle progression in response to DNA damages in the eye imaginal discs. These results suggest that RECQ5/QE interacts with cell cycle progression in response to DNA damages.

1861

Repetitive Element 1360 as a Target for Heterochromatin Formation in Drosophila melanogaster

A. Figueroa-Clarevega, K. Haynes, K. Huisinga, S. Elgin; Department of Biology, Washington University in St. Louis, St. Louis, MO

Drosophila melanoguster has served as an excellent model for the study of chromatin packaging, which impact levels of gene expression. Proximity to heterochromatin, the form of packaging associated with gene silencing, has the ability to induce PEV (Position Effect Variegation), in which a reporter gene is silenced in some of the cells where it is normally active. Earlier work has suggested that the repetitive element 1360, which is enriched in heterochromatic domains, can serve as an initiation site for heterochromatin formation in the fourth chromosome (Sun et al. 2004. Mol. Cell Bio. 24: 8210). To test this idea, we generated several fly lines carrying a transposable P-element containing one or four copies of 1360 upstream of an hsp-70 white reporter. Without the 1360 element upstream of hsp-70 white, only 1% of lines recovered from previous P-element mobilizations screens are variegating. We have observed that with one copy of 1360, 3% of the lines are variegating; with four copies of 1360, 11% of the recovered lines are variegating. These results suggest that increasing copies of 1360 increase the likelihood of initiating heterochromatin formation. Pericentric, telomeric and chromosome four heterochromatin are known to induce PEV. We are currently mapping the distribution of the insertion sites to determine whether increased 1360 copy number allows ectopic heterochromatin formation outside of these regions. Induction of Protracted Genomic Instability in Fission Yeast after Brief Exposure to Cr (VI) Ions

I. Papageorgiou, 1 C. J. Norbury, 2 C. P. Case 2; Orthopaedic Surgery, University of Bristol, BIRC Lab, Bristol, United Kingdom, 3Sir William Dunn School of Pathology, Department of Cell Biology & Pathology, University of Oxford, United Kingdom

Genomic instability occurs in a variety of cells after exposure to low doses of radiation and metal ions including chromium (VI). We have recently shown that many but not all aspects of genomic instability may be prevented through ectopic expression of the catalytic component of telomerase (Glaviano et al., 2005). In this study we investigated whether short-term exposure to Cr (VI) ions could lead to a genomic instability as assayed by minichromosome loss in the fission yeast Schizosaccharomyces pombe. Four hours of exposure to Cr (VI) ions caused a dose dependent increase in minichromosome loss, scored by the appearance of red (ade-) sectors in otherwise white (ade+) colonies. Subsequent measurement of further minichromosome loss events in cells derived from the ade- sectors of such colonies suggested that a long-lived state of chromosomal instability had been induced by the prior exposure to Cr(VI). Control experiments ruled out the possibility that the appearance of ade- progeny was due to events other than minichromosome loss, and furthermore showed no evidence for bystander effects such as those previously reported in mammalian cells. We conclude that fission yeast provides a convenient model system in which to investigate the genetic determinants of long-term chromosomal instability induced by metal ions.

The Chromodomain Protein, Chromator, Interacts with the JIL-1 Kinase and Regulates the Structure of Drosophila Polytenic Chromosomes

Y. Ding, U. Rath, H. Deng, H. Qi, X. Bao, W. Zhang, J. Girton, J. Johansen, K. M. Johansen; Biochemistry, Biophysics & Molecular Biology, Iowa State University, Ames, IA

The chromodomain protein, Chromator, was originally identified in a yeast two-hybrid screen as an interaction partner of the putative spindle matrix component, Skeletor, and localizes to the spindle and the centromeres during mitosis (Rath et al., J. Cell. Biochem. 93:1033, 2004). However, Chromator's localization to polytenic interbands suggests it also may play a functional role in maintaining chromatin structure during interphase. In this study we have generated two new hypomorphic Chromator alleles by EMS mutagenesis and analyzed the consequences of reduced Chromator protein function on polytenye chromosome structure. We show that in chrom/chrom mutants the polytenye chromosome arms were coiled and compacted with a disruption and misalignment of band and interband regions and with numerous ectopic contacts connecting non-homologous regions. Furthermore, we demonstrate that Chromator co-localizes with the JIL-1 kinase and that the two proteins interact within the same protein complex. The JIL-1 kinase localizes specifically to euchromatin interband regions of polytenye chromosomes and is the predominant kinase regulating histone H3S10 phosphorylation at interphase. That both proteins are necessary and may function together is supported by the finding that a concomitant reduction in JIL-1 and Chromator function synergistically reduces viability during development. Overlay assays and deletion construct analysis suggested that the interaction between JIL-1 and Chromator is direct and that it is mediated by sequences in the ade- sectors of such colonies suggested that a long-lived state of chromosomal instability had been induced by the prior exposure to Cr(VI). Taken together these findings indicate that Chromator and JIL-1 interact in an interband-specific complex that functions to establish or maintain polytenye chromosome structure in Drosophila. (Supported by NSF grant MCB0445182 and NIH grant GM62916).

Molecular Characterization of a Novel, CCCH Zinc Finger Protein, UKp83

M. Hará, 1 S. Miyakura, 1 S. Watabe 2; 1Department of Cellular and Environmental Biology, Tokyo Medical and Dental University Graduate School, Tokyo, Japan, 2Department of Laboratory Sciences, Faculty of Health Sciences, Yamaguchi University School of Medicine, Ube, Japan

UKp83 was first isolated as a cDNA of candidate gene of chromatin associated protein whose expression in gene screening was detected by antisera against isolated chromatin from sonicated interphase nuclei obtained from rat liver cells. To investigate the function and relation of this protein to chromatin, we have characterized some properties. The deduced primary structure of UKp83 indicates that it has a nuclear localization signal and five CCCH zinc finger motifs, and is 83k of molecular weight. Cellular immunofluorescence demonstrated that the UKp83 was localized within euchromatic regions in the interphase nuclei and similar to SC35 as a known marker for nuclear speckles, which represent subnuclear compartments enriched in splicing factors. However, when the nuclear envelope was disintegrated at the prometaphase of mitosis, UKp83 located on the chromosomes, though a part of the protein was dispersed into the cytoplasm. An in vitro RNA/DNA binding assay indicated that UKp83 was bound to ssDNA firstly, and less to both RNA homopolymers and dsDNA. GFP-UKp83, which produces a GFP and UKp83 fusion protein in cultured cells by transfection of the expression vector, was not seen to affect any cell function, as the same as GFP-Luc (luciferase). On the other hand, GFP-AS, which produces antisense-RNA of UKp83, warped nuclear and cellular shape of the expressed cells. The ways of reduction of both GFP-Luc and GFP-UKp83 producing cells were almost the same after transfection. However, the ratio of those cells was sharply down in GFP-AS comparing with both GFP-Luc and GFP-UKp83, and it was indicated that expression of antisense-RNA for UKp83 could induce cells to be in death. The results obtained from these experiments suggest that UKp83 seems to play important roles in a construction of the chromatin higher-order structure and in a cellular function and to be essential for cell viability.

Functional Dissection of the Sc35/SMC2 Protein in Chicken Di40 Cells

F. Lai, D. Hudson, W. Earnshaw; Institute of Cell Biology, Wellcome Trust Centre for Cell Biology, Edinburgh, United Kingdom

The mechanism by which genomic DNA is compacted nearly 10,000-fold to form the characteristic mitotic chromosome structure remains poorly understood. One factor thought to have a key role in this process is condensin, a pentameric complex of non-histone proteins composed of the SMC2 and SMC4 ATPases plus three auxiliary subunits (CapG/G2, CapD2/D3 and CapH/H2). Our lab carried out the first conditional knockout of one essential condensin subunit (Sc35/SMC2) in vertebrate cells. By quantitative Real-Time RT-PCR and immunofluorescence microscopy, we showed the down regulation of Sc35/SMC2 gene expression after addition of doxycycline. In cells lacking SMC2 protein, chromosomes can reach near normal levels of condensation but they are structurally abnormal and lack structural integrity. Furthermore, when isolated chromosomes are fractionated, the chromosome scaffold fraction appears to be largely missing. To investigate the role of ATPase domains function, we generated ATPases domains mutants deficient in ATP binding or hydrolysis. The analysis of these lines will allow us to understand how the ATPase function of SMC2 contributes to the assembly of the condensin complex and to the structure of mitotic chromosomes.

1866

Single-stranded Oligonucleotide-mediated Gene Repair in Mammalian Cells Has a Mechanism Distinct from Homologous Recombination Repair

Z. Wang, 1 Z. Zhou, 1 D. Liu, 1 J. Huang 1; 1The University of Hong Kong, Hong Kong, 2Peking Union Medical College, Beijing, China
Single-stranded DNA oligonucleotide (SSO)-mediated gene repair has great potentials for gene therapy and functional genomic studies. However, its underlying mechanism remains unclear. Previous studies from other groups have suggested that DNA damage response via the ATM/ATR pathway may be involved in this process. In this study we measured the effect of two ATM/ATR inhibitors caffeine and pentoxifylline on the correction efficiency in SSO-mediated gene repair. We also checked their effect on double-stranded break (DSB)-induced homologous recombination repair (HRR) as a control, which is well known to be dependent on the ATM/ATR pathway. We found these inhibitors could completely inhibit DSB-induced HRR, but could only partially inhibit SSO-mediated process, indicating SSO-mediated gene repair is not dependent on the ATM/ATR pathway. Furthermore, we found that thymidine treatment promotes SSO-mediated gene repair, but inhibits DSB-induced HRR. Collectively, our results demonstrate that SSO-mediated and DSB-induced gene repairs have distinct mechanisms.

1867
An EGFP-based Transgenic Mouse for Studying Single-Stranded Oligonucleotide-mediated Targeted Gene Repair
L. Lu, 1 K. S. E. Cheah, 1 D. Liu, 1 J. Huang; 1Biochemistry, The University of Hong Kong, Hong Kong, China, 2Institute of Basic Medical Sciences, Chinese Academy of Medical Sciences (CAMS) & Peking Union Medical College (PUMC), Beijing, China
Targeted gene repair using single-stranded oligonucleotide is a promising alternative to current gene therapy strategies. However, the detailed mechanism of this method remains elusive, and the repair efficiency has to be raised before this technique could be used clinically. Currently, almost all studies of this technique are carried out in immortalized cell lines, which may not be true reflections of the cells in normal conditions. In our study, an EGFP-based transgenic mouse was made to study single-stranded oligonucleotide-mediated targeted gene repair in normal cells. The mutated EGFP gene, driven by beta-actin promoter, contains an A to T mutation at the start codon. The reporter was integrated in mouse chromosome eight through gene targeting and the expression of the reporter was ubiquitous. We have tested the technique in embryonic stem cells and primarily cultured embryonic fibroblasts, however the repair events were rarely detected. Besides being a convenient tool for studying gene repair in various primarily cultured cells, this reporter mouse line would also be useful for studying gene repair in vivo.

Multiple Condensin Protein Complexes Build, Express, and Segregate the Genome: Evidence for Condensin I in the Worm
K. Sparh, 1 C. Sparks, 1 M. Child, 1 J. Carey, 1 T. Tabachn, 1 H. Liu, 1 M. McLeod, 1 J. R. Yates, 2 B. J. Meyer, 1 K. A. Hagstrom; 1Program in Molecular Medicine & Program in Cell Dynamics, University of Massachusetts Medical School, Worcester, MA, 2Department of Cell Biology, The Scripps Research Institute, La Jolla, CA, 1HMMI and Department of Molecular and Cell Biology, UC Berkeley, Berkeley, CA
Building proper chromosome structure is essential for genome maintenance, impacting processes from gene regulation to chromosome segregation. We are studying how conserved protein complexes called condensins govern chromosome organization. A canonical condensin complex contains five proteins: a heterodimeric core of structural maintenance of chromosomes (SMC) proteins, and three chromosome associated polypeptide (CAP) subunits. Previous work showed that C. elegans has two distinct condensin complexes, one with a conserved function in chromosome segregation during mitosis (condensin II), and another specialized for X chromosome gene regulation during dosage compensation (condensin I). These complexes were shown to share one core SMC subunit, while other subunits were distinct or as yet undefined. We report here the identification of the missing CAP subunits from each condensin complex, and present evidence that the core SMC subunits of condensin II may associate with the CAP subunits of condensin I to form yet a third condensin complex (condensin I). Evidence that certain subunits of the two known condensin complexes “mix-and-match” to form a third complex includes the finding that these subunits co-immunoprecipitate, co-localize, and perform common meiotic and mitotic functions. We propose that this third complex is analogous in structure and function to the human mitotic condensin I, resolving the previous paradox that C. elegans is the only higher eukaryote appearing to lack a mitotic condensin I. These findings pave the way to study unique or redundant activities among condensin complexes, and the mechanisms that regulate their differential localization, function, and cell cycle timing.

1869
The C-terminus of Stn1, A. cerevisiae Telomere Protein, Is Required for Telomere Length Regulation and Capping
R. Petreaca, H. Chiu, C. Nugent; University of California, Riverside, CA
The function of telomeres is twofold: cap the chromosome ends to protect against fusions and illegitimate recombination, and facilitate complete replication of linear eukaryotic chromosomes. In the budding yeast S. cerevisiae, STN1 is an essential gene with a critical role in these processes. The Stn1 protein is known to interact with three additional essential proteins: Ten1, a protein critical for negative regulation of telomere length, Cdc13, a single-strand telomere binding protein with roles in activating and inhibiting telomere elongation, and Pol12, the regulatory subunit of primase. To better understand the role of Stn1 in telomere protection and replication, we analyzed the regions of STN1 that are essential for viability. We found that strains with deletions covering the carboxyl terminal half of Stn1, stn1-t186 and stn1-t281, which do not encode amino acids from 187-494 or 282-494 respectively, were viable but have greatly elongated telomeres. Neither of these alleles retain an interaction with Cdc13p. Surprisingly, smaller deletions of the carboxyl terminus also destabilize the interaction with Cdc13p but such alleles are not viable. Telomere elongation in stn1-t186 and stn1-t281 is dependent on telomerase; moreover, viability of the strains requires elongated telomeres. Examination of telomere structure showed the presence of abnormally high levels of single-stranded TG3s. In addition, these strains displayed large chromosome end-to-end fusions. Thus, loss of the STN1 carboxyl terminus leads to defective chromosome end protection that allows fusion of elongated telomeres. These strains proliferate with reasonably high plating efficiency, and few cells activate the DNA damage checkpoint, although the checkpoint remains responsive to other types of damage, indicating that this telomere damage is not recognized as DNA damage. We propose that the elongated telomeres allow the formation of a terminal structure that masks the single-stranded telomeric sequences from the checkpoint surveillance machinery.

1870
RNA-mediated Nucleoid Architecture in Bacteria
R. L. Ohnwa, 1 K. Monkawa, 2 J. Kim, 1 T. Ohtia, 1 C. Wada, 1 K. Takeyasu; 1Graduate School of Biostudies, Kyoto University, Kyoto, Japan, 2Graduate School of Comprehensive Human Medicine, Philadelphia, PA
We have previously reported that, when Escherichia coli, Staphylococcus aureus and Clostridium perfringens was lysed under physiological salt condition, the fibers with the width of ~30 nm and ~80 nm, but not DNA, could be observed by atomic force microscopy (AFM). In E. coli, the loop structure composed of 80 nm fiber also appeared under the same lysis condition. These results suggest that the step-wise folding of DNA, in which 30 nm fiber built from naked DNA turns into 80nm fiber, is present in each loop from the central core. In the present study, we show that a nascent single strand RNA is involved in maintaining the step-wise folding of the nucleoid. In Escherichia coli, RNase A, but not RNase III or RNase II, broke down the thicker fibers into thinner fibers whose dimensions are ~10 nm. The nucleoid in Staphylococcus aureus also turned into 10-nm fiber from the thicker fibers with the treatment of RNase A. Rifampicin or chloramphenicol treatment to E. coli cells changed the majority of the nucleoid fibers into 10-nm one. These results indicate that RNA resistant 10-nm fiber is present in bacteria, and that the thicker fibers than 30 nm are built up from the 10-nm fiber with help of single strand RNA coupled with transcription and translation.

1871
SNP-based Oligonucleotide Microarrays Detect Loss of Heterozyosity (LOH) in a Child with Multiple Congenital Anomalies
T. G. Charles, 1 E. Geiger, 1 M. Vaddi, 1 T. Shaikh; 1Biology, Morgan State University, Baltimore, MD, 2Departments of Pediatrics and Genetics, University of Pennsylvania School of Medicine, Philadelphia, PA
Chromosomal rearrangements like microdeletions and microduplications have been shown to be the underlying cause of a significant proportion of human genetic diseases. We hypothesized that many children with various congenital anomalies (MCA) have submicroscopic microdeletions or microduplications. We use SNP-based oligonucleotide microarrays to detect copy number changes, which result from microdeletions or microduplications in patients with MCA. Here, we report a child with MCA of unknown etiology who was tested with the microarray. Her phenotype includes cranio-facial abnormalities, hypotonia, and global development delay. We did not detect any copy number changes in her genome. Surprisingly, we detected a large region (~20 Mb) on chromosome 16 with copy number neutral homozygosity. We hypothesize that this apparent loss of heterozygosity (LOH) is the result of the uniparental inheritance of this region of chromosome 16 (16q21-q22.1). We are currently testing the patient and her mother with microsatellite markers to further validate the microarray results. If we can confirm the LOH, this will strongly suggest that the phenotype seen in our patient is the result of uniparental disomy (UPD). UPD can cause disease either by unmasking a recessive mutation or due to imprinting of the region involved. Thus, our approach allows us to detect both copy number variation as well as LOH, that may be the underlying cause of genetic diseases.
Nuclear Translocation Levels Regulate Cell Cycle Dynamics of Condensin Distribution in the Yeast Genome

B. Wang,1 P. Butylin,1 M. Basral,1 M. Lichten,1 A. Strunnikov;1 1Laboratory of Gene Regulation and Development, NIH/NICHD, Washington, DC, 2Genetic Branch, Center for Cancer Research, NIH/NCI, Washington, DC, 3Laboratory of Biochemistry, Center for Cancer Research, NIH/NCI, Washington, DC

Mitotic chromosome condensation is established and maintained by condensin complex. However, the molecular mechanisms regulating condensin binding to the specific genomic sites remain largely unknown. In budding yeast, the nuclear organizer (NOR or rDNA) has been identified as the major target site for condensin binding in vivo. To understand the molecular pathways that determine condensin binding to nuclear chromatin, we analyzed the properties of condensin-bind sites within rDNA repeat during the cell cycle. The time course experiments revealed that condensin is enriched in rDNA repeat in a cell cycle dependent manner, which is negatively correlated with 35S rDNA transcription levels. Parallel analysis of RNA polymerase I (Pol I) transcription levels and condensin binding in wild type and fis1Δ mutants with full or minimal copies of rDNA further demonstrated that the bulk of mitotic condensin binding to 35S rDNA is drastically reduced or eliminated when Pol I transcription is maximized. Conversely, when rDNA transcription is repressed either by rapamycin treatment or by promoter shut-off, condensin binding to rDNA is increased. Thus, constitutive and/or periodic repression of Pol I transcription could be a crucial factor in determining the segregation proficiency of rDNA. In cells with an episonal NOR, where rDNA is actively transcribed, the whole-genome analysis showed that condensin released from nucleolus re-distributed to the secondary sites in the genome, with particular enrichment at subtelomeric regions, suggesting a genome-wide regulation of condensin control by rDNA transcription.

Chromatin (VD) Induces a Telomerase-dependent Bystander Effect to Cause Genomic Instability in Human Cells

N. M. Cogan,1 F. Lyng,1 C. Mothersill,1 C. P. Case;2 Clinical Science at North Bristol, University of Bristol, Bristol, United Kingdom, 2Chemical and Pharmaceutical Science, Dublin Institute of Technology, Dublin, Ireland, 3Medical Physics and Research, Juravinski Cancer Centre, Hamilton, ON, Canada

There is current interest in the role of the bystander effect in chromosomal and genomic instability. The bystander effect has so far been shown to occur following exposure to ionizing radiation. Cells directly exposed to radiation induce genomic instability in neighboring ‘bystander’ cells either through secretion of factors into the growth medium or through transfer of a signal via gap junctions. A previous study (Glaviano et al 2006) demonstrated that short term (24 hour) exposures to chromium and vanadium lead to an increase in genomic instability up to 30 days after exposure. The ectopic expression of hTERT protects against this instability. In the current study, we have addressed whether, like radiation, metals are able to induce a bystander effect that would cause chromosomal instability. To do this we treated BJ human fibroblast cells for 24 hours with 0.4 μM potassium dichromate (K₂Cr₂O₇). The cells were washed 5 times to remove any trace of metal ions and incubated in fresh growth medium for 1 hour. This medium was filtered and transferred to non-metal-exposed BJ cells for 24 hours. Our results show that there was an increase in breaks, nucleolar, nucleolccc, and γ-HAX foci in cells subjected to a medium transfer bystander treatment. We also demonstrated that ectopic expression of hTERT protects cells from the bystander response. In conclusion, we demonstrate for the first time, a metal-induced bystander effect that causes genomic instability and is reduced in the presence of telomerase. Glaviano et al (2006) Oncogene 25 3424-3435

Novel Insights into the Location of the P62 Complex and Its Role in Nuclear Import

K. Schwarz-Herion,1 T. Guan,2 B. Maco,1 U. Sauder,1 L. Gerace,2 B. Fahrenkrog;1 1Structural Biology, MHH Biozentrum Basel, Basel, Switzerland, 2Department of Cell Biology and Department of Molecular Biology, The Scripps Research Institute, La Jolla, CA

The nuclear pore complex (NPC) perforates the nuclear envelope (NE) of the eukaryotic cell and regulates the transport of proteins and RNA across the NE. One major component of the NPC is the p62 complex, which is located at the central pore of the NPC and has previously been described to be involved in protein import. The proteins of the p62 complex contain flexible domains called FG-repeats, which function as docking sites for transport receptors, and coiled-coil domains, which anchor the p62 complex to the NPC. Using immuno-electron microscopy with domain-specific antibodies and epitope-tagged proteins we could show how the coiled-coil domains of the p62 complex are anchored at the cytoplasmic side of the pore, whereas the flexible FG-repeat domains can traverse to the nuclear face of the NPC. Furthermore we studied the effect of distinct antibodies against the different compounds of the p62 complex on the protein import. For this purpose we used isolated nuclei of Xenopus oocytes to study the import of gold-labeled nucleoplasmin into the nuclei on electron microscopy level and analyzed the import of GFP-labeled nucleoplasmin into the nuclei of HeLa cells on fluorescence level. We could show that import of cargo was inhibited by certain combinations of antibodies against the p62 complex, whereas individual antibodies against single compounds of the p62 complex had minor effects on the import.

Topology of Yeast NDC1: Predictions for the Human NDC1 Homologue

C. K. Lau, V. A. Delmar, D. J. Forbes; Biology, University of California, San Diego, La Jolla, CA

The nuclear pore complex is the predominant structure in the nuclear envelope that spans the double nuclear membranes of all eukaryotes. Yeasts have an additional organelle that is embedded in the nuclear envelope: the spindle pole body, which functions as the microtubule organizing center. The only protein known to localize to and be important for the assembly of both these yeast structures is the integral membrane protein, Ndc1p. Here, we identify and analyze NDC1 homologues that are conserved throughout evolution. We show that the overall topology of these homologues is conserved. Each contains six transmembrane segments in its N-terminal half and has a large soluble C-terminal half of ~300 amino acids. Charge distribution analysis infers that the N- and C-termini are exposed to the cytoplasm. Limited proteolysis of yeast Ndc1p in cellular membranes confirms the orientation of its C-terminus. Although the functional domains of vertebrate NDC1 are not yet known, the human homolog contains three FG repeats in the C-terminus, a feature of many nuclear pore proteins. Moreover, a small region containing mutations which affect assembly of the nuclear pore in yeast is highly conserved throughout evolution. Hence, the NDC1 homologues are expected to function at nuclear pores.

A Novel Nuclear Pore/Kinetochore Protein Required for Correct Nuclear Pore Assembly

B. A. Rasala, A. Orjalo, Z. Shen, S. Briggs, D. Forbes; Biology, UC San Diego, La Jolla, CA

Nuclear pores span the nuclear envelope and act as gated aqueous channels to regulate the transport of macromolecules between nucleus and cytoplasm -- from individual proteins and RNA to entire viral genomes. By far the largest subunit of the nuclear pore is the Nup107-160 complex, which itself consists of at least nine proteins. As the major subunit, this complex is critical for nuclear pore assembly. At mitosis, the Nup107-160 complex in part localizes to the kinetochores, suggesting that it may also function in the process of chromosome segregation. To investigate the dual roles of the Nup107-160 complex at the pore and during mitosis, we set out to identify binding partners for the complex using both interphase and mitotic Xenopus laevis egg extracts and mass spectrometry. Only a small number proteins were identified to specifically co-immunoprecipitate with the Nup107-160 complex, most of which bind in both interphase and mitotic extracts, including a putative transcription factor. Like the Nup107-160 complex, this large protein localizes to nuclear pores in interphase and kinetochores in mitosis in mammalian cells. Importantly, its depletion by RNA interference leads to a severe nuclear pore disruption in the nuclear envelope and an increase in cytokinesis defects. We conclude that these identified and unexpected members of the nuclear pore and kinetochore that functions in both nuclear pore assembly and faithful cell division.

Different Lamin A/C Mutations Are Associated with Distinct Defects in Nuclear Mechanics

J. Lammerding,1 J. Y. Ji, L. G. Fong,1 A. Muchir,1 H. J. Worman,2 C. L. Stewart,2 G. S. Young,2 R. T. Lee;1 1Medicine, Brigham & Women's Hospital, Harvard Medical School, Cambridge, MA, 2Medicine, University of California, Los Angeles, Los Angeles, CA, 3Medicine and Anatomy and Cell Biology, Columbia University, New York, NY, 4Cancer and Developmental Biology Lab, National Cancer Institute, Frederick, MD

Mutations in LMNA (which encodes the nuclear envelope proteins lamin A and C) cause a variety of human diseases, including Emery-Dreifuss muscular dystrophy, familial partial lipodystrophy, and Hutchinson-Gilford progeria syndrome. At the cellular level, many of these mutations lead to characteristic defects in nuclear shape and morphology, but it remains unclear if these changes affect nuclear function and directly contribute to the disease mechanism. Here, we investigated the effect of specific lamin mutations associated with distinct laminopathies on nuclear mechanics by measuring nuclear deformations in fibroblasts subjected to biaxial strain. Normalized nuclear strain, defined as the ratio of nuclear to applied membrane strain, was assessed in fibroblasts from human subjects with Emery-Dreifuss muscular dystrophy, familial partial lipodystrophy, and Hutchinson-Gilford progeria syndrome patients, as well as healthy control subjects and from mouse models of these diseases. We found that mutations associated with muscular dystrophies resulted in decreased nuclear stiffness, potentially rendering cells more susceptible to physical damage in mechanically stressed tissues such as skeletal and cardiac muscle. In contrast, cells from familial partial lipodystrophy patients had normal nuclear
stiffness. Interestingly, skin fibroblasts from Hutchinson-Gilford progeria syndrome patients initially had normal nuclear stiffness, but developed increasingly stiffer nuclei with increasing passage number as the mutant prelamin A (progerin) accumulated at the nuclear envelope. These results indicate that not all nuclear shape abnormalities associated with LMNA mutations are “created equal;” instead, they can arise either from a functional loss of lamins A/C (as in many of the muscular dystrophies) or from the accumulation of a mutant protein at the nuclear envelope (as seen in progeria), with each scenario resulting in distinct changes in nuclear shape and mechanics. These alterations in nuclear mechanical properties could adversely affect cellular mechanotransduction signaling and cell viability under strain and contribute to the specific pathophysiology of these diseases.

1878

Post-translational Modification and Nuclear Localization of Lamin A/C in Mouse Embryonic Fibroblasts (MEFs)

B. Liu, Z. Zhe,; Department of Biochemistry, The University of Hong Kong, Hong Kong

Lamin A/C is one of the major components of nuclear envelope and nuclear matrix. Lamin A is firstly synthesized as pre-form with 18 extra amino acids, followed by farnesylation of the cysteine (-CSIM) by FT, proteolysis to release -SIM (-AAX) by Zmpste24/Rce1, methylation of the cysteine by ICMT, and lastly proteolysis to remove 15 amino acids by Zmpste24. Recently, LMNA mutations were identified in Hutchinson-Gilford Progeria Syndrome (HGPS) patients. Mouse models deficient for Zmpste24 also showed similar early ageing phenotypes as HGPS. In both human and mouse, the unprocessed prelamin A retains farnesy group in its C-terminus, which may interfere the integrity of nuclear lamina. Illustration of the complex post-translational proteolysis of prelamin A protein may help to better understand the possible molecular mechanism of laminopathy-based premature ageing. In our current study, we constructed pEGFP-prelamin A-3 and pEGFP-prelamin A-18, and transfected them into Zmpste24+/− or wild-type MEFs. Fluorescent microscopic and immunoblotting study suggested that (1) farnesyl or methyl group is not required for the nuclear envelope targeting of prelamin A; (2) Zmpste24 involves in the second cleavage to release 15 amino acids; (3) methylated, but not farnesylated cysteine is required for the second cut of Zmpste24; (4) farnesylcysteine is required for first proteolysis by Zmpste24/Rce1. Our results illustrate the biological relevance of different modification steps during the maturation of Lamin A, this may help to better understand the underlying mechanism of premature ageing caused by abnormal Lamin A.

1879

Regulation of the Inner Nuclear Membrane Protein Emerin by Tyrsoine Phosphorylation

K. E. Trifl, K. L. Wilson; Cell Biology, Johns Hopkins, Baltimore, MD

Emerin-Dreifuss muscular dystrophy (EDMD) is characterized by weakening of selected skeletal muscles, contractures of major tendons, and cardiac conduction defects. Loss of the inner nuclear membrane protein emerin causes X-linked EDMD. Emerin regulates gene expression, potentially via direct binding to transcriptional regulators like BAF, GCL, Lmo7, Bf, and mRNAs splicing factor YT521B. Emerin also binds structurally proteins (lamin A, actin, and Nesprins) suggesting additional roles in nuclear structure. The binding sites in emerin for many partners overlap, suggesting that emerin’s interactions are regulated. Twelve sites of tyrosine phosphorylation in emerin have been identified in five independent proteomic studies of cells treated with tyrosine phosphatase inhibitors. We propose that tyrosine phosphorylation of emerin regulates interactions with specific partners and hence its function. Supporting this hypothesis, BAF binding to emerin is significantly decreased by tyrosine phosphorylation. This effect is partly alleviated by a Src kinase inhibitor suggesting that Src kinases regulate BAF-emerin binding. We made single missense mutations (Y93A or Y93F) at the twelve tyrosine phosphorylation sites in emerin to identify their physiological roles in binding to specific partners in vivo. Mutations at either Y19, Y41, Y461, and/or Y167 disrupted binding to BAF in vivo suggesting that phosphorylation at these sites might inhibit binding to BAF. Residues Y19 and Y41 are located in the LEM domain which is sufficient to bind BAF. Interestingly, Y161 and Y167 did not disrupt BAF binding in previous in vitro studies suggesting that these residues either are part of a second region in emerin that binds to BAF or may affect BAF binding indirectly in vivo. We are also investigating the roles of three tyrosine kinases (Her2, EGF, and Src) in emerin regulation. Understanding how emerin is regulated is crucial to understanding emerin function and determining the molecular mechanism of EDMD.

1880

The Role of Kap95 during Nuclear Pore Complex Assembly

S. B. Rabelo, R. McAndrew, K. J. Ryan; Biology, Texas A&M University, College Station, TX

Nuclear pore complexes (NPCs) are large, proteinaceous structures spanning nuclear envelope (NE). They allow for the passive diffusion of small metabolites and proteins and the selective transport of large proteins and RNAs between the nucleus and cytoplasm. Proteomic studies have found that NPCs are assembled from multiple copies of approximately 30 individual proteins collectively termed nucleoporins or Nups. In higher eukaryotes, both the NE and NPCs are disassembled at the onset of mitosis and must be reassembled following chromsome segregation. Cells continue to assemble NPCS into a closed NE during interphase. In organisms where many of the differentiated cells are either slowly dividing or post-mitotic, NPCs assembled during interphase are likely to account for the majority of nucleocytoplasmic transport capacity. To study the molecular mechanism of NPC assembly into an intact NE, we are using the yeast Saccharomyces cerevisiae and are focused on a cytoplastic function of the karyopherin Kap95 during this process. Cells depleted of Kap95 fail to assemble NPCs and accumulate extended sheets of cytoplasmic membranes. To identify factors interacting with Kap95 at this stage, we are directly testing the kap95-E126K allele for enhanced fitness defects with mutant alleles of NUPs and genes involved in membrane fusion. So far, we have observed interactions between kap95-E126K and a subset of Nups. We have also conducted a multi-copy suppressor screen with kap95-E126K. Both NIC96 and NUP170 are able to suppress the growth phenotype of kap95-E126K when expressed from high copy plasmids. These two NUPs also displayed enhanced lethality with the kap95 allele. In addition to NIC96 and NUP170, we have isolated at least 3 other genomic inserts capable of suppressing the growth defect of kap95-E126K. Further characterization of these genetic interactions will provide insight into the role of Kap95 during NPC assembly.

Functional Domains of Sun1

Q. Liu, K. J. Roux, M. Crisp, M. Elsaage, B. Burke; Anatomy & Cell Biology, University of Florida, Gainesville, FL

The nuclear envelope (NE) forms the boundary between the nucleus and cytoplasm. It features biochemically distinct inner and outer nuclear membranes (INM and ONM) separated by a perinuclear space (PNS). The INM proteins Sun1 and 2 function as tethers for nesprin proteins in the ONM. This involves the interaction of the Sun/nesprin lumenal domains within the PNS. Since Sun proteins are associated with the nuclear lamina and nesprin proteins interact with components of the cytoskeleton, the Sun/nesprin complexes represent links in a molecular chain that connect the nuclear skeletton to the cytoskeleton. We have now sought to further characterize the Sun1 molecule which functions as a tether for nesprin 2 Gant. In this study we made use of several naturally occurring splice isoforms along with engineered deletion constructs to define domains required for Sun1 localization, membrane integration and homotypic oligomerization. We observed that the nucleoplasmic and luminal domains of Sun1 were each sufficient for NE targeting, suggesting at least two independent INM retention mechanisms. The largest isoform of Sun1 has four distinct hydrophobic sequences each of which could function as a transmembrane domain. We hypothesize that Nvj1p is anchored in the ONM through interactions with the vacuole membrane protein Vac8p to form nucleus-vacuole (NV) junctions. Nvj1p remains also lost in reporters with mutations that mildly reduce the hydrophobicity of the N-terminal sequence. These results indicate that not all nuclear shape abnormalities associated with LMNA mutations are “created equal;” instead, they can arise either from a functional loss of lamins A/C (as in many of the muscular dystrophies) or from the accumulation of a mutant protein at the nuclear envelope (as seen in progeria), with each scenario resulting in distinct changes in nuclear shape and mechanics. These alterations in nuclear mechanical properties could adversely affect cellular mechanotransduction signaling and cell viability under strain and contribute to the specific pathophysiology of these diseases.
Degradation, nuclear import was dramatically reduced. These results indicate that degradation of Nup98 is not sufficient to inhibit nuclear import. To determine if the viral 2A protease (2Apro) was responsible for degradation of NPC proteins, we incubated HeLa whole-cell lysates with purified rhinovirus 2Apro. The addition of 2Apro was sufficient to cause degradation of Nup153, p62 and Nup98, when levels of Nup98 were almost undetectable, nuclear import was indistinguishable from mock-infected cells. In contrast, at late times post-infection when Nup98, Nup153 and p62 were all disrupted (e.g. by individual point mutations) lead to tissue specific diseases. In 2003, a subtractive proteomic analysis of liver NEs extracted with either salt/detergent or alkaline solutions identified 67 novel putative NE transmembrane proteins (NETs). Subsequent analysis of the expression profiles of proteins in this dataset indicated that many had a clear preference for expression in liver, suggesting that each cell type or tissue may have a subset of unique NETs. Recently we performed a similar proteomic analysis of alkali-extracted lymphocyte NEs from either resting or activated cells and we are in the final stages of processing and analyzing the NE proteome of salt/detergent-extracted lymphocyte and muscle NEs. In our first dataset of expression in liver, suggesting that each cell type or tissue may have a subset of unique NETs. Recently we performed a similar proteomic analysis of alkali-extracted lymphocyte NEs from either resting or activated cells and we are in the final stages of processing and analyzing the NE proteome of salt/detergent-extracted lymphocyte and muscle NEs. In our first dataset of expression in liver, suggesting that each cell type or tissue may have a subset of unique NETs. Recently we performed a similar proteomic analysis of alkali-extracted lymphocyte NEs from either resting or activated cells and we are in the final stages of processing and analyzing the NE proteome of salt/detergent-extracted lymphocyte and muscle NEs. In our first dataset of expression in liver, suggesting that each cell type or tissue may have a subset of unique NETs. Recently we performed a similar proteomic analysis of alkali-extracted lymphocyte NEs from either resting or activated cells and we are in the final stages of processing and analyzing the NE proteome of salt/detergent-extracted lymphocyte and muscle NEs.
Defining the Cellular Populations in the Adult and Developing Heart

I. Banerjee, J. W. Fuseler, B. K. Thomas, T. A. Baudino; CDBA, University of South Carolina School of Medicine, Columbia, SC

The cell types in the adult myocardium function in a dynamic fashion to regulate the heart’s biomechanical, electrical and structural properties. The cardiac fibroblasts, myocytes, endothelial cells and vascular smooth muscle cells interact to regulate the function of the heart as a pump. What is critical to understand is the effect that developmental and pathophysiological signals have on cellular function in the heart. Alterations in number and location of the various cell types can cause altered cardiac function. Studies performed in the 1970’s established the cell populations in the heart as consisting of 30% myocytes and 70% non-myocytes, i.e. fibroblasts and endothelial cells (Nag 1979, Zak 1974). These studies were performed without the use of molecular markers and were largely based on electron microscopy morphological analysis and centrifugation studies. In this study, we make use of immunospecific markers and Fluorescence Activated Cell Sorting (FACS) analyses to quantify the cell populations during development, homeostasis and pathology in the murine heart. Analysis of the heart at birth demonstrated cellular populations of 10% fibroblasts, 60% myocytes, 3% endothelial and 27% smooth muscle cells. Physiological perturbations observed during the early neonatal period did not cause significant fluctuations in myocyte populations, but did cause significant increases in cardiac fibroblasts. The increase in cardiac fibroblasts was significant in each day observed postpartum, with the greatest increase in the early neonatal period. These data indicate that cardiac fibroblasts respond significantly to the biomechanical load in development. These studies also establish that during homeostatic in the adult heart, the cellular constituents consist of 26% fibroblasts, 55% myocytes, 7% endothelial and 10% vascular smooth muscle cells. Furthermore we have confirmed these results using morphometric and FACS sectional analyses. Taken together, these data taken will enable us to establish a model for defining the cellular constituents of the myocardium.

Protein Knockdown of Edg2 Inhibit Heart Contraction and Blood Circulation in Zebrafish

S. Hayashi, A. Inoue; Biology, Osaka University, Toyonaka, Japan

The cardiac myocytes have striated fibrous structures called myofibrils that contain characteristic myocyte-specific proteins such as cardiac myosin. In early embryonic stage, the heart has already been beating and the size of heart increased dramatically in embryo. Revealing the proliferation mechanism of cardiac myocytes is important not only for understanding the development of heart but also for the medical treatment of heart disease. But it has not known how differentiation and proliferation of cardiac myocytes occur in developing heart. In murine adult heart, it was reported that cardiac progenitors or stem cells exist, and it is considered that non-differentiated proliferative cardiac progenitors can proliferate but terminally differentiated beating cardiac myocytes cannot proliferate. However, there is a possibility that cardiac myocytes proliferate during early stage of embryo. We found that the cardiac myocytes obtained from chick day 7 embryos, expressing cardiac myosin heavy chain, a marker of differentiated cardiomyocytes, proliferated in dispersed culture. This observation suggests that the differentiated cardiac myocytes have the proliferative potential. By administration of bromodeoxyuridine, it was confirmed that embryonic cardiomyocytes passed through DNA synthesis. The cell cycle of cardiomyocytes in culture was estimated to be about 4 days and almost all cardiomyocytes proliferate in culture. Immunocytochemically, the sarcomeric cardiomyocytes were observed in embryonic chicken heart and also embryonic murine heart. We conclude that almost all differentiated cardiomyocytes enter the cell cycle and contribute the enlargement of functional heart in chick embryo.

A DNA Repair Protein Required for Normal Heart and Blood Development

Y. Wang, C. C. Shupenko, L. F. Melo, M. P. R. Strauss; Biology, Northeastern University, Boston, MA

Abasic (AP) sites in DNA are produced spontaneously and by many genotoxic and endogenous agents. The repair of such damage is initiated by AP endonucleases, which are highly conserved from E. coli to man. AP endo1, which constitutes 95% of the AP cleavage activity in mammals, is an embryonic lethal in mice. We are examining its role in embryogenesis in zebrafish. Zebrafish contain two genomic copies (zfAPEX1a and b) with identical coding sequences. zfAPEX1b lacks introns. Recombinant protein (ZAP1) is highly homologous with and has the same enzymatic properties as its human ortholog. ZAP1 is highly expressed throughout development. Embryos microinjected with morpholinoligonucleotide (MO) targeting the translation start site (TS) die at the end of the embryo. They are rescued with mRNA for human WT APEX1 but not APEX1 encoding endonuclease defective protein. Rescued embryos develop dysmorphic hearts, pericardial edema, few erythrocytes, small eyes and abnormal notochords. Embryos microinjected with MO targeting zfAPEX1a intron/exon junctions also pass the MBT with similar abnormalities. We conclude that AP endonuclease 1 is involved in both repairing DNA and regulating specific early stages of embryonic development. This remarkable result could lead to novel therapies in repairing fetal heart defects. Supported by NIH CA72702 and funds from Northeastern University.

Regulation of Ventricular Compaction; Laser Capture Microdissection and Microgenomic Analysis

Y. Li, M. Daniel, P. J. Gruber; Children's Hospital of Philadelphia, Philadelphia, PA

During embryonic heart development, the process of compaction plays a critical role in cardiac morphogenesis. Myocytes in trabecular (inner) layer are more differentiated, while those in compact (outer) layer are more proliferative. The overall objective of these experiments is to better understand the mechanisms that underlie ventricular morphogenesis. We specifically sought to generate new hypotheses to test through a combination of methods new to the study of ventricular compaction. We used microgenomic amplification of laser capture microdissected (LCM) ventricular myocytes to profile expression patterns of compact compared to trabecular myocardium. In brief, E14.5 murine embryos were cryosectioned (8um) at the midpapillary level of the ventricle. Trabecular and compact layers were separated by LCM. RNA was isolated and two rounds of amplification of the mRNA fraction from total cellular RNA were performed from these two cell populations and cRNA analyzed by Affymetrix 430 Mouse Genome chip microarrays. From 50 genes that have at least 2-fold change in each group, the top 5 previously unstudied genes in each group were further analyzed by a combination of qPCR and in situ hybridization. Two candidate genes were selected, Tangerin and Pde1c, both of which are highly up-regulated in trabecular myocardium. In situ hybridization analysis in e14.5 embryos confirmed that Tangerin and Pde1c are highly expressed in compact layer. These results confirm our hypothesis that these genes contribute to the compaction of the ventricular myocardium and have a significant role in the regulation of ventricular morphogenesis.

Knock Down of Edg2 Inhibit Heart Contraction and Blood Circulation in Zebrafish

T. Chan,1 K. Tsao,1 T. Chen,1 H. Lee,2 S. Lee1; 1Institute of Zoology, National Taiwan University, Taipei, Taiwan, 2Department of Life Science & Institute of Zoology, National Taiwan University, Taipei, Taiwan

Unsaturated lysophosphatidic acid (LPA) has been shown to induce vascular remodeling in vivo. However, targeted deletion of LPA receptor genes, edg2 and edg4, in mice resulted in no significant cardiovascular defect that makes the signal transduction of LPA-mediated vascular remodeling in puzzle. To better understand the regulation of LPA-dependent vascular remodeling, we have cloned edg2 and edg4 genes in zebrafish. Whole mount in situ hybridization showed that edg2 is specifically expressed at the pharyngeal arches and in close vicinity to heart in 3 day embryos. Similarly, edg4 is also observed in Edg4, but a reduced expression was evident in other organs including brain and trunk. Embryos injected with 5 ng per embryo edg2 antisense morpholinoligos (MO) at 1-cell stage appeared normal during the first 3 days post injection, but the blood circulation was gradually reduced and even stopped at around Day 5 post injection. In contrast, edg4 MO had no effect on circulation at 10 ng per embryo. To examine the effect of edg4 MO on the vasculature, we used the fli-egfp embryos, which reveal bright fluorescence in vessels. No significant abnormality in vessels was observed in edg2 MO-injected embryos. However, we found that the contraction of heart was gradually weaker that may contribute to the reduced flow in circulation. These results suggested that LPA may mediate the heart contraction via its receptor Edg2, but not Edg4 in developing zebrafish larvae.

Glomeruli Tissue Engineering by Niche Dynamics Utilizing Type V Collagen Fiber

Y. Masuoka, P. Miyata; Institute of Applied Biotechnology, University of Tsukuba, Tsukuba City, Japan

Complicated nephron cannot be completed by current tissue engineering. One barrier is that artificial tissue derived from renal cells can hardly fuse to patient tissue and both blood and urine flows cannot form after transplantation. Particularly, regeneration of glomeruli from tissue fused between microvascular and epithelial ureter is difficult. Although recent tissue engineering improved generation of renal tubes from ureteric buds at development stage, it can neither regenerate glomeruli nor induce microvascular formation within epithelial tissue. This study is to
develop a method using type V collagen fiber to regulate niche dynamics and induce kidney morphogenesis to balance vascular and epithelial formation. Our experiment showed type V collagen fiber existed ubiquitously at early metamorphoses, which incorporated into mesenchymal cap at ureteric bud branching tip and leded connection between glomeruli and ureteric bud. It existed at immature glomeruli while collagen IV at mature ones. This suggest phase changes of ECM occurred. Only V collagen induced vascular morphogenesis from mesenchyme. Experiment culturing adult glomeruli with metanephros showed glomeruli fused to ureteric buds tip to from a complete nephron when it was cultured in medium with V fiber. Microgravity was applied to culture system and result showed V fiber induced glomeruli formation with microvessel. Glomeruli requires both epithelial and vascular formation. But in vitro culture showed interaction of cells and factors for epithelial and vascular morphogenesis inhibited each other during renal development and caused failure formation of glomeruli. Separating cell and factor spatially is important. Type V works as a mediator not only keeping synergic excellerul environment but also allowing dynamics for phase changes. This niche dynamics induced mesenchyme aggregation and separately localized different tissue morphogenesis with harmony. In summary, V fiber ECM induces microvascular and glomeruli formation, and fusion between glomeruli and ureteric bud.

**exc-9, a LIM-domain Protein That Regulates Tubular Structure**

X. Tong, M. Buechner; Molecular Biosciences, The University of Kansas, Lawrence, KS

We are interested in the formation and maintenance of tubular structure. The excretory canal cell of the nematode *C. elegans* provides a simple single-celled model for this study. Tube formation can be studied without considering cell-cell interactions by using this model. The EXC proteins regulate apical diameter of the excretory canal; mutations in exc genes alter the diameter of excretory canal lumen and outgrowth of the canal. Exc-9 mutants show shortened cystic excretory canals. In addition to canal defects, hermaphrodite exc-9 mutants show non-penetrant tailtip defects, and males exc-9 mutants show non-penetrant ray defects. We cloned the exc-9 gene, and found that it encodes a small protein containing a single LIM domain. The LIM domain is a zinc binding, cysteine rich motif consisting of two zinc fingers. LIM domains mediate protein-protein interactions. Exc-9 shows high homology to CRIP (Cysteine-Rich Intestinal Protein), first identified as a cytosolic protein from the mammalian intestine. An exc-9 reporter construct is expressed in several nematode tissues including the excretory canals, the tailtip, the distal tip cells, several neurons, and the ureter cell seam. Overexpression of the reporter construct in wild-type background sometimes arrests the worms at the 2-fold stage of embryogenesis. This phenotype is similar to the phenotype of mutants in the homeobox gene *coh-6*, and suggests that coh-6 activates exc-9 transcription. Low levels of expression of a translational exc-9:gfp fusion construct partially rescue the cystic canal phenotype. High expression levels disrupt canal shape and length. This phenotype is similar to that of overexpression of a translational construct of exc-5, which encodes a guanine exchange factor for CDC42. Preliminary genetic interactions suggest that exc-9 functions downstream of exc-4 (CLC channel) and exc-2 proteins, but upstream of EXC-5. A yeast-two-hybrid assay is being performed to determine possible binding partners of EXC-9.

**Searching for Foxes in the Zebrafish Foregut**

L. Hammonds-Odie, K. Young, D. McGarity, T. Collins; Biology Department, Spelman College, Atlanta, GA

The genetic programs required for mesodermal interactions with endodermal cells in development, particularly as they relate to the formation of organs of the digestive system, have been the subjects of intense study in recent years. During embryogenesis, endoderm-dependent organ formation is accomplished through regional signaling pathways that specify the gut tube to form the thyroid, lungs, liver, pancreas, and gall bladder of vertebrates. Several transcription factors have been implicated in the development of the liver and pancreas. However, frequently in studies of the biliary system or pancreatic development, the gall bladder is completely ignored, despite the proximity. Transcription factors expressed in the foregut endoderm or in the surrounding mesoderm have potential roles in the divergence of the presumptive gallbladder from the hepatic diverticulum. The goal of this study is to document the expression of the zebrafish homologs of transcription factors for which a role in murine gall bladder development has been demonstrated. More specifically, we have examined the expression patterns of the forkhead transcription factors, FoxA2, FoxA3 and FoxF1 in staged zebrafish embryos using in situ hybridization. This work was supported by NIGMS/NIH GM008241-22052, NIH RIMI MD000215-01 and MIE NASA NCC8-227.

**Barx2 Regulates Lachrymal Gland Development**

C. W. Tsai, ’R. Meech,’ K. N. Gonzalez,’ H. Makarenkova,’ T. Collins; Neurobiology, The Scripps Research Institute, La Jolla, CA

A healthy eye is dependent on functions of ocular surface components, which include the cornea, conjunctiva and lacrimal gland (LG). “Dry eye” is a very common condition and is a result of defective function of the LG. Defects in the LG can be congenital or result from autoimmune diseases or aging. “Dry eye” can lead to severe problems and result in a variety of eye diseases, including cataracts, corneal ulcerations, and even blindness. Despite of the commonality of the dry eye condition, only recently have molecular genetic studies of LG development been initiated. Our studies have been centered on the homeodomain transcription factor Barx2 to identify its function in lacrimal gland development. The normal mouse LG at E19.0 consists of a long duct with two branching structures including extra-orbital and intra-orbital branches. In the Barx2 null mouse, the LG was poorly developed or entirely absent. In most cases the lacrimal gland was vestigial, close to the eye, and characterized by ectopic branching from the duct. Unwaveling, down-regulation of Barx2 in LG explants cultures using antisense oligonucleotide also resulted in branching defects. Moreover, gain of Barx2 function experiments show that Barx2 promotes cell migration, and regulates the expression of MMPs and cell adhesion molecules. Together these data suggest that Barx2 plays an essential role in regulating branching morphogenesis of the LG, possibly by modulating the extracellular matrix and cell-cell adhesion.

1898

**BIM Regulates Apoptosis during Mammary Ductal Morphogenesis and Its Absence Reveals Alternative Cell Death Mechanisms**

A. A. Mauleux,’ M. Overholtzer,’ T. Schmiede,’ P. Bouillet,’ A. Strasser,’ J. S. Brugge,’ Cell Biology, Harvard Medical School, Boston, MA; ’The Walter and Eliza Hall Institute of Medical Research, Melbourne, Australia

The adult virgin mammary gland is a highly organized tree-like structure formed by ducts with a hollowed lumen. Although lumen formation during puberty development appears to involve apoptosis, the molecular mechanisms that regulate this process are not known. Here we demonstrate that the BH3-only pro-apoptotic protein BIM is required for apoptosis during pubertal development and disruption of the Bim gene in mice prevents clearing of the lumen in terminal end buds (TEB). However, cells that escape apoptosis in the Bim-/- TEB are eventually cleared from the adjacent ducts by a caspase-independent death process. Interestingly, these cells, which are deprived of matrix attachment, undergo squamous differentiation prior to cell death. Squamous differentiation also takes place in vitro when immortalized mammary epithelial cells are detached from matrix, suggesting that this differentiation program is in fact a direct response to loss of attachment. These data provide important mechanistic information on the processes involved in sculpting the mammary gland in vivo and demonstrates that BIM is a critical regulator of apoptosis associated with this event.

1899

**Regulation of Mucin 1 in Pancreatic Ductal Epithelium: Identification of a Required Minimal Promoter Region**

S. Scott, B. Ghosh, S. D. Leach, Surgery, Johns Hopkins University, Baltimore, MD

The pancreas is composed of two main components: the exocrine tissue that produces digestive enzymes and the endocrine tissue that produces insulin and glucagon. The main components of the exocrine system are responsible for producing glucose regulating hormones, and an exocrine compartment consisting of acinar cells and an elaborate system of ducts. Although pancreatic ductal epithelium is altered in many human diseases, including pancreatic cancer, little is known regarding how ductal differentiation is regulated. We have used immunofluorescent staining to confirm the ductal specification of *Muc1* (*Muc1*) throughout development, and have observed subsequent restriction to the terminal ductal elements in the murine adult pancreas. In order to better understand the regulation of *Muc1* expression and to identify regulatory elements responsible for cell type-specific expression, we created constructs with two different 5' flanking regions fused to the lacZ reporter gene. When 2200bp and 756bp of the *Muc1* 5' flanking sequence were used to drive luciferase (2200bpG3L3 and -756bpG3L3, respectively) in human and murine pancreatic cell lines, activity was observed only in cell lines that were established from pancreatic ductal epithelium, with no expression in islet or acinar cell lines and no quantifiable difference between the activity of the two promoter regions. This indicates that regulatory elements necessary for the transcriptional regulation of *Muc1* may reside within the 756bp 5' flanking region of the gene. We are currently generating a number of constructs of varying lengths in order to more definitively map this region in hopes of identifying novel trans-acting regulators of ductal differentiation. Our results will also enable us to potentially create transgenic mice with EGF expression under the control of a specific and defined *Muc1* regulatory element. This will provide a system whereby we will be able to study the growth and differentiation of the pancreatic ductal system.
Prenatal Development of the Pancreas Is Normal in Shwachman-Diamond Syndrome Mouse Models

L. L. Chen, S. Zhang, P. R. Durie, J. M. Rommens: Program in Genetics & Genomic Medicine, Hospital for Sick Children, Toronto, ON, Canada; aGraduate Department of Molecular and Medical Genetics, University of Toronto, Toronto, ON, Canada; bDepartment of Pediatrics, Hospital for Sick Children, Toronto, ON, Canada; cDepartment of Pediatrics, University of Toronto, ON, Canada.

Shwachman-Diamond syndrome (SDS) is an autosomal recessive disorder characterized by exocrine pancreatic dysfunction, and hematological and skeletal abnormalities. It is caused by mutations in the SBDS gene, a member of a highly conserved protein family involved in RNA processing and/or ribosome biogenesis. Exocrine pancreatic insufficiency (as measured by serum enzyme levels), presents in infancy with maldigestion, poor growth and failure to thrive. Imaging studies show pancreata with reduced size, and autopsy results show extensive fatty replacement with intact ducts and islets, but sparse or no acinar cells. SDS disease models were generated with gene targeting technologies, to obtain inbred mouse strains that are homozygous for the hypomorphic R126T disease allele (SBd/+126T/126T) or heterozygous, with hypomorphic and null allele combinations (SBd/+126T). These mice strains display severe growth retardation and die perinatally. The murine pancreas experiences rapid growth during the course of its development, in the periods before birth and around the time of weaning. Further, some digestive enzymes are produced prior to birth. Early pancreatic development was examined using markers to evaluate cell morphology, differentiation, and enzyme production from E14.5 to perinatal stages. The prenatal development of the pancreas of the mutant mice appears comparable to their wild type siblings. Acinar lobules with peripherally positioned nuclei were readily distinguishable with interspersed clusters of islet cells. Further, immunohistochemical staining of pancreatic sections reveal intact islet and acinar components of the mutant pancreas with production of insulin, glucagon, and amylase. These findings suggest normal development during the embryonic period, such that loss of SBds affects the pancreas only postnatally. While postnatal models are required for more detailed analysis, we conclude that the onset of exocrine pancreatic dysfunction in SDS patients may occur as late as postnatal periods, with the regression or apoptosis of previously differentiated exocrine cells.

An Analysis of Cellular Processes Involved in Organogenesis of the Drosophila Embryonic Gonad

J. W. Weyers, A. B. Mihalitschov, Y. Takeda, M. Yan Doren; Biology, Johns Hopkins University, Baltimore, MD.

The successful formation of organs and tissues requires different cell types to cooperate while engaging in several cellular processes, such as migration, cell-cell adhesion, and cell-cell signaling. One model system in which to study these cellular processes and interactions is the early formation of the Drosophila embryonic gonad. Early gonad formation in flies requires several distinct steps, each of which involves different cellular events. There are two cell types in the embryonic gonad, germ cells (GCs) and somatic gonadal precursors (SGPs). To start, these cells must be properly specified; GCs form very early in embryogenesis, while the SGPs are specified out of the mesoderm in three different segments of the embryo. The GCs are passively carried into the gut during gastrulation, but then actively migrate to join the SGPs. As the germ cells approach and contact the SGP clusters, individual SGPs will undergo cell shape changes to completely ensheath each GC. Concurrently, in what is called SGP cluster fusion, the individual SGP clusters merge together into a band of cells stretching across three segments of the embryo. From there, the cells will coalesce into a properly structured round ball that is the embryonic gonad. The cellular mechanisms for ensemaphate, SGP cluster fusion, and coalescence are mostly unknown. To better understand the processes involved, we have performed a mutagenesis screen to find new genes involved in these mechanisms. Our screen identified 21 different complementation groups, representing new genes, that play a role in these events of gonad formation. An early description of these gene’s roles in the cellular events required for proper gonad formation will be presented.

The Study of Dolichol Phosphate Mannose Synthase I (DPMI) Homolog Y66H1A.2 in C elegans

D. Kim, J. Cho; Department of Biology, Yonsei University, Seoul, Republic of Korea.

Dolichol phosphate mannose synthase is one of the multiple enzymes involved in N-glycan assembly in ER. It catalyses the synthesis of dolichylphosphatemannosyl(Dol-P-Man) from GDP- mannose and dolichylphosphate. This enzyme is composed of a catalytic subunit DPMI and regulatory subunits DPM2, DPM3. It was reported that partial deficiency in human DPMI biosynthesis causes CDG(Congenital disorders of glycosylation) type Ie. We found that dpm1 homolog(y66h1a.2) in C elegans was mainly expressed in hypodermis and intestine. Functional block of dpm1 homolog by RNA interference caused developmental delay, formation of huge embryos or unfertilized oocytes, abnormal cleavage of embryos, egg-laying defect, and enlargement of intestinal lumen. The intestinal lumen enlargement was defined to be associated to dysfunction of digestion. We confirmed problems on ovary occurs when the funtion of DPM1 is inhibited; by mating wild type male and hemaphrodite, they could not produce any progenies. These results indicates that C.elegans DPM1 have important roles involved development.

The RhoGAP Crossveinless-c Links Trachealess and EGFR Signalling to Cell Shape Remodelling in Drosophila Tracheal Invagination

V. Brod, J. Casanova; Institute for Research in Biomedicine (IRB), Barcelona, Spain.

Organ formation requires coordinated changes in cell populations in terms of their proliferation, migration, differentiation and shape. These synchronized changes are controlled by the genes specifying cell fate and by the ability of cells to respond to extracellular cues. A major issue in morphogenesis is to understand how the activity of genes specifying cell fate affects cytoskeletal components that modify cell shape and induce cell movements. We have approached this question by investigating how a group of cells from an epithelial sheet initiate invagination to form the vertebrate eye. We are currently exploring the mechanisms of epithelialization in the eye and the acquisition of columnar epithelial morphology by the neural retina. We use the zebrafish, in which eye formation occurs rapidly, between 10 and 24 hours post fertilization (hpf). In addition, its unparalleled optical accessibility permits continuous observation of all of the cell movements during these events. Our screen revealed a novel role for the RhoGAP Crossveinless-c in regulating the activity of the trachealess patterning gene and the EGFR signalling pathway. Altogether, our results unveil a developmental pathway, linking genes specifying cell fate and signalling pathways with cytoskeleton modifications that underlie the early tracheal cell shape remodelling.

Tissue-specific Loss of BMP Signaling from the Pharyngeal Region Affects Thymus and Parathyroid Organogenesis

J. Gordon, S. R. Patel, N. R. Manley; Genetics, University of Georgia, Athens, GA.

The thymus and parathyroids originate from the third pharyngeal pouches that form as endodermal outpocketings on embryonic day 9 (E9.0) of mouse development. We have previously shown that Foxn1 and Gcm2 define the thymus and parathyroid domains within the primordium prior to organ formation. We recently reported that Bmp4 expression is confined to the thymus domain of the third pouch from E10.5, while its antagonist Noggin is expressed in a non-overlapping domain within the parathyroid region. Here, we have used a series of conditional gene knockouts to delete Bmp4 or Bmp8A from the pharyngeal endoderm and/or the surrounding mesenchyme using Fosq1Cre or Wnt1Cre mouse strains. Deletion of Bmp4 from the endoderm and mesenchyme prior to the onset of Foxn1 expression did not affect patterning of the primordium or initial organ differentiation, but did cause significant morphological defects, suggesting that the two processes are independently controlled. The thymus and parathyroid, which normally separate from each other at E12.5, remained closely associated at E13.5. In addition, we observed a reduction in condensing mesenchyme around the epithelium, resulting in partial disruption of the capsule and thinning of the basement membrane around the thymic primordium. This may in turn be responsible for the disruption migration of the thymus observed in the mutants at E12.5. These results suggest a common BMP-mediated mechanism may be responsible for mesenchymal condensation, capsule formation and separation of the parathyroid from the thymus during mouse embryogenesis. Deletion of Bmp4 from neural crest cells did not affect early thymus and parathyroid organogenesis, suggesting a requirement for reciprocal BMP-mediated signals between the pharyngeal endoderm and mesenchyme. Furthermore, deletion of Bmp4 after the onset of Foxn1 expression did not produce the same phenotype, providing evidence for temporal variation in the role of Bmp4 signaling during thymus and parathyroid organogenesis.

Cellular Mechanisms of Vertebrate Eye Morphogenesis

K. M. Kwan, C. Chien; Neurobiology and Anatomy, University of Utah, Salt Lake City, UT.

The vertebrate eye develops as an evagination from the neuroepithelium of the brain. This epithelial tissue undergoes a series of striking cell and tissue rearrangements to form initially the optic vesicle, and later, the optic cup. The goal of this project is to develop a cellular and molecular understanding of the morphogenetic movements responsible for generating the vertebrate optic cup. We are currently exploring the mechanisms of epithelialization in the eye and the acquisition of columnar epithelial morphology by the neural retina. We use the zebrafish, in which eye formation occurs rapidly, between 10 and 24 hours post fertilization (hpf). In addition, its unparalleled optical accessibility permits continuous observation of all of the cell movements occurring during eye morphogenesis. We are tracking these movements via timelapse confocal microscopy, using a variety of fluorescent proteins. Among these is the photactivatable protein, which allows us to follow movements of individual cells through time.

350
fluorophore Kaede, with which we can observe single cell behaviors during eye morphogenesis. Surprisingly, we find that neural retina cells in the early eye (10-16 hpf) display amoeboid behaviors, with active lamellipodial protrusions on both apical and basolateral surfaces. These protrusions have ceased by the time the optic cup is formed (24 hpf), by which point the cells achieve a columnar epithelial morphology. Protrusions cease in an asymmetric manner, with apical lamellipodia lost prior to basolateral lamellipodia. Interestingly, we find that apicobasal polarity is established early: at the onset of optic vesicle evagination, Par-3 is localized to the apical surface, and shortly after, centrosomes are oriented apically. Our current hypothesis is that formation of apicobasal polarity functions to suppress epithelial cell behaviors on the apical surface, while extracellular matrix, specifically laminin, is required to suppress lamellipodia formation on the basolateral surface. We are testing this using genetic mutants and morpholino knockdown combined with live imaging.

1907 Cytomegalovirus-induced Embryopathy: Mouse Submandibular Sialog gland Epithelial-Mesenchymal Ontogeny as a Model M. Melnick, 1 E. S. Mocarski, 2 G. Abichaker, 3 J. T. Tashjian, 1 Lab Developmental Genetics, University of Southern California, Los Angeles, CA, 3Dept Microbiology and Immunology, Stanford University, Stanford, CA

Human studies suggest, and mouse models clearly demonstrate, that cytomegalovirus (CMV) is dysmorphic to early organ and tissue development. CMV has a particular tropism for embryonic salivary gland and other head mesenchyme. CMV has evolved to co-opt cell signaling networks so to optimize replication and survival, to the detriment of infected tissues. It has been postulated that mesenchymal infection is the critical step in disrupting organogenesis. If so, organogenesis dependent on epithelial-mesenchymal interactions would be particularly vulnerable. In this study, we chose to model the vulnerability by investigating the cell and molecular pathways of CMV-infected mouse embryonic submandibular salivary glands (SGMs). We infected E15 SMG explants with mouse CMV (mCMV). Active infection for up to 12 days in vitro results in a remarkable cell and molecular pathology characterized by atypical epithelial hyperplasia, apparent epithelio-mesenchymal transformation, oncocytic-like stromal metaplasia, β-catenin nuclear localization, and upregulation of NFκB, Relb, Iκb, Stat3, and Cox2. Rescue with an antiviral nucleoside analogue indicates that mCMV replication is necessary to initiate and maintain SMG dysmorphogenesis. Our results indicate that mCMV infection of embryonic mouse explants results in dysplasia, metaplasia, and, possibly, anaplasia. The molecular pathology appears to center around the activation of canonical and, perhaps more importantly, noncanonical NFκB. Further, COX-2 and IL-6 are important downstream effectors of embryopathy. At the cellular level, there appears to be a consequential interplay between the transformed SMG cells and the surrounding extracellular matrix, resulting in the nuclear translocation of β-catenin. From these studies, a tentative framework has emerged within which additional studies may be planned and performed. NIH grants R01 DE014555 (TJ/MM) and ROI A130363 (ESM).

1908 Detection of Apoptotic Cells in Early Developmental Stages of Three Bivalves K. Perry, J. Lynn; Biological Sciences, Louisiana State University, Baton Rouge, LA

In general, bivalve larvae progress through several early life history stages before transitioning into juvenile and adult forms. Morphological alterations in early life stages likely require apoptosis for differentiation of tissues. Embryonic apoptosis events are not well documented for bivalve broadcast spawners with external fertilization. The occurrence of apoptotic blastomeres and cells were followed at 4 hour intervals through embryonic and larval stages for 24 hours after fertilization in two invertebrates, Dreissena polymorpha (zebra mussel) and Mytilus galloprovincialis (Mediterranean mussel), and one indigenous bivalve, Crassostrea virginica (eastern oyster). Apoptotic cells detected using the fluorescence-based TUNEL assay in cleavage (4-64 cells), ciliated blastula, and trochophore stages were compared. During cleavage stages, D. polymorpha had no detectable apoptotic cells similar to observations by Vega and Epel (2004, Mar Environ Res 58:799) in the sea urchin, however C. virginica and M. galloprovincialis embryos exhibited apoptosis in cleavage stages. There was a marked increase in apoptotic cells during the transition from the ciliated blastula stage to the trophophore stage in all three species. M. galloprovincialis embryos were exposed to increasing concentrations of the molluscicide Bayluscide® at fertilization and ending at 4 hrs and 24 hrs of exposure. Both the 4 hr and 24 hr exposures of Bayluscide® (3.9 µg/mL and 0.1 µg/mL assay concentrations respectively) induced significant numbers of apoptotic cells relative to controls. The stress-induced increases in the early stages of C. virginica and M. galloprovincialis development were in contrast to findings of Vega and Epel (2004). Using this data, it may be possible to monitor apoptosis as a consequence of environmental stress, signifying susceptibility in an ecosystem.

1909 Gene Expression as Artemia franciscana Embryos Encyst and Enter Diapause Z. Qiu, 1, S. Tsoi, 1 T. H. MacRae 2; 1Biology, Dalhousie University, Halifax, NS, Canada, 2OBstetrics and Gynecology, University of Arkansas for Medical Sciences, Little Rock, AR

Ooviviparous embryos of the crustacean Artemia franciscana develop into swimming larvae, whereas oviparous embryos cease development as gastrulae, encyst and enter diapause, a form of suspended animation. The metabolic activity of cysts, as these embryos are called, is reduced drastically and their ability to withstand stress is markedly enhanced. Subtractive hybridization was employed to analyze gene expression two days post-fertilization as Artemia embryos enter diapause. Of the 264 cDNA clones examined, 85 were similar to sequences in GenBank and these fell into four functional categories including environmental information processing, cellular processes, genetic information processing and metabolism. p26, a previously characterized small heat shock protein which is up-regulated in cysts was detected, providing confidence in the subtractive methodology. Analysis by semi-quantitative RT-PCR confirmed that seventeen genes were up-regulated and four down-regulated. Genes encoding a homolog of the human co-transcription factor p6, two new small heat shock proteins, putative cell cycle suppressor proteins, and metabolic enzymes were among those up-regulated. The co-transcription factor p8 may influence gene expression and it is potentially one of many regulatory proteins involved in establishing the diapause developmental program. The BRCA 1 associated protein (Bap-1) and functionally related proteins may modulate cell growth during transition into diapause, small heat shock proteins, protect Artemia embryos from physiological stress, and chitin related proteins contribute to cyst wall construction. This study represents the first systematic molecular characterization of early diapause in a crustacean embryo. The synthesis within oviparous Artemia embryos of proteins such as molecular chaperones, which have been detected in other organisms undergoing diapause, was established. In addition, novel differentially expressed genes were identified, thereby increasing the number of proteins known to be modified during early diapause in Artemia, and by extrapolation, in other organisms.

1910 Artemia, a Ferritin Homologue from Artemia franciscana, Is a Developmentally Regulated Molecular Chaperone T. Chen, 1 T. S. Villeeuneve, 2 K. A. Garant, 2 R. Amons, 2 T. H. MacRae 2; 1The College of Animal Science and Technology, Hunan Agricultural University, Changsha, China, 2Biology, Dalhousie University, Halifax, NS, Canada, 3Molecular Cell Biology, Leiden University, Leiden, The Netherlands

Encysted embryos (cysts) of the crustacean, Artemia franciscana, exhibit a level of stress tolerance seldom seen in metazoans, a property thought to depend partly on the regulated synthesis of artemin, a ferritin homologue. Artemia is an abundant heat stable protein produced in cysts which forms oligomers equal in molecular mass to those assembled by ferritin but fails to bind iron. The objective of this study was to better understand artemin function and to this end the protein was synthesized in transformed Escherichia coli and purified to apparent homogeneity with TALON™ affinity resin. Purified artemin consisted of oligomers approximately 700 kDa in molecular mass which dissociated into monomers and a small number of dimers upon SDS polyacrylamide gel electrophoresis. Artemin inhibited heat induced aggregation of citrate synthase in vitro, an activity characteristic of molecular chaperones. Apoferritin and ferritin also exhibited chaperone activity approximately equal to that shown by artemin, suggesting protection of cells by mechanisms other than iron sequestration. Transfected mammalian cells synthesizing artemin were more resistant to heat and H2O2 than were cells transfected with vector only. The data support the proposal that artemin is a structurally modified ferritin arising from either a common ancestor gene or by duplication of the ferritin gene. Divergence, including acquisition of a carboxy-terminal extension and ferroxidase center modification, eliminated iron sequestration, however chaperone activity was retained. Consequently, because artemin accumulates in large amounts, it has the potential to protect Artemia embryos against physiological stress during encystment and diapause without adversely influencing iron metabolism. This work expands the range of activities attributed to artemin, a protein reported previously to bind proteins and metabolic enzymes were among those up-regulated. The co-transcription factor p8 may influence gene expression and it is potentially one of many regulatory proteins involved in establishing the diapause developmental program. The BRCA 1 associated protein (Bap-1) and functionally related proteins may modulate cell growth during transition into diapause, small heat shock proteins, protect Artemia embryos from physiological stress, and chitin related proteins contribute to cyst wall construction. This study represents the first systematic molecular characterization of early diapause in a crustacean embryo. The synthesis within oviparous Artemia embryos of proteins such as molecular chaperones, which have been detected in other organisms undergoing diapause, was established. In addition, novel differentially expressed genes were identified, thereby increasing the number of proteins known to be modified during early diapause in Artemia, and by extrapolation, in other organisms.

1911 Mirror-imaged Doublets of Sterkiella histriorumascorn: Implications for the Development of Left-Right Asymmetry A. J. Bell, P. Satir; Anatomy/Structural Biology, Albert Einstein College of Medicine, Bronx, NY

Ciliated protozoa possess cellular axes reflected in the arrangement of their ciliature. Upon transverse fission, each daughter cell develops an identical ciliary pattern, ensuring perpetuation of the cellular axis. Cilia are generally spatially coordinated, forming a single columnar epithelial sheet. These spatially coordinated cilia may be visualized using ultrathin sections, some of which are capable of intracellular propagation and regeneration after excision. One such phenotype in the ciliate Sterkiella histriorumascorn (formerly Oxytricha falkas/trifilas) is the mirror-imaged doublet. These cells possess two distinct sets of cilia, juxtaposed on the surfaces, arranged in mirror-image symmetry, with a common anterior-posterior axis. We have examined whether individual ciliary components in mirror-image doublets of Sterkiella are themselves mirror-imaged. Ultrathin section analysis indicates that despite the global mirror-imaging of the ciliate, the detailed organization of the membranebilayer is reversed in the mirror-image doublet. This suggests that, like the cells from which they are derived, the mirror-image doublets are themselves mirror-imaged. Ultrastructural analysis indicates that despite the global mirror-imaging of the ciliate, the detailed organization of the membranebilayer is reversed in the mirror-image doublet.
oral apparatus, such that the effective stroke of the cilia propels food away from the mouth. Assembly of compound ciliary structures of both oral apparatuses starts out identically, but as the structures associated with the mirror-image oral apparatus continue to form, its primordial set of oral membranelles undergoes a 180° rotation in the plane of the ventral surface relative to the same structures in the typical oral apparatus. The overall symmetry of the oral apparatus thus appears to be obtained from the more localized assembly of individual basal bodies. “True” mirror imagery of the membranelles would require an enantiomorphic form of the individual ciliary components, particularly the basal bodies, which is never observed. These observations suggest a mechanistic hypothesis with implications for the development of left-right asymmetry not only in ciliates, but perhaps development of left-right asymmetry in general.

1916 The Paromycin Sensitive Aminopeptidase PAM-1 Regulates Centrosome Dynamics and Chromosome Segregation in C. elegans
S. Marshall, L. Washam, J. Kerschner, R. Lyceaz; Biology Department, Ursinus College, Collegeville, PA
PAM-1 is a C. elegans aminopeptidase that is highly related to mammalian PSA. We have identified mutations in this aminopeptidase in C. elegans and have discovered roles for this enzyme in regulation of meiotic exit, anterior-posterior polarity and chromosome segregation. We are analyzing the polarity and chromosome defects in detail in the early embryo.
Determination of Intercellular Forces during Drosophila Embryogenesis

X. Ma, P. Scully, M. S. Hatson; Physics & Astronomy, Vanderbilt Institute for Integrative Biosystem Research & Education, Vanderbilt University, Nashville, TN

Differences in intercellular tensions along cell-cell boundaries have been hypothesized as a driving force for cellular movements during morphogenesis. We have developed a method to measure these tensions in living fruit fly (Drosophila) embryos. The method combines confocal imaging of embryos expressing GFP-chimeras with laser-microsurgery. In the regime of low Reynolds number, the tension along a cell-cell boundary before an incision is well-approximated by the product of the viscous damping constant and the initial recoil velocity of adjacent cell edges after an incision. To measure this recoil velocity, a Q-switched Nd: YAG laser is used to cut a single cell edge while line-scan kymographs of adjacent cell edges are recorded at time resolutions as fast as 2 μm. The time-dependent cell edge positions are extracted from the kymographs using custom Imaged plugins based on the Lucas-Kanade algorithm. The post-incision recoil velocities are then estimated using either a double exponential fit or a Savitzky-Golay filter. Finally, a power spectrum analysis of cell-edge position fluctuations is used to determine the viscous damping constant. This technique has been applied to simulate kymographs to evaluate the robustness of the algorithm and to three distinct stages of Drosophila development - germ band retraction, early and late dorsal closure - that show differences in cellular tensions.

Integrins and TGFβ Family Member Dpp Interact during Drosophila Dorsal Closure

J. W. Bloore; Department of Biosciences, University of Kent, Canterbury, United Kingdom

Dorsal closure dorsal closure describes a morphogenetic event that occurs in the embryo when two epithelial sheets initially positioned laterally sweep up to the dorsal midline where they fuse to form a continuous epidermis. This process involves physical interaction between the epithelial sheets and the amnioserosa, another cell sheet that initially occupies the embryonic dorsal surface. It is contraction of the amnioserosa together with contraction of a supra-cellular actomyosin pursestring formed in the leading cell row of each epithelial sheet, which drives dorsal closure. Dpp is also expressed in the cells of the leading edge. It is not involved in pursestring formation, but does appear to have a role in promoting leading edge filopodia, the structures that knit the two epithelial sheets together at the dorsal midline. Integrins also function during dorsal closure, where they have been shown to mediate survival of the amnioserosa - in the absence of integrins the cells of the amnioserosa enter anoikis. We will present evidence for an additional role for integrins: the promotion of functional leading edge filopodia. Moreover we show, through live embryo imaging, that the dorsal closure phenotypes of integrin and Dpp pathway mutants are remarkably similar. These observations lead us to the hypothesis that integrins and Dpp act together to promote epithelial fusion at the dorsal midline. In support of this hypothesis we show that integrin and Dpp pathway mutants interact genetically. Currently we are attempting to determine whether there is a physical protein-protein interaction between the two. We suggest that they do and that this provides a novel way of generating a local Dpp signal.

A New Family of Nucleases: The Uracil-DNA Specific Nuclease of Pupating Insects

B. G. Vertessy, A. Bekesi, V. Maha, M. Pukanszky, I. Leveles, I. Zaguya; Institute of Enzymology, Budapest, Hungary

Uracil in DNA may arise by cytosine deamination or thymine replacement and is removed by members of the uracil-DNA glycosylase (UDG) superfamily. The surprising lack of the major UDG-superfamily member UNG from the fruitfly genome may allow the fly to tolerate thymine replacing incorporation of uracil in its DNA. Such incorporation is usually prevented by the enzyme dUTPase that removes dUTP from the DNA polymerization pathway. Simultaneous lack of dUTPase and UNG leads to biosynthesis and stable presence of uracil-substituted DNA in mutant E. coli strains. However, dUTPase is present in all multicellular organisms and is usually up-regulated in cells with active DNA synthesis. Fruitfly larvae present a surprising exception to this general rule: dUTPase is confined to the imaginal disks while larval tissues, associated with active DNA synthesis, do not contain any detectable dUTPase (Bekesi et al, 2004 J Biol Chem 279(21):23262-70). Here we asked if the putative presence of uracil-DNA in larval tissues, potentially accumulated due to lack of both UNG and dUTPase, might trigger any physiological response. Such response would require macromolecular (e.g. protein) factors specifically recognizing uracil-DNA; we therefore set out to identify such proteins from Drosophila extracts. We show that the most intensive hit of uracil-DNA pull-down experiments is a uracil-DNA specific nuclease (UDE) with no detectable homology to other proteins except a group of sequences present in genomes of other pupating insects. UDE protein is strongly up-regulated right before pupation by an edysone-controlled mechanism potentially involving betaFTZ-F1. These data imply the existence of a novel DNA nuclease family specific for uracil-DNA with a possible role in cell death during metamorphosis.

Functional Importance of Polymerization and Localization of Calsequstrin in Caenorhabditis elegans

J. Ahn, J. Cho, K. Ko, G. Singaruvelu; Life Science, Gwangju Institute of Science and Technology, Gwangju, Republic of Korea

Dual role of calsequstrin being the ‘Ca2+ donor’ and ‘Ca2+ acceptor’ makes it an excellent Ca2+ buffering protein within the sarcoplasmic reticulum (SR). We have isolated and characterized of the calsequestrin (csq-1) in C. elegans. To our surprise, csq-1(jh108) mutant showed no gross defect in muscle function as well as muscle development. However, csq-1 mutant is highly sensitive to perturbation of Ca2+ homeostasis. The rational of homology modeling, we investigated the domains of calsequstrin which are important for polymerization and cellular localization required for its proper buffering functions. The in vivo patterns of polymerization and localization of several mutated CSQ-1 were observed and then were correlated with the structures of different mutations for their proper polymerization and localization as well as their effectiveness for the rescue in Ca2+ perturbed conditions. Our results suggest that polymerization of CSQ-1 is essential, but not sufficient, for proper cellular localization and function of CSQ-1. In addition, the direct interaction between calsequstrin and myonidine receptor (RYR), is found by in vitro binding assay, suggesting that the cellular localization of calsequstrin is indeed modulated by the RYR via physical interaction in C. elegans.

Axis Specification during First Division in Primates: Pronuclear Orientation, Not the Second Polar Body (2Pb), Defines the Cleavage Plane

C. Simlerly, E. Jacoby, D. McFarland, C. Navara, G. Schuett, Pittsburgh Development Center, Pittsburgh, PA

In mammalian embryos, existence of oocyte polarity as a determinant of cleavage axis formation remains controversial. Time-lapse video microscopy (TLVM) of fertilized mouse zygotes suggested conflicting evidence regarding spatial cues (2Pb, sperm incorporation site) near the animal pole that may directly orient division planes. Alternatively, perhaps no specification of axis exists in the early oocyte and orientation of the two opposing pronuclei predicts cleavage planes. Here, in primate zygotes, TLVM was employed to observe pronucleus formation, migration, alignment and cytokinesis after fertilization or artificial activation. After intracytoplasmic sperm injection (ICSI), zygotes demonstrate both radial (157(294)) and tangential (137(294)) orientation pronuclei in the cytoplasm. The cortical site of cleavage furrow formation begins near opposed pronuclei and proceeds through the long axis of the ‘docked’ parental genomes regardless of 2Pb position. If the 2Pb is outside of the cleavage furrow, a massive cortical rotation positions it between the daughter blastomers. Following in vitro fertilization (IVF), cortical residing pronuclei are nearly always oriented radially near the site of sperm penetration and the first mitotic spindle aligns to permit the cleavage furrow to pass near the 2Pb. Following artificial activation, the single formed female pronucleus migrates randomly in the cytoplasm- the cleavage furrow forms nearest the adjacent cortex and passes through the site of the 2Pb. Conversely, after ICSI into enucleated oocytes (androgenesis), the male pronucleus migrates to a random cortical region and cytokinesis occurs irrespective of the 2Pb region. Collectively, cleavage furrow initiation in fertilized NHP zygotes depends on mitotic spindle orientation and equatorial chromosome alignment. Although the 2Pb may not be a rigid fiduciary mark of cytokinesis, a dynamic and complex signaling mechanism, with feed-back loops, between the cortex, central cytoplasm, mitotic spindle and chromosomes appears to underlie the supramolecular mechanism specifying the first cleavage axis in primates.

A Cell Biological Checkpoint for Development: Does the Spindle Checkpoint Regulate Asymmetric Spindle Positioning?

E. K. McCarthy, B. Goldstein, Biology, University of North Carolina at Chapel Hill, Chapel Hill, NC

The mechanisms that regulate asymmetric cell division are not well understood in any animal system. The first mitotic division of 2Pb may not be a rigid fiduciary mark of cytokinesis, a dynamic and complex signaling mechanism, with feed-back loops, between the cortex, central cytoplasm, mitotic spindle and chromosomes appears to underlie the supramolecular mechanism specifying the first cleavage axis in primate embryos.
anaphase transition, we disrupted proteasome activity by either treating embryos with a proteasome inhibitor or depleting embryos of a proteasome regulatory subunit. These treatments delay the metaphase to anaphase transition, as expected, and we found that these treatments also delay asymmetric spindle positioning. These results indicate that proper proteasome function is required for timely spindle positioning. As proper proteasome function is required for checkpoint signaling, we are currently further testing whether the spindle checkpoint directly regulates asymmetric spindle positioning. To test this, we are using the timing of spindle positioning after early inactivation of the checkpoint and also after constitutive activation of the checkpoint.

Phosphoinositides Are Required for Male Germ Cell Polarity and Sperm Tail Formation in Drosophila

H. Wei,1 G. Polevoy,1 J. Rollins,2 C. Buzin,2 J. A. Brill,1 1Developmental and Stem Cell Biology, Hospital for Sick Children, Toronto, ON, Canada, 2Biological Sciences, St. John's University, Jamaica, NY

Phosphoinositides (PIPs) are well established as important determinants in signal transduction, vesicle trafficking, cell polarity and actin assembly in cultured cells. However, the role of PIPs in the differentiation of multicellular organisms is less well understood. Here we describe a novel approach to studying PIPs in vivo. To investigate the role of PIPs in Drosophila spermatogenesis, we introduced a potent Salmonella PIP phosphatase SigD into developing spermatids. Germline cells expressing high levels of SigD lack detectable plasma membrane phosphatidylinositol 4,5-bisphosphate (PIP2) and accumulate phosphatidylinositol 4-phosphate (PIP4). In the cytoplasm. Spermatids exhibit defects in sperm tail formation, including accumulation of wavelike structures and absence of axoneme assembly. Low level SigD expression has only mild effects on PIP levels. In addition, sperm tail formation appears normal. However, spermatids lack the F-actin-based investment cones required to individualize mature sperm. Moreover, stable intercellular bridges (ring canals) that normally connect developing spermatids are absent and cell polarity appears disrupted, as nuclei are found at both ends of elongating spermatids. This suggests PIP levels are critical for actin cone assembly, ring canal stability and spermatid polarity. Expression of a YFP tagged PIP 5-kinase (YFP-Skil), which generates PIP, from PIP4, suppresses the membrane and axoneme defects caused by high levels of SigD, indicating that the observed phenotypes are due to altered PIP levels. As YFP-Skil localizes to ring canals at the distal end of elongating spermatids, we propose that PIP biosynthesis at the growing end is important for cell polarity and efficient flagellar outgrowth during sperm development.

Ankyrin-B and Ankyrin-G Determine the Physiological Segregation of Ion Channels between the Inner and Outer Segments of Photoreceptors

K. Kizhatil,1 N. Sandhu,2 N. S. Peachey,1 V. Bennett1 1Cell Biology and HHMI, Duke University, Durham, NC, 2Ophthalmic Research, Cole Eye Institute, The Cleveland Clinic Foundation, Cleveland, OH, 1Ophthalmic Research, Cole Eye Institute, The Cleveland Clinic Foundation and Cleveland VA Medical Center, Cleveland, OH

Vision requires the constant flow of a current between the photoreceptor inner and outer segments in the dark. The phototransduction cascade culminates in cessation of the "dark current" established between the photoreceptor inner and outer segments. Generation of the current requires the proper localization of distinct sets of ion channels between the inner and outer segments of photoreceptors. Specifically, localization of the cyclic nucleotide gated channel to the outer segment and the NaKATPase to the inner segment is critical for the current generation. These proteins are localized to the plasma membrane of the photoreceptor. We report that in photoreceptors of humans and mice ankyrin-B and ankyrin-G localize to the inner and outer segments in a mutually exclusive manner. We show that the inner segments of photoreceptors in the ankyrin-B haploinsufficient retina show a marked reduction of NaKATPase and the Na/Ca exchanger in a manner analogous to ankyrin-B haploinsufficient cardiomyocytes. These results show that ankyrin-B is the physiological binding partner of NaKATPase as well as Na/Ca exchanger in the inner segment of the photoreceptor. In addition, using coimmunoprecipitation and a cellular membrane recruitment assay we show that ankyrin-G interacts with the beta subunit of the cyclic nucleotide gated channels. Together these results show that ankyrin-B and ankyrin-G define distinct membrane domains of the photoreceptor essential for vision.

Subcellular Compartmentalization of Drosophila Neurons

M. M. Rolls,1 D. Satoh,2 T. Uemura,2 C. Q. Doe1,2 1Institute of Neuroscience, University of Oregon, Eugene, OR, 2Kyoto University, Kyoto, Japan, 1Howard Hughes Medical Institute, Eugene, OR

It has been well-established that vertebrate neurons are divided into subcellular compartments with distinct functions and protein compositions: the soma, axons, and dendrites. It has been unclear how much of this organization is shared by invertebrate neurons. In order to establish whether Drosophila neurons are a good system in which to study subcellular compartmentalization of neurons, we have investigated whether they are organized in the same ways as vertebrate neurons. Using localization of tagged markers in Kenyon cells in the larval brain, we find that many features of vertebrate neuronal organization are also present in Drosophila. We have determined that: (1) a marker of glutamatergic synapses is exclusively localized to dendrites, while synaptic vesicles are localized to both dendrites and axons (as they are in many vertebrate neurons that perform higher order processing); (2) the machinery responsible for protein synthesis is predominantly localized to the soma; (3) the microtubule cytoskeleton preferentially binds different markers in axons and dendrites, and (4) the proximal part of the neurite shares several features with the vertebrate axon initial segment. In addition, we have investigated microtubule organization in more detail in the Drosophila peripheral nervous system. By tracking EB1-GFP movements in neurons, we find that microtubule polarity is strikingly different in axons in dendrites, as is the case in vertebrate neurons. We conclude that the subcellular organization of Drosophila neurons is very similar to that of vertebrate neurons, and that this system will be a very powerful one in which to study neuronal polarity.

Cell Polarity: Can Wnt Act as a Positional Cue?

M. Roh,1 A. Mikels,2 R. Nusse,3 B. Goldstein,1 1Biology, University of North Carolina, Chapel Hill, NC, 2Developmental Biology, Stanford University, Stanford, CA

Establishing cell polarity is essential for normal development. Cell polarity requires intricate cell-cell signalling and remodeling of the underlying cytoskeleton - all phenomena that remain under-explored. The Wnt pathway is a conserved pathway, known to play a role in establishing cell polarity in a variety of organisms. Although this is a well-studied pathway, an outstanding question that remains is whether a Wnt signal can act as a positional cue. To address this, we are studying the four-cell stage C. elegans embryo. At this stage, signals from one cell to its neighbour result in polarization of the responding cell such that the responding cell divides asymmetrically. Two signals, MES-1 and MOM-2/Wnt, are sent from the signalling cell to polarize the responding cell and align the mitotic spindle as well as regulate gene expression. Although both pathways are required for polarized division, cell manipulation experiments suggest that it is the position of the Wnt signal that dictates spindle positioning (Goldstein et al., 2006). However, it remains elusive whether this is a direct effect of Wnt, or an indirect downstream effect. To address this issue, we use a novel approach in which beads coated with purified MOM-2/Wnt proteins are used to manipulate the position of the MOM-2/Wnt source on an isolated responding cell. We have also constructed a transgenic strain containing GFP-tagged tubulin in a novel approach to studying PIPs in vivo. To investigate the role of PIPs in Drosophila spermatogenesis, we introduced a potent Salmonella PIP phosphatase SigD into developing spermatids. Germline cells expressing high levels of SigD lack detectable plasma membrane phosphatidylinositol 4,5-bisphosphate (PIP2) and accumulate phosphatidylinositol 4-phosphate (PIP4). In the cytoplasm. Spermatids exhibit defects in sperm tail formation, including accumulation of wavelike structures and absence of axoneme assembly. Low level SigD expression has only mild effects on PIP levels. In addition, sperm tail formation appears normal. However, spermatids lack the F-actin-based investment cones required to individualize mature sperm. Moreover, stable intercellular bridges (ring canals) that normally connect developing spermatids are absent and cell polarity appears disrupted, as nuclei are found at both ends of elongating spermatids. This suggests PIP levels are critical for actin cone assembly, ring canal stability and spermatid polarity. Expression of a YFP tagged PIP 5-kinase (YFP-Skil), which generates PIP, from PIP4, suppresses the membrane and axoneme defects caused by high levels of SigD, indicating that the observed phenotypes are due to altered PIP levels. As YFP-Skil localizes to ring canals at the distal end of elongating spermatids, we propose that PIP biosynthesis at the growing end is important for cell polarity and efficient flagellar outgrowth during sperm development.

Drosophila Tao-1 Gene Is Required for the Cortical Microtubule Nucleation in the Oocyte

W. Yang, V. Riechmann; Institute for Developmental Biology, Universitity of Cologne, Cologne, Germany

In the Drosophila oocyte, microtubules (MTs) nucleate from the anterior and lateral cortices, with the exception of the posterior pole. These cortical MTs are organized in a gradient from anterior to posterior, with the highest density in the anterior part. Along this MT network, transcripts of axis determinants, bicoid, oskar and gurken mRNA are precisely transported to distinct locations. Thus, the polarized MT network determines the anterior/posterior axis. Although cortical MT nucleation is essential for polarizing the oocyte, how this is regulated is unknown. Many mutants affecting the polarity of the MT network have been identified, but most of these mutants show only partially impaired polarity and do not affect cortical MT nucleation. This is reflected by the distribution of bicoid, oskar and gurken, which localize aberrantly, but which are still transported in a polar manner in these mutants. In contrast, a mutant affecting cortical MT nucleation would completely abolish polar mRNA transport. Here we report such a novel MT phenotype affecting cortical MT nucleation. This phenotype is caused by a mutation in the gene encoding the conserved Ser/Thr kinase Tao-1. Tao-1 protein localizes at the oocyte cortex. In tao-1 mutants, TuRC+, y tubulin and Dgrip, are not enriched in the oocyte cortex but dispersed throughout the ooplasm. This is accompanied with a strong reduction of cortical MT nucleation and a strong accumulation of randomly oriented MTs within the ooplasm. Consistently, MT polarity markers are also present throughout the ooplasm rather than at the anterior and posterior poles. Therefore, polarity of the MT network is completely lost in tao-1.
Asymmetric cell division is a fundamental process to generate cell diversity during development. We use the early *C. elegans* embryos to study this process. In the one cell embryo the conserved PAR-proteins (partitioning defective) govern the establishment and maintenance of cell polarity. PAR-3, PAR-6 and PKC-3 form a protein complex (PAR-3/6/3 complex) and localize to the anterior cortex while PAR-2 is enriched on the posterior cortex. In order to define how the extracellular environment affects cell polarity, we analyzed the organization of individual cells plated on defined micro-patterned substrates imposing cells to spread on various combinations of adhesive and non-adhesive areas. The reproducible normalization effect on overall cell morphology and orientation quantification of the spatial organization of the actin network and associated proteins; the distribution of microtubules; and the positioning of nucleus, centrosome and Golgi apparatus. By using specific micropatterns and statistical analysis of cell compartments positions, we demonstrated that ECM geometry determines the orientation of cell polarity axes. The nucleus-centrosome orientations were reproducibly directed towards cell adhesive edges. The anisotropy of the cell cortex in response to the adhesive conditions did not affect the centrosome positioning at the cell centroid. Based on the quantification of microtubule plus end distribution we propose a quantitative model that accounts for these observations. In conclusion, we show that LARP-1 and NOS-3 have a novel role in cell polarity by regulating the expression of PAR-6 in the embryo.

Asymmetric cell division is a fundamental process to generate cell diversity during development. We use the early *C. elegans* embryos to study this process. In the one cell embryo the conserved PAR-proteins (partitioning defective) govern the establishment and maintenance of cell polarity. PAR-3, PAR-6 and PKC-3 form a protein complex (PAR-3/6/3 complex) and localize to the anterior cortex while PAR-2 is enriched on the posterior cortex. In order to define how the extracellular environment affects cell polarity, we analyzed the organization of individual cells plated on defined micro-patterned substrates imposing cells to spread on various combinations of adhesive and non-adhesive areas. The reproducible normalization effect on overall cell morphology and orientation quantification of the spatial organization of the actin network and associated proteins; the distribution of microtubules; and the positioning of nucleus, centrosome and Golgi apparatus. By using specific micropatterns and statistical analysis of cell compartments positions, we demonstrated that ECM geometry determines the orientation of cell polarity axes. The nucleus-centrosome orientations were reproducibly directed towards cell adhesive edges. The anisotropy of the cell cortex in response to the adhesive conditions did not affect the centrosome positioning at the cell centroid. Based on the quantification of microtubule plus end distribution we propose a quantitative model that accounts for these observations. In conclusion, we show that LARP-1 and NOS-3 have a novel role in cell polarity by regulating the expression of PAR-6 in the embryo.

Asymmetric cell division is a fundamental process to generate cell diversity during development. We use the early *C. elegans* embryos to study this process. In the one cell embryo the conserved PAR-proteins (partitioning defective) govern the establishment and maintenance of cell polarity. PAR-3, PAR-6 and PKC-3 form a protein complex (PAR-3/6/3 complex) and localize to the anterior cortex while PAR-2 is enriched on the posterior cortex. In order to define how the extracellular environment affects cell polarity, we analyzed the organization of individual cells plated on defined micro-patterned substrates imposing cells to spread on various combinations of adhesive and non-adhesive areas. Cell polarity is a shared feature of numerous cell types from bacteria to mammals. Strikingly, while cells exhibit various shapes and perform different functions, the core proteins establishing cell polarity are common to all eukaryotic cells types. *Drosophila* epithelia exhibit 2 types of polarity: an Apical/Basal (A/B) polarity and a second along the plane of the epithelium (Planar Cell Polarity or PCP). Biochemical and genetic evidence indicates that some A/B polarity and PCP factors can be in fact involved in both types of cellular polarization. Scribble, a protein that is identified through its requirement in A/B polarity of epithelial cells, form a complex with Dlg (Discs large) and Lgl (Lethal Giant larvae). Our results show that this polarity complex, physically and genetically interacts with Strabismus, a core PCK gene, to regulate epithelial patterning in *Drosophila* tissues.

**Hepatocyte Nuclear Factor 4α Provokes Microvillus Formation via Induction of ERM-binding Phosphoprotein 50**

H. Chiba, N. Sakai, M. Murata, M. Osanai, K. Takashi, N. Sawada; Department of Pathology, Sapporo Medical University School of Medicine, Sapporo, Japan

Microvilli are actin-based organelles on apical plasma membranes and involved in nutrient uptake and transduction of various stimuli. Numerous microvillus components, including ezrin/radixin/moesin (ERM) proteins, which upon phosphorylation link filamentous actins to transmembrane proteins, have been identified, but it is unclear which signals drive microvillus biogenesis. Here we show, using two distinct cell lines, that conditionally or ectopically expressed hepatocyte nuclear factor 4α (HNF4α) provokes EBP-binding phosphoprotein 50 (EBP50) expression and de novo formation of microvilli on cells expressing HNF4α alone. Notably, RNA interference in EBP50 inhibited these changes and microvillus development. Furthermore, we employed wild-type and RXRa/RXb-deficient F9 cells, and demonstrated that these retinoid receptors activated ezrin expression but hardly contributed to microvillus organization. These findings indicate that HNF4α, but not retinoid receptors, acts as a powerful morphogen to trigger microvillus formation via induction of EBP50.

**Teacher Professional Development Programs - Key to Student Success**

M. A. Sognier, C. W. Houston; Universities Space Research Association, NASA Johnson Space Center, Houston, TX, 2Educational Outreach, University of Texas Medical Branch, Galveston, TX

To inspire the next generation of STEM-based career workers, UTMB has implemented: 1) Teacher professional development programs and 2) student science enrichment pipeline programs (Mol Biol Cell 15:231a). To meet the needs of area teachers, the UTMB Office of Educational Outreach provides six programs. 1) The Annual Science Teacher Conference is a one-day event where K-12th grade teachers experience workshops provided by leading educational experts and view science education vendor exhibitors. 2) The Galveston County Regional Collaborative for Excellence in Science teaching is part of a state-wide network providing high intensity sustained teacher workshops where educators in grades K-12 receive more than 100 contact hours/year of standards-based content with accompanying kits/supplies for classroom implementation. 3) The teacher Institute for the Advancement of Space Biomedical Science provides 4-12th grade teachers with a one-week immersion experience in space sciences followed by another week to develop space-related, standards-aligned classroom science activities. These activities, published as the Space Connections book, are also now available in Spanish. 4) The High School Summer Research Program provides teachers with a biomedical sciences immersion experience. Teachers spend 8 weeks in a faculty mentor’s research lab learning state-of-the-art science and technology while performing a project that is presented in a formal poster session and also developing an experience-based classroom activity. 5) The Science Education Resource Center loans educational kits (FOSS, GEMS, etc.), supplies, and equipment for classroom use. This is an essential resource for many teachers where district funding cannot provide needed supplies to effectively teach content. Participation in these high-quality, high-intensity professional development programs increases teachers content knowledge, provides necessary supplies, establishes an effective teacher network, and enhances their ability to inspire students to pursue future STEM-based careers. Supported by grants from the Howard Hughes Medical Institute, National Space Biomedical Research Institute, and Texas Regional Collaboratives.

**A Study of the Impact of an Informal Science Education Program on Middle School Students’ Science Knowledge, Science Attitude, STEM High School and College Course Selections, and Career Decisions**

M. A. Ricks; Baytown, TX

The Summer Science Camp (SSC) I at the University of Texas Medical Branch (UTMB) is an informal summer science education program for 7th and 8th grade pre-college students. The SSC I program engages participants in authentic hands-on laboratory-based scientific experiments and STEM (science, technology, engineering and mathematics) related experiences. The SSC I program expected to increase participants’ science knowledge and affect a positive influence on their attitudes and outlook toward science careers and issues. This study has a twofold purpose represented respectively by a quantitative and qualitative approach. Study approach one intended to assess improvements and changes in participants’ science knowledge and science attitudes based on their SSC I experiences. Data from participants in the 2005 UTMB 7th and 8th grade SSC I were used to address this perspective and assess the program’s impact on changes in students’ science knowledge and science attitudes. Study approach two assessed information about decisions previously (1993-1999) participants may have made in selecting advanced STEM courses, and career decisions as a result of participation in the SSC. This second study perspective used data from questionnaires, interviews, and program evaluation forms collected from the 1993-1999 SSC participants. The findings were statistically significant for Study approach one, showing an increase in participants’ science knowledge and science attitude. Study approach two also determined statistical significance through contextual descriptions about the STEM selections of former SSC I participants from a retrospective point of view. The outcomes of this study suggest that the innovative hands-on learning activities, problem-solving experiences, and use of authentic scientific tools were important elements for students’ meaningful understanding and appreciation of science concepts. The study proposes that the elements of this informal program are important and recognizable forces that impact students’ science learning, science attitudes, interests, and decisions.

### 1937

**Pre-college Education: Basic Research Is an Excellent Educational Tool**

M. C. Fields; Neuroscience Research Course, Sidwell Friends School, Washington, DC

The Neuroscience Research Class at Sidwell Friends School (SFS) is an elective which allows students to participate in a course that replaces the traditional method of teaching with a research approach. Summer reading of scientific articles supplied by the instructor provides the necessary background for students to begin a three-month investigation in the fall. Collaborating with scientists via the internet and in person exposes participants to scientific methods, research, and analysis. This course promotes critical thinking, problem solving, and data analysis through statistical methods. Students gain an appreciation of scientific research while they master concepts from the core of biology, including but not limited to immunology, neuroscience, cytology, developmental biology, genetics, protein synthesis, and DNA replication. Modern research techniques used in neuroscience and molecular biology are investigated and performed. Students are no longer the passive recipients of knowledge, but acquire it actively and through collaborative effort to complete the research and produce a scientific poster for presentation at a scientific meeting (SSC I, Biological Society, Society for Neuroscience). Current projects include studying the neurobiology and behavior of weakly electric fish, the developmental biology of zebrafish, researching slow wave sleep patterns in crustaceans, and tectemicroscopy. Student-designed protocols for these projects as well as data and conclusions are included in this poster. This poster also presents the origins and history of the course as well as the mechanics for conducting such a class.

### 1938

**Innovative Use of Assessment Rubrics Promotes Successful Scientific Collaboration in the High School Biology Classroom**

E. M. Stone; Berkeley High School, Berkeley, CA

Alternates of assessment are especially useful for measuring learning for students who do not perform well using traditional assessment methods. In a long-term effort aimed at creating different types of assessment that are effective for all students in the high school classroom, a computer-based curriculum called “Cell Reproduction & Human Diseases” was designed in the Web-based Inquiry Science Environment (WISE; http://wise.berkeley.edu). Different methods for assessing what students know and understand pre/post test drawings of cell division, embedded ongoing assessment questions, modeling tasks, multiple-choice test items, and a final poster presentation on a disease related to mitosis or meiosis. Previously the poster has been assessed for understanding of cell division defects and mechanisms of disease and treatment. Those student teams that are more successful at working together to research and present their poster have been able to produce a higher quality final product; however, the collaborative effort was not explicitly assessed. Thus a Group Collaboration Rubric was designed to measure this essential component of the scientific process. The rubric assesses components that categorize successful collaboration in the research laboratory: sharing ideas, distributing work, using time efficiently, and decision-making. When using the rubric, students are asked to provide specific evidence that describes the extent to which they met criteria for effective scientific collaborations. Evaluation of the use of this rubric in the classroom indicates that the value of collaboration becomes more transparent to students. Moreover, students demonstrate an ability to honestly and
critically reflect on what they can do to improve teamwork with their classmates. Ideas will be presented for how the different assessment tools developed in this work can be applied to other learning contexts and across secondary, undergraduate, and graduate curricula.

1939

Teaching Scientist Volunteers about K-12 Science Education, Pedagogy, and Partnership

P. Caldera, J. MacCormack; University of California, San Francisco, San Francisco, CA

Many scientists today see opportunities to share their commitment to science with the wider community and are interested in lending their expertise to teachers and their students with a view to improving science education. Scientists are enthusiastic about sharing their science knowledge and skills, but they generally have had limited experience in K-12 classroom settings. Based on our experience with scientist volunteers working in K-12 classrooms, the Science and Health Education Partnership (SEP) at the University of California, San Francisco, developed a workshop series to support scientist volunteers in their teaching efforts. Utilizing hands-on, interactive science activities, this workshop series is designed to equip scientist volunteers with teaching strategies that will enable them to: focus on the concrete in their teaching; involve all students in classroom lessons; get to know learners through pre-assessment; incorporate inquiry-based methods in their approaches; consider all aspects of lesson-planning (e.g., setting specific lesson goals, managing materials, addressing language needs); and work in partnership with teachers by acknowledging and relying on teachers' expertise in areas such as classroom management and cognitive development. First offered ten years ago, the workshop series has evolved over the years to better address the needs of scientist volunteers. Scientist volunteers who have taken part in the workshop series consistently rate the workshops very highly, report improvement in their teaching skills, and have integrated many of the ideas and strategies in their work in K-12 classrooms.

1940

Transformation of a Traditional Biology Laboratory Course into a Research Experience

E. Vasquez, C. Ricart, M. Echegaray, R. Chiesa; Biology, University of Puerto Rico at Cayey, Cayey, Puerto Rico

The traditional laboratory exercises of a General Biology course have been substituted with research projects where students go through the process of identifying a problem, developing an experimental design, analyzing data, and interpreting results to reach meaningful conclusions. In this approach, the professor becomes a mentor and the students, who are mostly freshmen, become researchers. Our data demonstrate that this strategy is highly successful by empowering students with scientific knowledge acquired through a hands-on experience. It has also developed a keen interest in most participants to pursue advanced degrees in science. The effect that this experience may have in retention, overall academic performance, and skills is being assessed through a longitudinal study. So far we have impacted seventy students in two years. Thirty research projects have been completed, many of which have been presented at scientific meetings. This learning model allows for deep understanding of fundamental scientific concepts and the true nature of the scientific endeavor.

1942

Engaging Undergraduates in the Emerging Field of Synthetic Biology

A. M. Campbell, E. E. Zwick, K. A. Haynes, S. Simpson, L. J. Heyer, W. L. Harden, S. N. Rosenmold, T. T. Eckdahl, A. D. Brown, T. L. Butner, L. H. Heard, E. L. Jensen, K. J. Mallory, B. J. Ogden, J. Poest, M. L. Broderick; Department of Biology, Davidson College, Davidson, NC, Department of Business, Davidson College, Davidson, NC, Biology, Hampton University, Hampton, VA, Department of Biology, Missouri Western State University, St. Joseph, MO, Department of Mathematics, Missouri Western State University, St. Joseph, MO, Research experiences that are multidisciplinary, challenging, and team-oriented provide undergraduates with the training they need to be successful scientists. We found that the emerging field of synthetic biology offers ideal research training. Synthetic biology uses mathematics, biology, and the principles of engineering to program cells to carry out new functions. We competed in the 2006 International Genetically Engineered Machines (iGEM) Synthetic Biology Jamboree at MIT, along with 36 other teams from around the world. Our multi-institutional team included sophomore and junior undergraduates majoring in biology and mathematics with little or no previous research experience. The team defined a good mathematical problem—the pancake problem (sorting by flipping). These devices allow us to design appropriate DNA devices for these applications (e.g., control recombination of genetic elements) and DNA computing (e.g., evolution of syntonic chromosones). The project involved creating simulations, investigating pancake graphs, modeling kinetins, searching databases for components (i.e., genes and enzymes), using the iGEM registry for some parts, constructing our own parts, and engineering bacteria to carry out inversions. We found synthetic biology to be an inexpensive and enjoyable way to learn, teach, share, collaborate, and conduct original research with undergraduates.

1943

Cell Biology and Genetics Laboratory Modules Incorporating the Desert Tree Lizard as a Model Organism

P. A. Marshall, C. E. Deutch, D. Dennis; Integrated Natural Sciences, Arizona State University at the West Campus, Phoenix, AZ

The Department of Zoology and the Desert Natural Science Institute at the University of Arizona have adopted a new curriculum at the West Campus that leading to a B.S. degree in the Life Sciences. This curriculum includes two semesters of General Biology, core courses with laboratories in Fundamentals of Genetics, Cell Biology, and Ecology, and clusters of upper-level electives in Cellular, Molecular, and Physiological Biology, Organismal Biology, and Integrative Systems Ecology. An innovative feature of this curriculum is the inclusion of experimental work with the desert tree lizard (Urosaurus ornatus) in many different courses to link them together thematically. While the experiments in the General Biology course focus primarily on the morphology and behavioral ecology of these organisms, those in the required courses in Fundamentals of Genetics and Cell Biology are designed to introduce students to techniques in modern cell biology. In the laboratory for the Fundamentals of Genetics course, students carry out a two-week project using non-denaturing gel electrophoresis in agarose gels to study the occurrence of alleles of acosta hydratase and the NADP-dependent L-malate dehydrogenase in different individuals in captive populations. In the laboratory for the Cell Biology course, students perform a two-week project using SDS-polyacrylamide gel electrophoresis to compare the proteins found in various lizard organs including heart and liver. In both cases, the students gain experience in casting and running gels, in staining and imaging the gels digitally, and in analyzing the images quantitatively. Additional ideas will be presented for how the different assessment tools developed in this work can be applied to other learning contexts and across secondary, undergraduate, and graduate curricula.

1944

Biotechnology for Science-Phobes

T. L. Beaty; Chemistry & Physics, Le Moyne College, Syracuse, NY

The majority of college non-science majors who must take a science course to graduate are wary and nervous about this curricular requirement. “Biotechnology: Wonder Drugs to Mutant Bugs” is an introductory biotechnology course designed for these students. They learn the basic science concepts underlying several important fields of biotechnology, including DNA fingerprinting, genetic screening, recombinant DNA, nuclear transfer cloning, and bioprospecting. Due to the students’ resistance to learning science, care is taken to ensure their understanding of essential concepts (i.e., molecular polarity and gene expression) and techniques (i.e., gel electrophoresis and fermentation), which are important to a wide range of biotechnology applications. Historical relevance and societal implications are integrated into each unit to help students gain an appreciation of the “big picture.” By the end of the course, students can interpret popular media reports of biotechnology, discuss the general product line of an active biotech company, and debate the ethical considerations of specific applications.

1945

How Does Using Critical Literacy Help Teachers Understand Implications of the Human Genome Project?

M. L. Gleason, 1 E. E. Zwack, 1 K. L. M. Kleine 1; Biological and Environmental Sciences, Georgia College & State University, Milledgeville, GA, 1Early Childhood and Middle Grades Education, Georgia College & State University, Milledgeville, GA

In a reading- and writing-intensive course taught in the summer of 2006 at a small liberal arts university we used a critical literacy approach (Alvermann and Hagood, 2000) to help teachers challenge their subtle attitudes, values, and beliefs about the ethical, legal, and social implications (ELSI) of issues arising from advances in human genetics. Sixteen in-service middle and high school teachers (half each from science and English) were collaboratively taught by a biologist, a linguist, and a science educator, with the assistance of two graduate students. Learning was measured by 1) pre- and post- assessments of content acquisition; 2) change in depth of students’ oral responses over time; 3) number of genetic practices and ELSI concerns identified by students upon a reviewing of the film GATTACA (Nichol, 1997), 4) formal essays written during the course, and 5) a final journal entry completed about the meaning and applicability of
critical literacy as a pedagogical tool. In a concept mapping post-assessment 100% used all terms correctly compared with 50% in the pre-assessment; similarly 88% provided propositions that accurately established relationships between concepts, compared with only 38% before. Early oral responses showed that only two teachers had some familiarity with prenatal genetic diagnosis options compared with 16 by course’s end. Identification of genomic practices and ELSI concerns by teachers during the second viewing of GATTACA ranged from 3 to 24 (mean = 13) practices and 5 to 26 issues (mean = 18). Gains as evidenced through writings and journal entry were difficult to enumerate, but were enlightening and, with the aforementioned data, supported our premise that the personalized focus on the integration of thoughtful reading and writing in this class enhanced the teachers’ professional and intellectual development, preparing them to provide a critical literacy approach in their classrooms this fall.

1946 
Representing Time and Space in Animations of Molecular Machines
J. E. Honts; Biology, Drake University, Des Moines, IA
The sarcoplasmic calcium pump/ATPase is an example of a macromolecular machine that is frequently depicted in textbook and teaching resources in terms of its structure and mechanism. We have initiated a study that compares the pedagogical effectiveness of various representations of this ion-pumping molecular machine. In spring 2006, 26 students participated in a study comparing 9 models of representing change in the structure and function of this pump over time. In one of these, motion was continuous over the pumping cycle (a “fluid animation”). In the other, key frames were selected from the fluid animation, so that time was represented in a discontinuous manner (a series of static “snapshots”). Participants were randomly assigned to view one of the two presentations. A short written pre-viewing evaluation was administered to assess the students’ understanding of the structure and mechanism of the calcium pump. Students were also asked to draw a diagram representing the structure and function of the pump. Upon completion of these tasks, students were asked to view their assigned presentation for ten minutes (sufficient time for several repetitions of the presentations). Following viewing, students were asked to repeat the written evaluation, draw a new diagram, and answer several questions concerning the presentations. An analysis of scores on the pre- and post-viewing evaluations revealed no statistically significant difference between the two groups with respect to scores obtained on the post-viewing evaluation. Both groups did, however, show a significant improvement in post-viewing over pre-viewing scores. The student responses also revealed that a small number of students developed specific misconceptions as a result of viewing the presentations. While these largely relate to minor aspects of the structure and mechanism, they will be investigated further so that they can be remedied in revisions of these presentations and others under development.

1947 
Student Mental Models of Cellular Structure: A Non-Majors’ Perspective
I. Ecarma-Robinson, J. Robinson, M. L. Casem; Biological Science, California State University, Fullerton, Fullerton, CA
The objective of this research was to investigate the mental models of cellular structure held by undergraduates outside of the biology major and to examine the impact of instruction on student perceptions. Students were prompted to draw and label a cell. Drawings were collected post-instruction from students enrolled in a lower division, general education biology survey course. Student-generated images were evaluated using a calibrated rubric that assessed the diversity of elements within the drawing, and the correlation between the image and the label. The majority of students represent a cell as being eukaryotic (containing a nucleus) and round or oval in shape. Non-majors were equally likely to label the primary line of their drawing as cell wall versus membrane (30% vs 39%). Non-majors’ drawings did not include details of the phospholipid bilayer. The average student-generated drawing included 5.3 ± 0.6 distinct items and 5.0 ± 0.25 labels; however, the match between label and image averaged 2.7 ± 0.08. The most common labels were nucleus, mitochondria, and ribosome, while the most common images reasonably represented the nucleus, ribosomes, and generic vesicular structures. The general biology course is taught in multiple sections by multiple instructors. A statistical relationship exists between the course instructor and performance of students as regards the complexity of their drawings, the number of labels used in the drawing, and their ability to correctly associate the name of a structure (label) and its appearance (mental model). The results of this research indicate that undergraduates completing a non-majors’ general survey course in biology possess a mental model of the cell that is relatively similar and simple to the mental models reported by beginning biology majors. The variation in student drawings as a function of instructor may reflect differences in the emphasis placed on cellular structure or instructional strategies employed by diverse faculty members.

1948 
Student Mental Models of Cellular Structure: A Biology Major’s Perspective
A. Nazarain, M. Shin, S. Shirzadegan, M. L. Casem; Biological Science, California State University, Fullerton, Fullerton, CA
The objective of this research was to gain insight into student mental models of cellular structure, to examine the impact of instruction on student perceptions, and to identify misconceptions. Students were prompted to draw and label a cell. Drawings were collected pre- and post-instruction from students enrolled in a lower division cellular biology course. Drawings were also collected from graduating seniors. Student-generated images were evaluated using a calibrated rubric that assessed the diversity of elements within the drawing, and the correlation between the image and the label. The majority of all students represent a cell as being eukaryotic (containing a nucleus) and round or oval in shape. Only 37% of beginning students label the cell’s plasma membrane and only 4% provide details of the phospholipid bilayer compared with graduating seniors of whom 72% labeled the membrane and 32% represented the bilayer structure. Student drawings are significantly more complex post-instruction (7.2 ± 0.09) compared with pre-instruction (3.84 ± 0.12), and remain at about the same level for graduating seniors (6.83 ± 0.16). At least half of all beginning biology majors tested included a nucleus that assessed the diversity of elements within their initial drawing. Post-instruction, or at graduation, over half the students tested also included the rough ER, smooth ER, Golgi apparatus, ribosomes, and vesicles in their drawings. Graduating seniors used more labels in their drawings compared with post-instruction students (7.78 ± 0.17 vs 7.13 ± 0.13) and significantly more of their drawings matched between label and image (3.7 ± 0.02). Misconceptions related to cell walls, membranes, and chloroplasts were identified. Results of this study indicate that student mental models of a cell are enhanced by instruction and that gains made early in the major are retained at graduation. Student perception of a cell favors eukaryotic over prokaryotic and animal over plant cells, possibly indicating an instructional bias.

1949 
Incorporation of an Original Research Theme into Three Advanced Undergraduate Laboratory Classes in Cell Biology, Molecular Biology, and Biochemistry
C. M. O’connor, M. J. Pietelli, A. R. Wyman; Biology, Boston College, Chestnut Hill, MA
An integrated group of three advanced undergraduate laboratory classes in cell biology, molecular biology and biochemistry were designed to introduce students to original research, using the fission yeast, Schizosaccharomyces pombe, as an experimental model. Each of the three courses studies discrete aspects of a common research theme with discipline-specific tools. Common research foci are protein repair enzymes and enzymes that protect cells from reactive oxygen species (ROS). These enzymes were chosen for study because of their strong evolutionary conservation and because of growing evidence that these enzymes protect organisms against a variety of degenerative diseases. After an introduction to the biology of ROS, students chose to study thioredoxin peroxidase, glutathione peroxidase, thioredoxin and superoxide dismutase. Students used genomics resources to guide the construction of molecular clones and yeast strains. Students worked in teams to develop hypotheses, design and conduct experiments, and analyze and present experimental data. Cell biology students constructed yeast strains that overexpressed the ROS protective enzymes and monitored the effects of enzyme overexpression on resistance to oxidative stress. Students in the molecular biology class studied the expression of the same enzymes under a range of controlled environmental conditions and developed new expression vectors. Biochemistry students overexpressed the enzymes in bacteria, purified the enzymes, and developed enzymatic assays used to biochemically characterize the yeast enzymes. Integration of research activities among the three classes provided students with an interdisciplinary perspective to the research problems and built a learning community of students and faculty. A common website, the Boston College Biology Commons (BC2), provides a central forum with links to class data, experimental protocols, tutorials and database links. Students responding to questionnaires express a sense of greater competency and a higher level of satisfaction with these project-based classes compared with more scripted laboratory classes.

1950 
Courses to Integrate Biology, Computer Science, and Physics for Undergraduate Science Majors
R. P. Donaldson,1 S. Church,1 R. Sinha,2 M. E. Reeves; 1Biological Sciences, George Washington University, Washington, DC; 2Computer Science, George Washington University, Washington, DC, 1Physics, George Washington University, Washington, DC
Our objective is to develop courses that bring together quantitative-computational skills and physical principles with the concepts of molecular biology in the first year of a university education. A pilot course was developed and taught this year to 16 students to test the feasibility of this approach. We implemented a series of active learning modules in two courses, Biology of Proteins and Introduction to Bioinformatics. The first course included solving problems on the effects of pH on amino acids, enzyme kinetics, computational simulations of chemical reactions, networks and differential equations, the principles of entropy applied to proteins, 3D visualization of protein structures, and group research projects on selected protein families. Formative assessments were weekly quizzes, homework problems, and written and oral reports. The second course involved the use of online databases, understanding basic bioinformatics algorithms such as sequence alignment, 358

2006 ASCB Annual Meeting Abstracts
implementing gene prediction methods, and creating phylogenetic trees. Students were expected to formulate questions and explore various methods of analysis based on data available in the databases. Students engaged in projects on complex questions that often revealed the limits of available data relative to the types of questions that interested the students. For the freshmen, their development as scientists was apparent based on increasing complexity of their projects as well as the solutions proposed when database or computational limits hindered their research projects. We observed that freshmen were more adventurous than upperclassmen in their choice of projects and willingness to conform database or computational limits in their research. A significant challenge in implementing the courses was in selecting appropriate students. We assessed learning and attitude outcomes for the students who took these courses in the 2005-06 academic year. Three of the 12 freshmen in the courses did research internships the following summer. Supported by grants from HHMI and the GWU CCAS Teaching Initiative.

1951
Isolation and Characterization of Yeast Mutants Defective in Chromosome Segregation in an Undergraduate Genetics Research Laboratory Course
H. Sleister; Drake University, Des Moines, IA
In an effort to expose undergraduate students to scientific inquiry, an upper-level genetics project-based laboratory course was developed. Students are immersed in a research project with the ultimate goal of identifying proteins important for chromosome transmission in mitosis. After mutagenizing yeast Saccharomyces cerevisiae cells, students implement a genetic screen that allows for visual detection of mutants with an increased loss of an ADE2-marked yeast artificial chromosome (YAC). Students then genetically characterize the mutants and begin efforts to identify the defective gene in these mutants. While engaged in this research project, students learn a variety of technical skills in both classical and molecular genetics. Furthermore, they learn to collaborate and gain experience in sharing scientific findings with others in the form of written papers, poster presentations, and oral presentations.

1952
Report of Observation-, Experience-, and Exercise-based Understanding Class of Cell and Human Biological Systems for Integration of Cell Biology and Health Education at the University of Tokyo
T. Sakurai, Y. Atomi, Department of Life Sciences, The Graduate School of Arts and Sciences, The University of Tokyo, Tokyo, Japan
Understanding of own cell and life system which work in his/her body may contribute to cell biology education as well as health education. At the 44th Annual Meeting, we made a presentation of report of the class of cell biology education and health education in physical exercise class for undergraduate students. We named the class “Sport Science Course.” In this course, students learn cell and body systems through dynamism at different of self-individuals, functional tissues in mammalian, and cells in mammalian tissues and cultured cells on dishes. Self-recognition, exercise physiology for self body are effective for extracting motivation of learning and understanding self biological system of the body. In the physical exercise course for freshmen of the University of Tokyo, we give five contents 1) Integrative brain system and disagreement of his/her intention and the output, 2) Measuring of his/her own body alignment and flexibility, 3) Supporting system of endurance running from heart rate and respiratory responses to gravity, linear and non-linear phenomena, respectively, 4) Observations of mammalian tissues, beating cultured primary heart cells, muscle cells during differentiation process from myoblasts to myotube and neuronal cells, and 5) Information of basic life support for accident in physical exercises. In observation of tissue and cells, use of fluorescent dyes helps us to perceive our body from cellular basis. Especially beating heart cells and a process of muscle differentiation are appropriated for understanding automanaged, self-propagating chemical system constituted by fibrous protein cytoskeleton and motor system developing tension from cell to human body. A principle of a use dependency in brain and muscle function at cellular level is educable hypothesis for self-oriented health education. This class orients to the understanding of our own body and cell systems by observation-, experience-, and exercise-based learning methods.

Integrating Technology in the Teaching of the Undergraduate Molecular Cell Biology Curriculum
D. B. Taylor; College of Science, Benedictine University, Lisle, IL
Structural biology and bioinformatics are common tools of the modern day cell biologist. How do faculty members teaching Molecular Cell Biology in a post-genomics era engage students in interactive learning about macromolecular structure/function relationships in an undergraduate (UG) curriculum? A fundamental problem is that of visualization: •High-end molecular modeling software requires dedicated expensive workstations and is best used for individual research projects •Chalkboard drawings do not illustrate the intricacies of macromolecular structure/function •The web-based exhibits allow the simultaneous viewing of molecules while reading descriptive text •The exhibits are investigatory •The exhibits allow students to learn about macromolecular structure at their own pace •Another tool ideal for the integration of technology in the teaching of Molecular Cell Biology is the multimedia software tool The Dynamic Cell •Available at Springer-Verlag 2000. The Dynamic Cell depicts the cell in a series of animated 3-D scenes providing instructor and student with an interactive visual tour of the cell demonstrating structure/function relationships of complex cellular processes in a dynamic fashion (http://www.springer.de). The advantages of using The Dynamic Cell as a tool to integrate visualization of 3-D structures of macromolecules with cellular processes in the teaching of Molecular Cell Biology will be discussed. Supported in part by the Scholl Endowed Chair in Health Sciences.

Making Connections: An Inquiry-based Cell Biology Course That Integrates Biology and Chemistry
C. H. Sullivan, C. J. Brubaker, N. Greg Little, V. Pratt, J. C. Robison; Biology, Grinnell College, Grinnell, IA
In a restructuring of the biology curriculum to better emphasize investigative learning and to support a new Biological Chemistry major, the core course, Biology 251 Molecules, Cells, and Organisms was developed. BIO 251 is an intermediate course that predominantly serves two student audiences. Biology majors will proceed to the Organisms, Evolution and Ecology course while biological chemistry majors follow BIO 251 with Introduction to Biological Chemistry. All students entering BIO 251 have taken at least one semester of introductory chemistry and an introductory biology course that emphasizes an inquiry-based approach to studying biological questions related to a specific research topic. Therefore our students have a common set of analytical skills: reading primary literature, defining good questions, designing experiments, analyzing and presenting data, and writing scientific papers. BIO 251 is organized to capitalize on these skills by allowing laboratory work to drive the content and order of lectures and other classroom activities. The course consists of four modules: mutagenesis, gene expression, metabolism, and organismal movement using two species of bacteria, several plant species, and Caenorhabditis elegans. Each module teaches the students basic techniques that can be expanded into a student-designed project. Students keep a laboratory notebook and write two scientific papers based on their independent projects. Pre-test/post-test comparisons demonstrate significant improvement in the areas of factual information, data interpretation, and experimental design. A second important goal of our core curriculum is to emphasize the connections between biology and chemistry, and we require organic chemistry 1 as a co-requisite for Bio 251. Workshops for biology and chemistry faculty have produced a student manual (Investigations) that emphasizes common approaches used in teaching biology and chemistry courses at Grinnell. The second outcome of this workshops is an archive of lecture examples, problem sets, and exam questions that students will encounter in both courses.

Student Mobility Profile: An Instrument for Measuring the Effectiveness of Efforts to Improve Teaching and Learning
W. S. Bradshaw; J. Nelson, 2 J. D. Bell; 1Microbiology and Molecular Biology, Brigham Young University, Provo, UT; 2Physiology and Developmental Biology, Brigham Young University, Provo, UT
The process of educational renewal, including efforts to improve the learning of cell biology, should incorporate assessment - a rigorous evaluation of whether or not changes made to a course actually achieved their intended goals. The Student Mobility Profile (SMP) is a novel statistical instrument designed to facilitate such an assessment. The SMP will process data obtained from the beginning and end of a scholastic interval, scores from a first and final exam, or from a pre and post semester problem-solving exercise, for example. An important advantage is that it can be applied post hoc allowing one to utilize existing data from past versions of a course for comparison to recent offerings in which innovations have been attempted. The results of the analysis indicate the presence or absence of systematic factors leading to either improvement or decline in performance of the student population over the time period being assessed. Consequently, instead of indicating whether students have simply acquired the factual information from the course, the analysis reveals the extent to which they have improved in their ability to learn. For example, the teacher might discover whether students have developed additional expertise in practicing an important scientific skill, such as drawing valid conclusions from experimental data. The theory and statistical procedures that underlie the instrument are described, along with examples of its application in university science courses. The results of computer simulations to determine the range and limitations of this instrument will also be reported.

2006 ASCB Annual Meeting Abstracts

359
In the absence of a laboratory fundamental issue in biology are still accessible to students by asking simple, creative questions. Here we queried developmental challenges between mouse and fly using standard computational genomic approaches. The genetics of Drosopha has identified a number of genes involved in oogenesis and early development. In Mus genetic screens are more difficult to perform; as a result the genetics of oogenesis and early development are not as well characterized. We utilized Drosophila as a genetic screen for use in Mus by establishing a computational search for Mus homologs of Drosophila genes involved in oogenesis and early development. Conserved genes are functionally significant, while genes which are apparently absent in mouse may identify divergent strategies for solving the same developmental challenge. Using Flybase as a starting point we generated a list of over 100 target genes; in particular genes which function in germ-line stem cells (such as vasa and nanos), oocyte determination and anterior-posterior axis formation (gurken and pamilo), dorsal group genes (mago nashi and cappucino), terminal genes (torso and torshilde) and posterior group genes (oskar and staufen). In a progressive fashion we searched for homologs by gene name at SWISS-PROT and Entrez Gene, by protein sequence similarity at SWISS-PROT and MGI, and by conserved protein domains using ProDom. For protein sequence similarity searching we used BLAST and PSI-BLAST to find bi-directional best hits. Our results discovered "better-fit" homologs of previously identified homologs, new homologs, and an apparent absence of homologs. Interestingly, most of the missing homologs are genes involved in polarity establishment in Drosophila oogenesis, a process which appears to be fundamentally different in Mus. The next steps are to refine the meaning of a negative result and determine when in evolution the "missing" homologs dropped out.

**Trends in Histology Laboratory Teaching in US Medical Schools**

R. A. Bloodgood,1, 2 R. W. Ogilvie; 1Cell Biology, University of Virginia School of Medicine, Charlottesville, VA, 2Cell Biology and Anatomy, Medical University of South Carolina, Charleston, SC

Laboratory instruction for U.S. medical students has been undergoing dramatic change. Between the 1960-61 and 1985-86 academic years, total laboratory teaching hours at the Case Western Reserve University School of Medicine declined by 65% (Guth et al., 1992, Acad. Med. 67:203-206). Nationwide, hours of laboratory instruction in all the anatomical sciences declined by 52% between 1967 and 2003 (Gartner, 2003, Clinical Anatomy 16:434-439). Factors contributing to this decline probably include increased emphasis on NIH funded research, managed care, changes in medical practice, reductions in total hours allotted to basic science teaching, and advances in computer-aided instruction. To identify recent trends in histology laboratory instruction in U.S. medical schools, a detailed web survey was administered to histology course directors, with about two-thirds of U.S. medical schools responding. Consistent with the long term trend of declining total laboratory teaching hours in U.S. medical schools, there is an ongoing reduction in the number of hours of faculty-directed histology laboratory instruction that each medical student receives, with a concomitant reduction in hours of faculty time devoted to histology laboratory instruction. In terms of the tools used in the histology laboratory, there has been a dramatic increase in the use of various forms of computer-aided instruction (including Virtual Slides). Contrary to expectations, this increase in the use of Computer-Aided Instruction (CAI) (and especially Virtual Microscopy) has not been accompanied by an equivalent elimination of the use of microscopes and glass slides. Rather, the clear trend has been toward a blending of the new computer-based instruction technologies with the long-standing use of microscopes and glass slides. Many of the course directors surveyed here argue that the intimate involvement of trained faculty is the key to the quality of histology laboratory education, rather than the choice of instructional tools.

**Teaching Postdoctoral Fellowship: A Means of Faculty Development and Curriculum Enhancement**

D. C. Barnard, M. S. Ledbetter; Biology, College of the Holy Cross, Worcester, MA

We have developed and pilot tested a "teaching postdoctoral fellowship" as a means to enrich the experience of future faculty members, enhance the curriculum of an undergraduate institution, and provide research expertise not otherwise available to the research program of an undergraduate department. Dr. Barnard, a molecular biologist with expertise in bioinformatics, has had a two-year appointment at Holy Cross, supported by College funding budgeted for sabbatical replacement and an NSF grant to Dr. Ledbetter. He taught three courses each year, including a specialty seminar in Bioinformatics (twice), a laboratory section of General Biology (once), and a general education course on the Human Genome Project (three times). He assisted Dr. Ledbetter and her research students in computer assisted microscopic studies and guided two students of his own in the summer and during the academic year. And he participated fully in lab meetings, weekly journal club, and department activities while developing research and teaching collaborations with two other faculty members. He also fulfilled the requirements of the Certification Program in Undergraduate Teaching offered through the Worcester Consortium of Higher Education, which assisted Dr. Ledbetter in mentoring his teaching. The experience of juggling the demands of both teaching and research taught him crucial skills in both areas, as well as time management. He will continue his career at Worcester State College in the fall, one of several positions he was offered. Through this experiment Holy Cross tested interest in Bioinformatics as a potential curriculum addition, and Dr. Ledbetter benefited from Dr. Barnard's expertise in an area of research unfamiliar to her. Our experience has been completely satisfactory. We recommend it as a way to combine faculty development, curriculum enhancement, replacement of faculty on leave, and research initiatives to the benefit of all four.

**The Binding of a 60S Ribosomal Subunit Is Sufficient to Open the Pore of a Translocon in the Endoplasmic Reticulum**

D. C. Barnard, M. S. Ledbetter; Biology, College of the Holy Cross, Worcester, MA

We have previously reported that the release of a nascent chain from a translationally-active, ribosome-bound translocon (RBT) creates an open pore through which small molecules can cross the membrane of the rough endoplasmic reticulum (RER) (JBC, 276:22655; JBC, 278:4397). The pore of a translocon remains open as long as a ribosome remains bound, closing only after its removal by the addition of high salt or EDTA. The goal of our present study was to determine if a translocon pore closed by the removal of ribosomes can be re-opened by the addition of purified 60S ribosomal subunits. We have measured the permeability of the RER in CHO-K1 cells to 4-methylumbelliferyl-alpha-D-glucopyranoside (4MG), whose entry can be detected when it is hydrolyzed by lumenal alpha-glucosidase II. Polysomes isolated from CHO-S cells were disassembled with puromycin and high salt, and 60S subunits were purified by sedimentation on 10-35% sucrose gradients. The purified 60S subunits exhibited no alpha-glucosidase II activity. The addition of 60S subunits to EDTA- stripped ER membranes produced a saturable, concentration-dependent increase in permeability, with an apparent Km of about 20nM. In contrast, the addition of 60S subunits to puromycin-treated, unstripped membranes did not produce a significant increase in permeability. The lack of effect with unstripped membranes was consistent with the binding sites for the 60S subunits being occupied unless the membranes were previously stripped with EDTA. Heating the 60S subunits to 90C for 5 min. eliminated their ability to increase the permeability. We conclude that the binding of a 60S subunit, alone, is sufficient to open the pore of a translationally-active translocon. Other components of the protein translation machinery, such as the signal sequence of a nascent chain, are not required to open the pore and increase its permeability to small molecules.

**Early Post-natal Death of Knock-in Mice Expressing a Mutant BIP**

M. Mimura,1, 2 M. Kasai,3 H. Jin,1 K. Kimura,1, 2 S. Tanabe,1 T. Aoe1; 1Department of Anesthesiology, Chiba University Graduate School of Medicine, Chiba, Japan, 2Department of Medicine and Clinical Oncology, Chiba University Graduate School of Medicine, Chiba, Japan

The endoplasmic reticulum (ER) provides a folding environment where secretory and transmembrane proteins interact with chaperones. Some membranous imperfect proteins are stably retained in the ER, while other membranous and soluble ones require transport to the Golgi complex and retrieval for ER quality control. BIP is one of the most abundant ER chaperones, assisting in protein translocation, folding and degradation. When secreted from the ER in the company of imperfect proteins, BIP is recognized with a carboxyl terminal Lys-Asp-Glu-Leu (KDEL) sequence and retrieved by the KDEL receptor from the post-ER compartment. Yeast studies show that the deletion of retrieval motif from BIP Kar2 is dispensable in a single cell. In order to investigate the physiological significance of BIP and its retrieval in multi-cellular organisms in vivo, we established knock-in mice expressing a mutant BIP with the retrieval sequence deleted by homologous recombination. The embryonic fibroblasts derived from the homozygous mutant embryo expressed the mutant BIP, which was enhanced by ER stress instead of the wild-type one. We found that a fraction of the mutant BIP was secreted in the medium in the resting state and that loss of the mutant BIP was compensated by the active UPR as seen in the yeast studies. The mutant BIP embryos grew apparently as well as the wild ones. However, the homozygous mutant BIP neonates died early after birth, indicating that the retrieval of BIP is essential for survival of mammalian.
The Endoplasmic Reticulum Stress Response Mediates a Component of Cellular Defense in Caenohabditis elegans Against Bacillus thuringiensis Pore-forming Crystal Toxins

L. J. Bischof, R. V. Arioa, Biological Sciences, University of California, San Diego, La Jolla, CA
B. thuringiensis produces crystal (Cry) toxins that are invertebrate specific pore-forming toxins that target intestinal epithelial cells. Specific Cry proteins intoxicate nematodes, including C. elegans. To address how an epithelial cell may mount a defense against these toxins, C. elegans mutants that are hypersensitive to intoxication by Cry5B have been identified. This approach has found endoplasmic reticulum stress response genes as being important components of this cellular defense. The three ER stress signaling pathways in C. elegans are ire-1, pek-1, and atf-6. The ire-1 gene and its downstream target, xbp-1, were found to confer a hypersensitive phenotype to Cry5B by using both mutants and RNA interference. This pathway is activated when the worm ingests Cry5B as shown by ire-1 mediated alternative splicing of xbp-1. Also, a GFP fusion gene controlled by xbp-1 is upregulated specifically in intestinal cells upon Cry5B ingestion. Lethal concentration toxicity assays indicate that while these mutants are hypersensitive to Cry5B, they are not more sensitive to intoxication by the heavy metal CeSO4 or the oxidative stress agent H2O2. This data argue for a specific role for the ire-1 pathway in defense against Cry toxins. Intestinal specific expression of xbp-1 rescues the Cry5B hypersensitive phenotype indicating this pathway is required in the cell targeted by the toxin. In addition to the ire-1 pathway, atf-6 mutants are also hypersensitive to Cry5B but less so than ire-1. Investigations of the pek-1 pathway are in progress, but current data does not indicate a significant role in cellular defense against Cry5B. Therefore, while all 3 pathways are involved in the ER stress response, the ire-1 pathway is most specific for mediating a cellular response to Cry5B. These results reveal a new physiological role for the ER stress response pathway, namely in cellular defense against bacterial pore-forming toxins.

Subcellular Localization and an Enzyme Activity of Fatty Acid Transport Protein 5 in the Liver

J. Manaka, N. Takahashi, K. Toyama, M. Ohno, K. Higashi, K. Motojima; Biochemistry, Meiji Pharmaceutical University, Tokyo, Japan
The liver plays a central role in fatty acid metabolism including energy utilization, incorporation into lipoproteins and membrane lipids, and storage. Uptake of fatty acids into hepatocytes is a key step in the metabolism and mediated by several transport proteins. However, the physiological role, mechanism of the uptake, control of expression, and functional regulation of each transporter have not been elucidated. In this study, we examined these issues by focusing mostly on one of the fatty acid transport proteins (FATPA). FATP5 that is uniquely expressed in the rodent liver.

Protein-tyrosine phosphatase 1B (PTP1B) is an endoplasmic reticulum (ER)-bound phosphatase that is a key regulator of receptor tyrosine kinase signaling (such as epidermal growth factor receptor and insulin receptor). The objective of this study is to map and quantify the dynamics of PTP1B movement ex vivo, and correlate it with PTP1B-substrate(s) interaction. Photoinactivation, fluorescence recovery after photobleaching (FRAP) and “substrate-bleaching” approaches were utilized to study the dynamics of PTP1B movement. Wild type PTP1B exhibited fast dynamics and mobility on the ER as revealed by photoinactivation and FRAP studies. Recovery of PTP1B fluorescence was observed within seconds (~20 seconds) after photobleaching.

Regulated Expression by PPARα and Unique Localization of 17β-hydroxysteroid Dehydrogenase Type 11 in Mouse Intestine and Liver

Y. Yokoi, Y. Horiguchi, R. Shirai, K. Higashi, K. Motojima; Biochemistry, Meiji Pharmaceutical University, Tokyo, Japan
We recently identified 17β-hydroxysteroid dehydrogenase type 11 (17β-HSD11) as a peroxisome proliferator-activated receptor α (PPARα)-regulated gene in the intestine (Motojima, 2004, Eur J Biochem 271:4141). 17β-HSD11 was also induced in the liver and intestine by feeding mice with various plant seeds and grains (Motojima and Hirai 2006 FEBS J 273: 292). In this study, we characterized the 17β-HSD11 at the protein level to obtain a clue about its physiological role in the intestine and liver. For this purpose, specific antibodies against the 17β-HSD11 recombinant protein and the synthetic peptide were obtained. Western blotting analysis showed that administration of a PPARα agonist induced 17β-HSD11 protein in the jejunum but not in colon much higher than in the liver of mice. Immunohistochemical analysis using tissue sections showed that 17β-HSD11 was induced mostly in intestinal epithelia and hepatocytes with heterogeneous localization both in the cytoplasm and vesicular structures. The subcellular localization study using Chinese hamster ovary cells and the green fluorescence protein-tagged 17β-HSD11 suggested that it mostly localized in the endoplasmic reticulum (ER). However, under the conditions where lipid droplets were formed in the cells, most GFP signals shifted from ER to around the lipid droplets, suggesting that the localization of 17β-HSD11 changes according to the physiological conditions. Dual localization of endogenous 17β-HSD11 in the liver and intestine was confirmed by subcellular fractionation followed by Western blotting and immunohistochemical analysis of the tissue sections containing lipid droplets. Taken together, these data suggest that 17β-HSD11 associated with lipid droplets is not a mere ER-contaminant, but a bona fide protein comprising the membrane component of both intracellular compartments, and 17β-HSD11 may play an unknown role to cope the exogenously overloaded lipids from the natural diets.

Identification of the Targeting Domain in the Foremost Lipid Droplet Lipase Family

E. B. Goldberg, W. J. Brown; Molecular Biology and Genetics, Cornell University, Ithaca, NY
Lipid droplets (lipid bodies, adiposomes) are highly conserved storage organelles for neutral lipids and cholesterol esters. Recently, a new family of cytoplasmic lipases named Pataxin-like phospholipid transfer proteins (PNPLA) was identified. In the regulation of lipid droplet metabolism, here we report the first identification of a targeting domain for a PNPLA family member. Transient transfection experiments of truncated versions of PNPLA5 (GS2-Like) fused to GFP revealed that the N-terminal two-thirds of PNPLA5 contains the Pataxin-homology domain, and was cytoplasmic and diffusely distributed. Conversely, a construct containing only the C-terminal third of the protein was localized to lipid droplets. Additional truncation mutants revealed a crucial C-terminal 25 amino acid domain for lipid droplet localization. Within this domain, there is homology with other members of the PNPLA family, such as ATGL (Adipose Triglyceride Lipase, or PNPLA2) and Adiponutrin (PNPLA3), suggesting a conserved lipid droplet targeting motif (LTM).

Probing the Dynamics of the Neuronal Endoplasmic Reticulum with a Novel Lentiviral Vector

V. C. Jones, L. McKeown, A. Verkhovsky, O. T. Jones; Faculty of Life Sciences, University of Manchester, Manchester, United Kingdom
The endoplasmic reticulum (ER) is an extensive, complex endomembrane system, containing channels and receptors that allow its lumen to act as a dynamic calcium store. In response to electrical or chemical stimulation, ER calcium can be released under strict spatiotemporal control to regulate processes ranging from synaptic plasticity to growth cone guidance. Currently, there is much controversy over the nature of the ER in neurons and how this intersects with calcium signalling. We hypothesize that in neurons the ER is a dynamic structure with a response to electrical or chemical stimulation, ER calcium can be released under strict spatiotemporal control to regulate processes ranging from synaptic plasticity to growth cone guidance. We hypothesize that in neurons the ER is a dynamic structure with a

Dynamics of Cellular Protein-Tyrosine Phosphatase 1B Movement and the Effects of Substrate Interaction on Phosphatase Mobility

F. G. Haj, V. Roukos, S. V. Peever, B. Neel, P. Bastaean; Medicine, Harvard University/Beth Israel Deaconess Medical Center, Boston, MA; European Molecular Biology Laboratories, Heidelberg, Germany
Protein-tyrosine phosphatase 1B (PTP1B) is an endoplasmic reticulum (ER)-bound phosphatase that is a key regulator of receptor tyrosine kinase signaling (such as epidermal growth factor receptor and insulin receptor). The objective of this study is to map and quantify the dynamics of PTP1B movement ex vivo, and correlate it with PTP1B-substrate(s) interaction. Photoinactivation, fluorescence recovery after photobleaching (FRAP) and “substrate-bleaching” approaches were utilized to study the dynamics of PTP1B movement. Wild type PTP1B exhibited fast dynamics and mobility on the ER as revealed by photoinactivation and FRAP studies. Recovery of PTP1B fluorescence was observed within seconds (~20 seconds) after photobleaching.
regions of the ER. Altering microtubules by treating cells with nocodazole dramatically decreased PTP1B mobility, which could be restored to normal levels after drug withdrawal. In addition, cells expressing the "substrate-trapping" PTP1B D181A (PTP1B D/A) mutant exhibited increased tyrosine phosphorylation at discrete cellular locations that correlated with trapping of substrate(s) at these sites. Interestingly, the dynamics of PTP1B D/A movement in the ER was significantly decreased compared to wild type. Moreover, using immunofluorescence and electron microscopy we showed that areas of cell-cell contact are regions of extensive substrate-trapping. The enhanced substrate interaction at these regions correlated with, and most probably caused the decreased mobility of PTP1B D/A at these areas. These studies provide major insight into the dynamics of PTP1B movement and the effects of substrate(s) interaction on this process.

1969

Bax Inhibitor-1 Contributes to the Homeostasis of Calcium and pH

H. Kim,1 K. Ha,2 G. Lee,2 D. Kim,2 S. Chae,2 H. Chae2; 1Department of Dental Pharmacology, School of Dentistry, Wonkwang University, Iksan, Republic of Korea, 2Department of Pathology and Cardiovascular Research Center, Medical School, Chonbuk National University, Jeonju, Republic of Korea

It was the aim of this study to investigate the effect of the anti-apoptotic protein-Bax inhibitor-1 on the regulation of cellular Ca\textsuperscript{2+} homeostasis. The expression of BI-1 decreased the amount of Ca\textsuperscript{2+} that could be released from intracellular stores. Analysis of the kinetics of Ca\textsuperscript{2+} store depletion revealed that BI-1 increased the permeability of the ER membrane. In BI-1 cells, Ca\textsuperscript{2+} leaks passively at lower rates from stores with IP3R inhibitor-IP3 or RyrR abrogator, but the kinetics of leaky calcium remains higher in BI-1 cells in the presence or absence of the calcium channel inhibitors relatively to Neo cells. The C-terminal is a highly conserved sequence that is present in all BI-1. The data indicate that the full length of BI-1 is capable of self-tetramerization. Deleting the final 9 amino acids from the full-length human BI-1 resulted in an inactive channel, attributed to impaired assembly of a tetrameric BI-1 complex. Based upon the Bioinformatic search data, we have investigated the effect of BI-1 on [Ca\textsuperscript{2+}]i and pH, using the fluorescent indicators Mag-fura-2 and BCECF, respectively. In BI-1 cells, acidic condition evoked a much larger and faster [Ca\textsuperscript{2+}]i increase than in Neo cells. The pHi was also much more decreased in BI-1 cells in the presence of calcium. In summary, BI-1 function revealed a significant regulation in ER Ca\textsuperscript{2+} homeostasis and pH regulation.

Contribution of a Sub-Region of the Endoplasmic Reticulum in ER-mediated Phagocytosis

E. Gagnon,1 L. Morrow,2 S. Duclos,1 J. Bergeron,3 M. Desjardins1; 1Pathologie et Biologie Cellulaire, Université de Montréal, Montreal, PQ, Canada, 2Anatomy and Cell Biology, McGill University, Montreal, PQ, Canada, 3Department of Pathologie et Biologie Cellulaire, Université de Montréal, Montreal, PQ, Canada

We have shown recently that the endoplasmic reticulum (ER) participates in phagosome biogenesis, a process that we referred to as ER-mediated phagocytosis. The contribution of ER to the phagosome membrane was further shown to provide functional properties favoring the cross presentation of exogenous peptides on MHC class I molecules. The ability of ER and phagosomes to interact has been recently challenged (Touret et al., Cell 123:157-170, 2005). In the present study, we used a variety of approaches, including some of the tools developed by Touret and colleagues, to show that a sub-region of the ER participated in phagocytosis. Western blot analyses indicated that phagosomes isolated from macrophages expressing the ER tracer KDEL-GFP contained several ER proteins but no detectable GFP. Furthermore, immunofluorescence microscopy of the ER protein calnexin and the overexpressed ER marker KDEL-GFP, indicated that these two molecules co-localized only to a sub-region of the ER. ER regions displaying a strong labeling for calnexin in the cell periphery, as well as the nuclear envelope, were devoid of KDEL-GFP. These results indicate that the overexpression of the tracer KDEL-GFP in macrophages results in the accumulation of this molecule in a sub-region of the ER that does not participate in phagocytosis. The use of a sub-region of the ER for phagocytosis might favor a rapid recruitment of membrane from an internal source while minimizing the potential deleterious effect of this process on other key functions of the ER.

1971

Proteomics Characterization of Endoplasmic Reticulum Proteins with Unknown Function

M. D. Jain,1 H. Nagaya,2 A. Gilchrist,1 C. Au,3 J. Paiement,3 J. J. M. Bergeron1; 1Department of Anatomy and Cell Biology, McGill University, Montreal, PQ, Canada, 2Department of Pathologie et Biologie Cellulaire, Université de Montréal, Montreal, PQ, Canada

Based on the analysis of 140 000 tandem mass spectra we have characterized 350 proteins of unknown function assigned to the ER and Golgi apparatus of rat liver parenchyma. Using a proteomics clustering tool as well as the kinetics of interaction between these expressed in BHK cells and were therefore predicted to be newly uncovered molecular chaperones. Both the proteomics clustering tool as well as the kinetics of interaction between these newly uncovered chaperones and tyrosinase predicted that two were functional in the rough ER and likely in proximity to the translocon. The third chaperone was predicted to be localized to the smooth ER with markedly later kinetics of interaction with tyrosinase. One of these proteins has been named previously as nicalin, which we characterize as a likely translocon-associated chaperone. The second also co-distributed with translocon proteins, and the third, more distally located chaperone we have named EDEX.

1972

Molecular Characterization and Functional Analyses of a Unique, Class-I, Secretory Nuclease from the Human Pathogen, Leishmania donovani

M. B. Joshi,1 D. M. Dwyer; Cell Biology Section/LPD, NIAID/NIH, Bethesda, MD

Leishmania donovani, a primitive protozoan pathogen of humans, resides and multiplies in highly restricted, microenvironments within their hosts (i.e. in the gut lumen of their sandfly vectors and in the phag-lysosomal compartments of infected mammalian macrophages). Like other tyrosinomatisated parasites, they are purine auxotrophs and are totally dependent upon salvaging these essential nutrients from their hosts. In that regard, we identified and characterized the biochemical and functional properties of a unique, 35 kDa, nuclease from these organisms. Our studies demonstrated this enzyme was constitutively released/secreted by both in vitro grown promastigotes and axenic amastigotes as well as, by in vivo-derived amastigote developmental forms of the parasite. Using a molecular approach, we identified, characterized and epistemically expressed the gene, LdNuc which encodes this new Class I nuclease family member from these organisms. Results of both structural and functional analyses showed that the LdNuc expressed-enzyme had properties identical to the native, wild-type, parasite released/neclease. Further, both LdNuc mRNA and secretory nuclease activity were differentially up-expressed by amastigotes >> promastigotes. Biochemical analyses showed that the LdNuc secreted nuclease could hydrolyze a variety of synthetic polynucleotide substrates as well as, both single- and double-stranded DNAs and RNAs. Based on these observations, we hypothesize that this leishmanial "secretory" nuclease could act, at a distance away from the parasite, to hydrolyze host-derived nucleic acids to satisfy the essential purine requirements of these organisms. Thus, LdNuc must have essential roles in facilitating the survival, growth and development of this important human pathogen.

1973

Identification, Biochemical and Molecular Characterization of Secreted Lipases in the Human Pathogen Leishmania

A. M. Shakarian,1 G. Meguans2, M. Joshi,1 D. M. Dwyer1; 1Biology and Biomedical Sciences, Salve Regina University, Newport, RI, 2Laboratory of Parasitic Diseases, NIAID/NIH, Bethesda, MD

The human pathogen Leishmania, found in the tropics and subtropics are investigated as models of human parasitism. Emphasis is placed on characterizing both the biochemical functions and gene structure of secreted proteins toward defining their roles in parasite survival and development. Lipases are ubiquitous enzymes that hydrolyze the ester linkages of fats to form glycerol and fatty acids. These enzymes are involved in biological activities ranging from antigenic variation and cell signaling to nutrient acquisition and have been implicated as virulence factors in some pathogens. Culture supernatants of Leishmania promastigotes were incubated with various 4-nitrophenyl fatty acids. Results of these assays identified lipase activities from in vitro culture supernatants of Leishmania. Subsequently, a PCR-based strategy identified a candidate lipase gene from Leishmania. The L. major genome database revealed 3 putative secretory lipases. The homologue of one of these, designated LIP3, was cloned. Sequence analysis of LIP3 revealed an ORF of 927 bp and a deduced protein of 306 aa with a predicted molecular mass of 33.0 kDa. Further analysis showed a putative 24aa signal peptide and the absence of an anchor motif, both consistent with a secretory molecule. Moreover, an active enzyme active site was identified. Southern analysis revealed the presence of more than one copy of this gene in the Leishmania genome. RT-PCR revealed that this gene is expressed in both promastigotes and amastigotes. Interestingly, amastigotes preferentially use fatty acids as an energy source. To further characterize this lipase, an epitope-tagged construct was epistemally expressed. Western
analysis revealed that the expressed protein was secreted by transfected *Leishmania*. Taken together, our data supports the hypothesis that lipase activity is secreted by *Leishmania*. Further characterization of this gene and protein will lead to a better understanding of the role of lipases within the biology of the important group of human pathogens.

Protozoan Parasite Exit May Be Preceded by Fusion between the Parasitophorous Vacuole Membrane and the Host-Cell Membrane

S. León,1, J. Diaz;2 A. Corrales,2 G. Cortés,4 M. Caballero,1 1Departamento de Biología, Facultad de Ciencias, Universidad Nacional de Colombia, Bogota, Colombia, 2Departamento de Biología, Facultad de Ciencias, Universidad Nacional de Colombia, Bogota, Colombia, 3Laboratorio de Biofísica, Centro Internacional de Física, Bogota, Colombia, 4Departamento de Biología, Facultad de Ciencias, Universidad Nacional de Colombia, Bogota, Colombia, 5Grupo de Microscopía y análisis de Inmunes, Instituto Nacional de Salud, Bogota, Colombia

Introduction: Protozoa like *Leishmania* and *Plasmodium* are intracellular parasites confined to a compartment known as the parasitophorous vacuole. Two main models have been postulated for parasite exit. One supports the idea that parasite exit requires lysis of the parasitophorous vacuole membrane and the host membrane. The other model supports the idea that parasite exit is preceded by fusion between the parasitophorous vacuole membrane and the host membrane. We present data that supports the second model. Methodology: Two models were studied: infection of the macrophage-like cell line J774.A1 with *Leishmania amazonensis* and infection of human erythrocytes with *Plasmodium falciparum*. The infection cycle was followed in vitro and percentage of infection, parasite number and viability were measured in the presence of inhibitors of membrane fusion. Fluorescence microscopy, electron microscopy and electrophysiology were used to determine membrane capacitance, an indirect measurement of membrane area. Results: Leupeptin and NEM, two inhibitors of membrane fusion alter the decrease in parasite number observed in the *Leishmania* infection cycle in macrophages suggesting retardation of parasite exit whereas cytchalasin-B, an inhibitor of the cytoskeleton had no effect. There is a progressive increase in membrane capacitance of macrophages infected with *Leishmania* up to 72 hours post infection, with a drop at 96 hours. DilC16 labeling of erythrocyte membrane is transfer to intracellular membranes upon *Plasmodium* exit. Labeling with NBD-PE and RHO-PE macrophages and erythrocytes are altered by *Leishmania* and *Plasmodium* infection respectively. Conclusions: The changes in membrane capacitance of the host-cell membrane support the idea of fusion between the parasitophorous vacuole membrane and the host membrane.

Malaria Transmission-blocking Antigen, Pfs230, Mediates Human Red Blood Cell Binding to Exflagellating Male Parasites and Oocyst Production

S. Eksi,1 B. Czesny,1 G. van Gemert,1 R. W. Sauerwein,2 W. Eling,2 K. C. Williamson,1 Biology, Loyola University Chicago, Chicago, IL, 2Medical Microbiology, University of Nijmegen, Nijmegen, The Netherlands

Exflagellation of male *Plasmodium* parasites can be stimulated by simulating conditions in the mosquito midgut, one of the most visually dramatic events in the lifecycle of the malaria parasite. Following emergence from the red blood cell (RBC), male parasites undergo rounds of nuclear division and form axonemes which extend out from the body of the parasite. The extended axonemes move with a vigorous whipping motion before releasing as individual motile microgametes to find and fertilize a female gamete. Before the microgametes are released he can associate with uninfected RBCs in the bloodmeal and draw the RBCs in toward the body of the parasite where the RBCs are retained. In wild type parasites this results in a cluster of 2-13 uninfected RBCs, called an exflagellation center. *Plasmodium falciparum* transmission-blocking vaccine candidate and gamete surface antigen, Pfs230, was found to be important for both exflagellation center formation and subsequent oocyst formation. Two clones distinct Pfs230 gene disruptions (D1.356 and D2.560) and a Pfs48/45 disruptant that result in Pfs230-minus Pfs48/45-plus and Pfs230-minus Pfs48/45-minus gametes, respectively, successfully emerge from RBCs and males exflagellate producing microgametes. However, exflagellating Pfs230-minus males, in the presence or absence of Pfs48/45, are unable to interact with RBCs and form exflagellation centers. Oocyst production and mosquito infectivity is also significantly reduced, 96-972% and 76-71%, respectively. In contrast, the expression pattern of other known sexual-stage specific antigens, including the Pfs230 paralog (PfsMB5), Pfs16, Pfs47 or Pfs25, were not altered. These results suggest that Pfs230 is the surface molecule on males that mediates RBC binding and plays an important role in oocyst development, a critical step in malaria transmission.

1976

Plasmodium Falciparum Ring-infected Erythrocyte Surface Antigen (RESA) Stabilizes Rhysbyocyte Spectrin Tetramer and Reduces Malaria Invasion

X. Pei,1 X. An,3 X. Guo,1 R. Coppell,1 N. Mohandas,3 Red Cell Physiology Laboratory, New York Blood Center, New York, NY, 1Department of Microbiology, Monash University, Victoria, Australia

Erythrocyte surface antigen (RESA) of *Plasmodium falciparum* is the first malaria protein shown to interact with erythrocyte skeletal protein, spectrin. However, the structural basis and functional sequel of this interaction remain unknown. In the present study, we first defined the binding motifs involved in the interaction. We show that spectrin bound to a 107 amino acid fragment of RESA (residues 663-770) and that this RESA fragment bound specifically to only one of the 37 spectrin repeats, repeat 16 of spectrin. Repeat 16 of spectrin has been previously shown to play a major role in regulating spectrin tetramer formation. In the present study, we demonstrated that binding of RESA fragment to spectrin stabilizes spectrin tetramers both in vitro and in situ. Importantly, resealing of the RESA fragment into erythrocyte ghosts resulted in both increased resistance of cells to heat-induced vesiculation and to enhanced membrane mechanical stability. Surprisingly, the invasion of RESA fragment ressealed-erythrocytes by malaria parasite, *Plasmodium falciparum*, is significantly diminished compared to control cells. Based on these findings, we conclude that association of RESA with repeat 16 of spectrin stabilizes spectrin tetramers, which in turn leads to the stabilization of erythrocyte membrane skeleton. Our data further suggest a role of spectrin tetramers in regulating thermal stability of erythrocyte membrane and in malarial parasite invasion.

1977

Three-dimensionally Cultivated Cardiomyocytes Infected by *Trypanosoma cruzi*: Possible New Model of In Vitro Chagasic Chronic Cardiomyopathy

D. Adesse, E. M. Azzam, M. I. Rossi, B. Borovjevic, M. N. Meirelles, L. R. Giaroni; Ultraestructura e Biologia Celular, Fiocruz-Brasil, Rio de Janeiro, Brazil

Chagas disease, caused by *Trypanosoma cruzi*, is endemic in Latin America, affecting 16-18 million people and 90 million are at risk of becoming infected. Chronic Chagasic Cardiomyopathy (CCC) is considered a progressive disease in which patients present myocarditis with inflammatory infiltrate, fibrosis and myocardial hypertrophy. Persistence of infection, presence of parasite antigens at the inflammatory site or autoimmune processes are hypotheses proposed to explain the pathological lesions in the hearts of infected patients. Moreover, it was demonstrated that cardiomyocytes can respond to in vitro *T. cruzi* infection by expressing TNF-α and IL-1β mRNA thereby demonstrating an inflammatory response. We recently developed a functional cardiac microtissue that mimics the in vivo situation once the cells secrete Extracellular Matrix (ECM) and self-organize in a 3D architecture, forming a spherical structure. The cardiac microtissue produces growth factors including vascular endothelial growth factor (VEGF) and when co-cultured with endothelial cells, vascular structures are produced, improving the contractile activity of microtissue. We now have this cardiac microtissue as a new 3D model of *T.cruzi*-cardiac tissue interaction and show that it reproduces in vitro important aspects observed during the chagasic cardiomyopathy. Our results show that *T. cruzi* successfully infects and completes its intracellular cycle inside cardiac microtissue, causing alterations in ECM, increasing the cardiomyocyte area and then total cardiac microtissue volume - aspects that may reflect the cardiomagnetically observed during Chagasic disease. Moreover, *T. cruzi* infection induces migration of inflammatory cells throughout the microtissue. Taken together, our results show that this new approach that more closely reflects what happens in vivo at flattened cultures and is likely to bring new insights in important associated aspects related to chagasic cardiomyopathy.

1978

Active Uptake of Host Eukaryotic Functions by the Intracellular Pathogen *Toxoplasma* J. D. Romano, N. Banó, I. Coppens; Molecular Microbiology and Immunology, Johns Hopkins Bloomberg School of Public Health, Baltimore, MD

The obligate intracellular parasite *Toxoplasma gondii* actively invades mammalian cells, forming a specialized parasitophorous vacuole (PV) upon entry. From within this niche, the parasite redirects various host organelles to the PV in order to divert nutrients from them and to interfere with host immunity. Using time-lapse confocal microscopy we observed that shortly after invasion the PV moves directionally towards the host cell's nucleus. Surprisingly, we found that specific microtubules and actin destabilizing compounds have no effect on the migration of the PV to the cell center. However, several hours post-infection, the network of host microtubules is completely reorganized to surround the PV. To better understand the association of host microtubules with the PV, the dynamics of the host microtubule-organizing center (MTOC) was studied in *Toxoplasma*-infected cells. Early during infection, evaginations of the PV membrane were observed to extend towards the host MTOC in a subset of PVs. After 24 h of infection, the host MTOC was stably anchored to the PV surface. Concomitantly, host Golgi localized near the PV. Encelated host cells were then used to determine the respective contribution of the host cell and the parasite to the association of host structures post-infection. PV membrane formation, recruitment of host structures (i.e. ER, mitochondria, PV, microtubules), cholesterol scavenging from host endocytic organelles and parasite multiplication were unaffected in cytoplasts as compared to nucleated cells. These data implicate that *Toxoplasma* is actively involved in usurping many host eukaryotic functions and that new host transcripts are not essential to the early development of this parasite.

MicroRNA-mediated Post-transcriptional Gene Silencing Is Involved in Cholangiocyte Defense against Cryptosporidium parvum Infection
X. Chen, P. Splinter, S. O’Hara, N. LaRusso; Mayo Clinic College of Medicine, Rochester, MN

Our previous studies demonstrated that microRNA (miRNA), Let-7i, regulates TLR4 translation and infection of biliary epithelial cells (cholangiocytes) with Cryptosporidium parvum, a parasite that causes intestinal and biliary disease, decreases Let-7i expression and is accompanied by an increased expression of both TLR4 and associated production of the antimicrobial protein, human β-defensin 2 (HBD2). Here, we further explored: i) the mechanism by which C. parvum infection suppresses expression of Let-7i; and ii) the significance of Let-7i-mediated TLR4 translation in epithelial defense. Using an in vitro model of biliary cryptosporidiosis, we found that C. parvum infection suppresses Let-7i transcription 4-fold, a process blocked by the specific NF-κB inhibitor, SN50. Furthermore, using a mobility shift assay, we observed a shift in the Let-7i promoter fragment, which contains a NF-κB consensus motif, following C. parvum infection. Using a pGL3-Basic luciferase construct that contains the promoter elements of Let-7i, we determined found that C. parvum infection decreased Let-7i promoter-driven luciferase expression. In contrast, no decrease of luciferase expression was detected in infected cells in the presence of SN50. Consistent with our previous studies, exposure to C. parvum induced a two-fold (p<0.05) increase in HBD2 expression in biliary epithelial cells. HBD2 expression was decreased up to 85% (p<0.05) in cells with forced expression of Let-7i; in contrast, in contrast, forced suppression of Let-7i increased expression of HBD2 up to 45% (p<0.05). Moreover, we detected a significantly higher parasite burden (20%) increase) in cells with forced Let-7i expression. In contrast, a significantly lower parasite burden (40% decrease) was detected in cells with forced Let-7i suppression. Taken together, our results suggest that C. parvum suppresses Let-7i expression in cholangiocytes via activation of the NF-κB pathway, a process that is involved in cholangiocyte defense against C. parvum infection, possibly via regulation of TLR4 expression to mediate HBD2 production.

Cholesterol in Intracellular Microsporidians and Host Cells Measured with Fluorescent Probes
E. Weinrider, H. Hale-Donze, D. Burkh; Biological Sciences, Louisiana State University, Baton Rouge, LA

Apicomplexa and most other intracellular parasites rely on the host cell for cholesterol since the parasites are devoid of sterol synthesis facility. How does it work in microsporidian parasites? In this study, the distribution of cholesterol in the parasite was investigated. Two questions were asked. (a) What is the distribution of cholesterol in different stages of microsporidian parasites; and, (b) what is the distribution of the cholesterol that the microsporidians have the capacity to produce cholesterol from precursors in the absence of host cells? For cholesterol distribution in parasites or in the host cells, fluorescent probes were used. Dehydroepiandrosterone (DHEA), a fluorescent cholesterol analog and the polypeptide antibiotic filipin were the primary probes used. The filipin-binding results indicate the microsporidian spores of Encephalitozoon and Nosema have cholesterol confined to the plasma membrane; however, the discharged invasive sporoplasm cell lacks cholesterol in the outer membrane. This supports other published data which indicates the outer membrane of the discharged sporoplasm comes from the membrane of the extrusion apparatus during spore discharge. To determine whether microsporidian parasites can make cholesterol, purified sporoforms from discharged spores were incubated on coverslips in medium with 500 nmol of mevalonate or 300 nmol of HMG CoA for 6 h. The cells were subsequently examined for cholesterol synthesis with the use of the probe filipin.

1981

Apoptosis as a Host Defense Mechanism in Crassostrea virginica and Its Modulation by Perkinsus marinus
S. Greweal, I. M. Sokolova, F. M. Hughes; Biology, University of North Carolina at Charlotte, Charlotte, NC

In several organisms apoptosis is an important defense against intracellular parasites in order to contain the infection and limit the spread. Meanwhile, parasites often attempt to suppress host cell apoptosis to extend their survival and increase their proliferation. Perkinsus marinus is an intracellular protozoan parasite of the eastern oyster, Crassostrea virginica. Perkinsus infects hemocytes (oyster immune cells) and is responsible for large scale mortalities. In this study we investigate the hypothesis that hemocytes increase apoptosis as a host defense against Perkinsus and that Perkinsus counters by suppressing this response. To investigate this hypothesis, acute effects were examined in vitro while longer-term responses were investigated in vivo. Initial light microscopic analysis of circulating hemocytes indicated that granulocytes predominate (~70%). Following in vitro infection (MOI 1:1), phagocytosis increased in a time-dependent manner. At 15 minutes, approximately 40% of hemocytes had either phagocytosed, or were closely associated with, Perkinsus; whereas by two hours this had increased to 65%. In response to infection, hemocyte apoptosis (Annexin V) increased within 15 min and was significantly enhanced by 2 hours, suggesting the induction of apoptosis as a host defense. To examine a more chronic response, oysters were infected in vivo (2x10⁵ Perkinsus/gram) for 16 days. At day-1, apoptosis was elevated, accompanied with a significant decrease in circulating hemocytes. However, by day-2, apoptotic levels returned to baseline and remained there, despite light to medium infections being established (Mackin scale). These results suggest that Perkinsus counteracts the initial hemocyte apoptotic response to ensure proliferation and spread within the host. Together these results indicate that apoptosis is one of the defense mechanisms employed by the oyster host to control the infection and that Perkinsus suppresses this response. Future studies will begin to investigate the molecular mechanisms of this interaction.

1983

Salmonella Induced Filaments and Salmonella-containing Vacuoles Display Dynamic Movement in Host Cells
J. Szeto, 1 A. Namolovan, 1 M. Ohlson, 2 S. Miller, 2 J. Brumell; 1Cell Biology, Hospital for Sick Children, Toronto, ON, Canada, 2Department of Microbiology, University of Washington, Seattle, WA

Salmoneella enterica serovar Typhimurium (S. Typhimurium) occupies a membrane-bound niche in host cells during infection, the Salmonella-containing vacuole (SCV). From here, S. Typhimurium uses its Salmonella Pathogenicity Island 2 (SPI-2)-encoded type III secretion system (T3SS) to inject bacterial effector proteins into the host cell to modulate various activities. Several hours after infection, membranous tubules termed Salmonella-induced filaments (Sif) arise from the SCV. Here we used GFP-Lamp1 to visualize Sif dynamics using live cell imaging. Our studies revealed that Sifs undergo rapid extension, retraction, branching, and swelling. Live cell imaging also revealed that SCVs exhibit intracellular movement independently of Sifs. For statistical analysis, we documented the localization of Lamp1 SCVs in fixed infected HeLa cells. We determined that wild-type SCVs gradually migrate to a perinuclear, Golgi-associated position; however, the discharged invasive sporoplasm cell lacks cholesterol in the outer membrane. This supports other published data which indicates the outer membrane of the discharged sporoplasm comes from the membrane of the extrusion apparatus during spore discharge. To determine whether microsporidian parasites can make cholesterol, purified sporoplasm from discharged spores were incubated on coverslips in medium with 500 nmol of mevalonate or 300 nmol of HMG CoA for 6 h. The cells were subsequently examined for cholesterol synthesis with the use of the probe filipin.

Sema3E Enhances Metastasis of Ovarian Endometrioid Carcinoma in a Plexin D1-dependent Way
P. Huang, 2 M. Tsou, 2 S. Hsu, 1; 1Graduate Institute of Pathology, College of Medicine, Taipei, Taiwan, 2Department of Pathology, National Taiwan University & University Hospital, Taiwan

Malignant ovarian endometrioid carcinomas, usually accompanied with metastasis upon diagnosis, account for 10 to 20% of epithelial ovarian cancers (EOCs) and are refractory to chemotherapy. Consequently, ovarian endometrioid carcinomas can serve as a promising model to study cancer progression originated from ovaries. Using two well-established human endometrioid carcinoma cell lines with different ability in invasion (P0 cells: low invasiveness, P4 cells: high invasiveness), we found that among all class 3 semaphorins, Sema3E was significantly over-expressed in the high-invasive endometrioid carcinoma cells. However, the receptor for Sema3E, Plexin D1 and/or neuropilin, showed no difference. Statistical analysis of 39 patients with ovarian endometrioid carcinomas diagnosed from 1999 to 2005 at NTUH demonstrated positive correlation between tumor grade and Sema3E expression level assessed by immunohistochemistry. When xenografts Sema3E was stably introduced into the low-invasive P0 cells, Sema3E augmented cellular invasiveness and migration in a concentration-dependent way as assessed by wound healing and Transwell chamber assay in vitro. In vivo, xenografted P0 cells with stably expressed Sema3E resulted in multi-focal tumor metastasis in bilateral lungs of SCID mice, in strong contrast to non-metastasis of P0 cells without Sema3E expression. We further revealed that furin-cleaved p61-Sema3E, not unprocessed p87-Sema3E, enhanced cellular invasiveness and migration. When Plexin D1 was functionally knocked-down by siRNA in the presence of over-expressed Sema3E, Sema3E no longer promoted cellular invasive and distant metastasis. Our study strongly argues for the pivotal role of Plexin D1 signaling pathway triggered by over-expressed Sema3E in the regulation of invasiveness and migration ability of ovarian endometrioid carcinoma via a paracrine and/or autocrine manner.

Filamin A is a Novel Cavelin1-dependent Target of Insulin-like Growth Factor-I Signaling: Role in Cancer Cell Migration

D. Ravidi,1 R. Reich,1 M. Liscovitch1 Biological Regulation, Weizmann Institute of Science, Rehovot, Israel, 2Pharmacology, Hebrew University, Jerusalem, Israel

Cavelin-1 (Cav1) is a 52-kDa transmembrane protein constitutively expressed on the surface of many cell types. It has been suggested to be involved in cell migration but its exact role and mechanism of action remain obscure. We have previously reported that expression of cavelin-1 is up-regulated in human breast cancer (MCF-7/Cav1) cells results in up-regulation of a phosphorylated high molecular weight putative Akt substrate, provisionally designated pp340. We now show, using differential detergent extraction, SDS-PAGE and mass spectrometry, that the major protein in the pp340 band is the actin filament cross-linking protein filamin A. The identity of filamin A was confirmed by mass spectrometry and western blotting. Notum is expressed at high levels in mouse embryos and in various adult organs including liver, lung, kidney, ovary and brain. No expression was detected in the thymus, heart and spleen. Finally, by using semiquantitative RT-PCR, we found that Notum is expressed at high levels in mouse embryos and in various adult organs including liver, lung, kidney, ovary and brain. No expression was detected in the thymus, heart and spleen. Furthermore, our results suggest that filamin A may mediate the effects of cavelin-1 on IGF-I-induced cancer cell migration.

Expression and Purification of the Recombinant Bryohealins (Bryopsis plumosa lectins) Produced in Escherichia coli Cells

K. S. Yoon, T. A. Klosekova, K. Y. Ko, G. H. Kim, K. P. Lee Biology, Konkuk National University, Konkuk, Republic of Korea

Bryohealins, a N-acetyl-D-glucosamine and N-acetyl-D-galactosamine specific lectins from the marine green alga Bryopsis plumosa, were produced in Escherichia coli from a cDNA clones subcloned to a various expression vectors. The recombinant lectins (rBryohealin-1 and rBryohealin-2) were purified by a combination of affinity chromatography and gel filtration. By SDS-PAGE and Western blot, rBryohealin were highly pure with an apparent molecular mass of 27 kDa and 12 kDa, respectively. The primary amino acid sequence of the recombinant Bryohealin were found to be identical to the native proteins. The purified recombinant protein could agglutinate red blood cells of mice, and the agglutination activity was inhibited by N-acetyl-D-glucosamine and N-acetyl-D-galactosamine. These results suggest that the recombinant Bryohealin 1-protein is a potent agglutinin to have a structure and function similar to that of native protein.

Identifying the Role of Cortactin Phosphorylation in Breast Cancer Invasiveness

C. C. Mader, K. Machida, B. J. Mayer, A. J. Koleske1 Cell Biology, Yale University, New Haven, CT, 2Molecular Biophysics and Biochemistry, Yale University, New Haven, CT, 3Genetics and Developmental Biology, University of Connecticut Health Center, Farmington, CT

Cortactin is known to promote actin driven cell motility and has increased expression levels in invasive breast cancers. Originally shown to be a substrate of the Src oncogene, cortactin is also a substrate of Abl and Nrcot receptor tyrosine kinases. The role that phosphorylation of cortactin plays in breast cancer invadopodia is unclear. The goal of this study is to identify potential binding partners of Abl/Arg phosphorylated cortactin and the potential role which this phosphorylation plays in promoting breast cancer invasiveness. We find that Arg binds cortactin with a Kd of >3μM while a truncation mutant lacking the SH3, SH2 and kinase domains binds with higher affinity (Kd=0.5μM). However, Arg mutants lacking the PxxP motifs do not bind to cortactin. This suggests that cortactin binds to Arg via the internal PxxP motifs and this binding is regulated by the Arg N-terminus. Interestingly, phosphorylactin interacts selectively with the Arg SH2 domain and not the SH2 domains from Abl, Src, Nck, and Grb. A nonphosphorylatable cortactin mutant did not show this interaction. This shows that phosphorylation of cortactin may act as a switch causing interaction with Arg through two different binding motifs depending on cortactin’s phosphorylation state. Using breast cancer cell lines we show that phosphorylated cortactin levels are significantly increased in highly invasive lines. To determine if phosphorylation of cortactin affects interaction with downstream actin regulatory binding partners, we are examining the binding interaction of different truncation and phosphorylated forms of cortactin with the Arp2/3 activator N-WASP. We are also performing colocalization studies to show the effects of cortactin phosphorylation on N-Wasp colocalization in breast cancer invadopodia. Overall, our results suggest that Arg-mediated tyrosine cortactin phosphorylation plays a role as a switch to promote more motile or invasive cellular phenotypes.

Expression of 15-Hydroxyprostaglandin Dehydrogenase in Gastric Cancer

A. Thiel,1 A. Ganesan,1 A. Nykänen,1 H. Tai,2 C. Haglund,3 T. V. Petrova,4 A. Ristimäki1,4 1Molecular and Cancer Biology Research Program, University of Helsinki, Biomedicum, Helsinki, Finland, 2Department of Pathology, Helsinki University Central Hospital, Helsinki, Finland, 3Department of Oncology, Helsinki University Central Hospital, Helsinki, Finland

We have previously shown that expression of cyclooxygenase-2 (COX-2) is elevated in 55% of gastric carcinomas and also is an independent prognostic factor in this disease. COX-2 is critical for the conversion of arachidonic acid to prostanooids, especially to prostaglandin E2 (PGE2), the most abundant prostaglandin in gastrointestinal tumors, which is thought to play a major role in carcinogenesis via modulation of apoptosis, proliferation, angiogenesis. Now we report that the expression of 15-hydroxyprostaglandin dehydrogenase (15-PGDH) is reduced in gastric cancer. This enzyme catalyzes the inactivation of PGE2 by converting the 15-OH to a 15-koeto group. We showed on a cancer profiling array which contained 27 DNA samples from gastric tumor and corresponding normal tissues from individual patients that the expression of 15-PGDH was five-fold lower in tumor vs. normal samples (P<0.0001). Furthermore we used immunochemistry to stain 133 gastric tumor specimens with rabbit polyclonal 15-PGDH and found that only 18% of the tumors expressed 15-PGDH. In gastric cancer cell lines treatment with interleukin-1 reduced the expression of 15-PGDH mRNA and protein levels. We will use a 15-PGDH-promoter construct to study whether this downregulation is due to reduced activation of the promoter. Our results suggest that downregulation of 15-PGDH is an important step in gastric tumorigenesis, which contributes to the high tumor levels of PGE2 and tumor progression.
interaction between integrin beta4 and FAK. Indeed, we demonstrated that in several tumor cell lines, such as MDA-MB-231, HCT116, and B16 but not in MCF7 and HeLa, integrin beta4 could co-immunoprecipitate FAK protein endogenously. It implicated the participation of this interaction in tumorigenesis. Moreover, the interaction required an 11-amino-acids motif within FAK’s amino-terminus. Among them, 2 out of 11 amino acids exhibited a critical role in interaction with integrin beta4. Our data resolved, in the first time, a physical interaction between integrins and FAK, suggesting a strong link regarding integrin-FAK signaling events. Future work will decipher the signaling pathway(s) and biological significance through the integrin beta4-FAK interaction, which will shed a light on better strategies for cancer therapies.

1991

Identification of Genes Potentially Involved in Initiation and Progression of Epithelial-Mesenchymal Transition (EMT) in the Non-Tumorigenic Human Mammary Epithelial Cell Line MCF10A

P. D. Gascard, K. L. Andrarawea, M. H. Barcellos-Hoff; Cancer Biology, LBNL, Berkeley, CA

Epithelial-Mesenchymal Transition (EMT) is a hallmark of tumorigenesis. It is characterized by a loss of epithelial architecture and acquisition of a mesenchymal phenotype with change in cell shape and increased motility. We have developed a unique EMT model in the non-tumorigenic human mammary epithelial cell line MCF10A. MCF10A cells were subjected to a 24h irradiation 5 hours after plating at clonal density and subsequently cultured for 8 days in presence of 400pg/ml recombinant transforming growth factor-beta (TGF-beta). In these conditions, cells got disorganized and displayed a concomitant loss of expression of E-cadherin and the tight junction protein ZO-1 and a gain of expression of N-cadherin and vimentin. Strikingly, neither irradiation nor TGF-beta alone recapitulated the EMT phenotype. As a first step to elucidate the mechanisms responsible for the intriguing synergy between irradiation and TGF-beta in initiating EMT, we compared transcript expression levels of sham, irradiated, TGF-beta-treated and irradiated-TGF-beta-treated MCF10A cells. Ten EMT signature genes, whose expression was mostly altered in double-treated cells, were identified. Among the eight up-regulated genes, the most significant included the recently characterized interleukin IL-32/NK4, whose up-regulation may explain over-expression of other interleukins, such as IL6 and IL8. Other up-regulated genes included: the transcription factor TCF7/LEB1 and the fibroblast growth factor FGF2/FGF7, which have been both previously reported to down-regulate E-cadherin transcription; the ecdy-nucleotidase NTSE/CD73, whose over-expression has been documented in tumor cells; the radiation-inducible immediate early response gene IER3/IEX-1; activin A (INHBA), cyclo-oxygenase 2 (COX2/PTGS2); and the nucleoporin-like protein NUP1. The scavenger receptor SCARB2 and the secreted frizzled-related protein 1 gene SFRP1 were the two genes significantly down-regulated in double-treated cells. Taken together, these data suggest that MCF10A cells shift towards a tumorigenic phenotype upon EMT. The biological significance of these gene expression alterations in EMT initiation and progression remains to be investigated.

1992

UVB-Induced Dephosphorylation of Stat3 by T-Cell Protein Tyrosine Phosphatase (T-PTP)

D. J. Kim, J. DiGiovanni; Department of Carcinogenesis, The University of Texas M.D. Anderson Cancer Center, Science Park-Research Division, Smithville, TX

Ultraviolet B radiation (UVB) can cause DNA damage, induce gene mutations and modulate intracellular signal transduction contributing to the development of skin cancer. Signal transducer and activator of transcription 3 (Stat3) regulates various physiological functions including apoptosis, cell cycle regulation, and tumor angiogenesis through regulation of gene expression, and its constitutive activation is associated with human epithelial cancers. Recent studies indicated that Stat3 was rapidly dephosphorylated in keratinocytes after UVB irradiation. Vanadate treatment desensitized keratinocytes to UVB-induced apoptosis with the recovery of phosphorylated Stat3 protein levels, implying that a tyrosine phosphatase is involved in this mechanism. In the current work, the mechanism whereby UVB exposure leads to rapid dephosphorylation of Stat3 was examined. Western blot analysis showed that the nuclear form of T-PTP, which is known to dephosphorylate various signaling molecules, was constitutively expressed in cultured mouse keratinocytes. After UVB exposure, activated stat3 was rapidly reduced, whereas the level of T-PTP was not changed. Further analysis revealed that translocation of T-PTP from cytosol to nucleus was increased in response to UVB irradiation. Consistent with western blot analysis, dephosphorylation of Stat3 by T-PTP was rapidly increased after UVB irradiation of cultured keratinocytes. Stat3 target genes, such as cyclin D1 and c-Myc, were also down-regulated following UVB exposure. In mouse epidermis in vivo, the level of phosphorylated Stat3 was initially decreased, following by a significant increase at later time points after UVB exposure. The expression patterns of cyclin D1 and c-Myc followed the changes in activated Stat3. In addition, dephosphorylation of Stat3 by T-PTP was initially up-regulated, and then decreased in vivo after UVB exposure. These results suggest that T-PTP is responsible for the rapid dephosphorylation of Stat3 following UVB and may serve as part of an initial protective mechanisms against UV skin carcinogenesis. ECTO-NOX Proteins, a Family of Cell Surface NADH Oxidases, Are Labeled by Biotin and Selectively Isolated from Plasma Membrane Preparations

S. C. Dick, Z. Jiang, V. D. Kane, D. M. Morre, D. J. Morre; Foods and Nutrition, Purdue University, West Lafayette, IN, 1Medicinal Chemistry and Molecular Pharmacology, Purdue University, West Lafayette, IN

Biotinylation of plasma membranes and cell surfaces was performed to further purify ECTO-NOX proteins, a group of proteins with hydroquinone oxidase activity as well as disulphide-thiol interchange activity (Morre and Morre. 2003. Free Radical Research 37:795-808). Soybean plasma membranes contain the constitutive form of ECTO-NOX known as CNOX. Previous studies using immunoprecipitation and gel slice analyses of partially purified proteins suggested the molecular weight of soybean CNOX to be 54 ±2 kDa. When a soybean plasma membrane preparations were biotinylated, reactive bands of 57 and 68 kDa were observed on Western blots using anti-CNOX antibodies. HeLa S (a cervical carcinoma cell line) cells contain the constitutive form CNOX as well as the tumor-specific nCNOX. Biotinylation the cell surface of HeLa S cells produced labeled proteins of 68, 52, and 34 kDa on Western blots using a nCNOX-specific anti-peptide antibody. The proteins at 52 and 34 kDa corresponded to molecular weights previously ascribed to nCNOX (Chueh et al. 1997. Arch. Biochem biophys. 342:32-47; Yantiri et al. 2001. Jbid 391:149-159), and the 29 kDa band corresponded to a protamine resistant fragment of nCNOX (Kelker et al. 2001. Biochemistry 40: 7351-7354). Biotinylation of HeLa S plasma membranes produced labeled proteins of 68, 52, and 34 kDa using avidin-alkaline phosphatase as a probe, and a protein of 68 kDa using the anti-nCNOX peptide antibody. When probed with anti-CNOX antibodies, a protein at 57 kDa was revealed suggesting the biotinylated protein of 57 kDa represents the polypeptide chain of CNOX.

Predicting Breast Cancer Metastasis Using Protein Networks

H. Chuang, E. Lee, T. Ideker; 1 Bioinformatics, UCSD, San Diego, CA, 2Bioengineering, UCSD, San Diego, CA, 3Biosystems, Korea Advanced Institute of Science and Technology, Daejeon, Republic of Korea

Accurate prediction of metastatic potential is vital to determining the appropriate therapy for breast cancer patients. Current strategies analyze gene expression profiles to identify disease-correlated markers, without utilizing or revealing information on how genes interrelate within a larger functional network. To address this limitation, we apply a network-based approach that classifies expression profiles using pathway modules extracted from a huge human protein-protein interaction network consisted of 57,235 interactions among 11,203 proteins. Modules are sub-networks which have discriminative activities between good and poor prognosis patients. The quantitative activity of a defined module was inferred from the expression values of its member genes. A logistic regression based classifier is built based not on expression levels of individual genes but the activity levels of network modules. We show that network-based classification has two major advantages over previous approaches. First, it improves 8% of the performance when classifying metastatic versus non-metastatic breast tumors in terms of ROC AUC (Area Under Curve). Second, the discriminative network modules provide high-level models of the molecular mechanisms underlying metastasis. Many known breast cancer susceptibility genes such as BRCA1, TP53 and ESR1, which are not expression responsive, are included in our network modules but not able to be detected by previous approaches. The network-based approach integrating protein interactions with breast cancer expression profiles leads to increased classification accuracy and, simultaneously, provides an implicit view of the biological processes underlying metastasis.

1995

Computational Analysis for Splicing Sequences of Tumor-associated NADH Oxidase (iNOX) Exon4

V. D. Kane, X. Tang, C. P. Kuntz, S. C. Dick, D. J. Morre, D. M. Morre; Foods and Nutrition, Purdue University, West Lafayette, IN, 1Medicinal Chemistry and Molecular Pharmacology, Purdue University, West Lafayette, IN

Pre-mRNAs subject to alternative splicing contain conserved exonic sequences that direct the spliceosome to either include or exclude that exon in the final product. These sequences have been classified as Exonic Splicing Enhancers (ESEs) which promote exon inclusion, or Exonic Splicing Silencers (ESSs) which direct exon exclusion (Eisenstein, M. Nature. 2005). Serine/Arginine-rich proteins (SR proteins) and heteromultimeric ribonucleoproteins (hnRNPs) bind ESE and ESS sequences, respectively (Chen, C.D. et al. 2005: Genes & Development 13:593-606). Our laboratories have demonstrated that exon4 is not present in the final mRNA transcript for tumor-associated NADH oxidase (iNOX) in cancer cells (X. Tang, unpublished). In this study, the gene sequence for iNOX, located on the X chromosome, was analyzed via Genscan (genes.mit.edu/GENSCAN) for the presence of possible ESE and ESS sequences (Chew, S.L. et
A Model System for Cancer-specific Expression of tNOX Exon4-minus Splice Variant mRNA

C. P. Kunz, X. Tang, C. C. Kane, D. M. Morris, D. J. Morre; Foods and Nutrition, Purdue University, West Lafayette, IN

A cancer-specific (pancancer) cell surface NADH oxidase with protein disulfide-thiol interchange activity designated as tNOX, is a member of a larger family of related cell surface NADH oxidases or ECTO-NOX proteins. Expression of tNOX at the cell surface results from an exon4-minus splice variant mRNA transcript (X. Tang, unpublished). To investigate the mRNA-processing events leading to the splice variant, 3T3 (mouse) and HUVEC (human vascular endothelial) cells were inoculated with SV-40 (ATCC pml-2) and characterized post-infection for tNOX presence at the cell surface by Western blot analysis and presence of drug- (capsaicin)-inhibited NADH oxidase activity, a defining characteristic of tNOX protein. With SV-40-infected 3T3 cells, tNOX was absent on day 3 post-infection but strongly present on day 6 post-infection. With SV-40-infected HUVEC cells, the kinetics of tNOX appearance were similar with 32 kDa and 34 kDa bands indicated by Western blot analysis being absent on day 3 post-infection and increasingly evident on days 5 and 7 post-infection. The SV-40-infected HUVEC cells exhibited proteins cross-reactive with anti-tNOX antibodies at 32 and 34 kDa plus a protein, also cross-reactive with anti-tNOX antibody, corresponding to a previously described INOX-specific protein with a Mr of 52 kDa (Yantiri and Morre, 2001. Arch. Biochem. Biophys. 391:149-159). Control (uninfected) 3T3 and HUVEC cells lacked tNOX presence. The findings suggest that either model system, SV-40-infected 3T3 cells or SV-40-infected HUVEC cells, offer a relatively narrow window post-infection (between day 3 post-infection and days 5 to 7 post-infection) for exon4-minus mRNA initiation and delivery of tNOX to the cell surface. The 3T3 system is presently under investigation to test the involvement of exonic splicing silencer sequence-binding proteins as initiators of the cancer-specific expression of the tNOX protein.
2006 ASCB Annual Meeting Abstracts

IX) and Src (PP2) inhibitors. The cells were then stained for beta-actin and results were quantified via robotic microscopy and an image analysis algorithm optimized for images derived from confluent cell cultures. MDCK cells were exposed to concentrations of the GSK 3 inhibitor IX ranging from 0.6 to 10 micromolar with approx. 1250 cells analyzed per well. GSK inhibitor IX led to a dose-dependent 3.4-fold increase in Total Cytoplasmic Area, a 3.3-fold increase in Total Cytoplasmic Intensity (Z’ = 0.63), and a 1.8-fold increase in Total Nuclear Intensity. For HeLa cells, beta-cell-permeable PP2 increased 2.2-fold by 5 micromolar GSK-3 inhibitor IX. Similarly, Total and Median Nuclear Intensity (MNI) increased 2.6- and 2.3-fold and the ratio Median Nuclear/Median Membrane Intensity was increased 39% at 10 micromolar (Z’ = 0.70). In contrast, 20 micromolar PP2, reduced nuclear beta-actin by 27% and blocked the ability of GSK 3 inhibitor IX to induce nuclear localization of beta-actin. Thus-beta-actin distribution can be quantified utilizing high-throughput/high content microscopy, and Src activity may be essential for Wnt induced nuclear translocation of beta-actin in HeLa cells.

2001

Comprehensive Analysis for the Acquisition of Invasiveness in Mammary Epithelial Cells

S. Hashimoto, S. Wei, A. Hashimoto, K. Miura, H. Sabe; Molecular Biology, Osaka Bioscience Institute, Suita, Japan

Metastases are the major cause of human cancer death and correlate well with invasive properties of the tumors. In the case of primary tumors of the human breast, genome analyses have so far suggested that most of specific genetic alterations in the invasive ductal carcinoma have also been found in the ductal carcinoma in situ, which is apparently non-invasive. Gene expression profiles have also shown that these pathologically discrete stages of breast carcinomas are highly similar at the transcriptosome levels. Therefore, what cellular changes evoke invasive phenomena during progression of human breast carcinomas remains largely unknown. Both hypoxia and epithelial-mesenchymal transition (EMT) have been highly implicated in invasive, as well as metastatic activities of different types of cancer cells. NMuMG mouse mammary gland epithelial cells undergo EMT upon TGFB treatment. We isolated several clones from NMuMG cells, that respond both to TGFB and hypoxia (3% O2) to become highly invasive in a Matrigel chemoinvasion assay. By gene expression profiling of these cells under nonoxia, hypoxia and TGFB-treatment, we identified genes whose expression is common to both TGFB and hypoxia and EMT in mammary epithelial cells as compared with those under normoxia. Among them, we found that expression of NM23-M1, as well as its protein, is drastically downregulated under hypoxia and EMT. Forced expression of NM23-M1 inhibits matrigel invasion of NMuMG cells under hypoxia and EMT. A human homolog of NM23-M1, namely NM23-H1, was previously reported to be a tumor suppressor in melanoma. We will show a mechanism by which hypoxia and EMT commonly downregulate expression of NM23-M1. Our results suggest an aspect in which epigenetic events are deeply involved in processes acquiring invasiveness in breast carcinomas.

2002

A Novel Three-Dimensional Model to Quantitatively Study the Radial and Vertical Invasion of Melanoma

C. M. Gharai, V. Suresh, S. R. Peyton, C. B. Rauh, S. C. George, A. J. Putnam; 1Biomedical Engineering, University of California, Irvine, Irvine, CA, 2Chemical Engineering & Materials Science and Biomedical Engineering, University of California, Irvine, Irvine, CA

Melanoma, which accounts for 80% of all skin cancer deaths, is characterized by the aberrant growth of melanocytes within the epidermis (radial growth phase) and eventual penetration of transformed cells through the basement membrane into the underlying dermis (vertical growth phase). To study this progression and quantify the 3-D invasion of melanoma in vitro, we have developed a 3-D culture system in which cells coated onto microcarrier beads are embedded within a fibrin hydrogel with an over-coated dermal fibroblast monolayer. In particular, beads were coated with human epidermal neonatal melanocytes (HEM), radial growth phase melanoma cells (M14s), or highly metastatic melanoma cells (C8161,9) and observed over a 7-day period to monitor 3-D cell proliferation and penetration into the surrounding matrix. An image processing algorithm developed to quantitatively assess cell invasion revealed that the in vitro invasion of each cell type recapitulated its in vivo phenotype. Specifically, the radial invasion of C8161s was nearly three times greater than M14s, which were over twice as invasive as HEMs. Removing the fibroblast monolayer did not significantly affect C8161 and HEMs invasion, but led to far more aggressive and uncoordinated invasion of M14s. A confocal technique developed to study vertical invasion in this system confirmed that HEMs and M14 invasion remained planar while C8161 vertical penetration, regardless of fibroblast presence, was dramatically more extensive. Similar results were also obtained in matrices containing interstitial type-I collagen, except that the radial invasion of C8161s, in addition to M14s, became uncoordinated in the absence of fibroblasts. Collectively, these data demonstrate the utility of this novel 3-D model of melanoma invasion to quantitatively assess radial and vertical invasion in vitro. This system may be useful to screen the efficacy of pharmacologic inhibitors on melanoma growth, and may provide new mechanistic insights regarding the progression of melanoma.

2003

Evaluation of the Protective Effect of Fish Oil and Selenium on the Lung and Serum of 1,1'-Dimethyl-4,4'-Bipyridinium Dichloride Intoxicated Rats

1,1'-Dimethyl-4,4'-Bipyridinium Dichloride (paraquat) is a broad-spectrum herbicide known to produce lung injury via oxidative stress-mediated mechanisms. Different pharmacological strategies have been explored to reduce the formation of these reactive oxygen species and/or prevent their toxic effects in the treatment of paraquat poisoning. The present study was carried out to investigate the possible protective effects of fish oil (20 mg/kg) and selenium (0.26 mg/kg) against the toxic effects of paraquat. The present study was carried out to investigate the possible protective effects of fish oil (20 mg/kg) and selenium (0.26 mg/kg) against the toxic effects of paraquat. Eighty adults' albino rats were used in this study; they were classified into eight groups. Control, fish oil, selenium, paraquat (10 mg/kg), selenium + fish oil, paraquat + fish oil, paraquat + selenium and paraquat + selenium + fish oil. Selenium and fish oil were given orally for 12 consecutive days and paraquat was given intraperitoneally 24 hours before decapitation of the animals. Fish oil by itself increased lipid peroxidation and HDL-cholesterol markedly, catalase while LDL-cholesterol and triglycerides were decreased. Paraquat increased serum and lung lipid peroxidation and decreased catalase, and glutathione levels. Selenium alone or when it combined with fish oil pretreatments ameliorated these disturbances in prooxidant-antioxidants balance. These results indicate that antioxidant pretreatment prior to paraquat may have some beneficial effects against paraquat-induced lung injury. Also the beneficial effects of fish oil are improved when it provided with selenium.

2004

TRPV1 Induces a p53-dependent Apoptosis of Human Bladder Cancer Cells

R. Luciarrini, C. Amanti, M. Mosca, M. Rabini, S. Caprondi, A. Di Spilimbergo, M. A. Cardarelli, G. Mammana, G. Santoni; 1Experimental Medicine and Public Health, University of Camerino, Camerino, Italy, 2Pathological Anatomy and Cytodiagnostic, ASUR 9, Macerata, Italy, 3Pathological Anatomy and Cytodiagnostic, ASUR 9, Camerino, Italy, 4Urology Operation Unit, ASUR 9, Macerata, Italy

The p53 tumor suppressor gene is the most frequent mutated gene in human cancer. The present study was undertaken to analyse the expression and role of TRPV1 in human normal urothelial cells and bladder TCC lines expressing both p53 wild-type and p53 mutations. Thus, we evaluate by qRT-PCR, the expression of TRPV1 in human RT-4, TCCSUP, J82 and EJ cell lines. As normal control urothelial cells (HUC) and normal bladder tissues were utilized. As evaluated by quantitative real-time PCR analysis, TRPV1 mRNA is up-regulated in low grade, p53 wild-type expressing RT-4 cells, and unchanged or markedly down-regulated in high-grade TCCSUP, J82 and EJ cells harboring p53 mutations. By cytofluorimetric, confocal microscopy and western blot analyses we found that the expression of TRPV1 protein in normal HUC, and RT-4, TCCSUP, J82 and EJ cells, parallels the mRNA expression with low-grade RT-4 cells showing higher expression; in addition TRPV1 protein localizes on the plasma membrane and cytoplasm in RT-4 and TCCSUP cells, whereas negligible or negative TRPV1 expression is found in J82 and EJ cells. The TRPV1 channel is functional in RT-4, but not TCCSUP, J82 and EJ cells, as evaluated by its ability to induce increase of [Ca2+] in response to the TRPV1 agonist, capsaicin (CPS) stimulation. CPS treatment, also reduces in a dose-dependent manner, RT-4, TCCSUP, J82 and EJ cell viability, with RT-4 showing the higher sensitivity. Moreover, CPS exposure induces, increase in PS externalization, caspase-3 activation, Go/G1 subdiploid oligonucleosomal DNA fragmentation and apoptosis on RT-4, but not TCCSUP, J82 and EJ cells. The CPS-induced apoptosis of RT-4 cells, is associated to a time-dependent increase of p53 protein level, and induces p53 phosphorylation at the Ser-15, -20 and -392 residues. Overall, these findings suggest that bladder cancer cells expressing the p53 wild-type and TRPV1 are highly susceptible to CPS-induced apoptosis.

2005

Inhibition of NFkβ by a Novel Curcumin Analogue

A. L. Kasinski, Y. Du, S. Thomas, A. Sun, J. Snyder, D. Liotta, H. Fu; 1Department of Pharmacology, Emory University, Atlanta, GA, 2Graduate Program in Genetics and Molecular Biology, Emory University, Atlanta, GA, 3Graduate Program in Molecular Systems Pharmacology, Emory University, Atlanta, GA, 4Department of Chemistry, Emory University, Atlanta, GA

NFkβ is a transcription factor which is activated in response to various stimuli and has been shown to play a critical role in regulating inflammatory and immune responses. However, constitutive activation of NFkβ has also been associated with the development of various diseases, including cancer. Therefore, there is a need for the development of new and specific inhibitors of NFkβ. In our study, we have developed a novel curcumin analogue which is selectively and effectively inhibits NFkβ. The analogue has been shown to inhibit NFkβ activity at micromolar concentrations and has been shown to be safe in cell-based assays. Our findings suggest that this novel curcumin analogue has potential as a therapeutic agent for the treatment of diseases associated with NFkβ activation.
degradation. The inhibition of IκBα degradation was due to the inability of the inhibitor of kappa B kinase β (IKKβ) to phosphorylate IκBα, suggesting that EF24 may interfere with IKKβ activity. Using recombinant IKKβ and IκBα in an in vitro kinase assay, we show that EF24 but not curcumin effectively inhibited the ability of IKKβ to phosphorylate IκBα. These data suggest NFKB as a major target of EF24. Characterization of such small molecules with low to no toxicity will yield new avenues to explore the treatment of various forms of cancer as well as to unravel additional molecular mechanisms involved in cellular pathways.

Dynamics On Cancer Interrelated P53-MDM2 Feedback Loop Regulated By P19ARF

H. Liu, T. Zhan, Y. Han, Y. Z. Zhao, T. J. Zhao 2, Hebei University of Technology, Tianjin, China, 2China Institute of Atomic Energy, Beijing, China

The p53 tumor suppressor protein plays a key role in preventing the development of cancer and is inactivated in many human malignancies. Because some of the cellular effects of activated p53 can be irreversible, keeping p53 function under tight control in normal cells is critical. A key player in the regulation of p53 is the Mdm2 protein. This duality defines a negative feedback loop, which is widely recognized. P19ARF is another important new tumor suppressor protein, it has its own independent promoter. The P19ARF protein can increase the level of p53 by neutralizing Mdm2 which destabilize p53, ultimately play a role in suppressing cancer. During the years, several models addressing p53 in the context of statistical theories of multistage tumorigenesis have been proposed. We now present a dynamical model of the p53-Mdm2 feedback loop regulated by P19ARF both in individual cell and in population of cells. In our attempt to capture the gross mechanisms of p53-Mdm2 interactions regulated by P19ARF, we have investigated numerically how different parameters can shape the types of behavior that the system can exhibit. In particular, we show that specific assumptions characterizing the interactions between p53 and Mdm2 regulated by P19ARF lead to an oscillatory behavior of p53, Mdm2 and p19 protein levels after a sufficiently strong damage signal. Such oscillation may enable the more effective execution of a reversible p53 response. In agreement with this prediction, the levels of three proteins are proved to satisfactorily fit experimental results reported in lung cancer cells. The dynamical model of cancer interrelated P53-MDM2 feedback loop regulated by P19ARF and its numerical results will help to understand the origin of cancer and oscillatory behavior of p53, Mdm2 and P19ARF more deeply and rationally.

The Human Microneta Mir-21 Modulates Tumor Sensitivity to Chemotheraphy In Vivo by Modulating PTEN Dependent Signaling

R. Henson, F. Meng, H. Wehbe, T. Patel; Scott and White Clinic, Temple, TX

miRNAs (miRNAs) are endogenous regulatory RNA molecules that can mediate gene expression. Increased expression of selected miRNAs such as miR-21 occurs in several types of human cancer. We have recently shown that miR-21 can modulate PTEN expression in human cholangiocarcinoma cells in vitro (Gastroenterology 130(7):2113-29). Altered miR-21 expression could therefore modulate cell survival pathways and contribute to resistance to chemotherapy. Thus, our aim was to assess the role of miR-21 in the regulation of chemoresensitivity in human cholangiocarcinoma in vivo. Mz-Cha-1 human cholangiocarcinoma cell xenografts were established in eight week old male athymic nu/nu lines. Once tumor volume exceeded 200 mm³, mice were injected intra-tumorally (4 ng/mouse tumor) with either anti-miR-21 (n=6) or control anti-miRNA (n=6). The chemotherapeutic agent gemcitabine (120 mg/kg) was administered i.p. every three days for a total of 3 doses, and tumor volumes measured by serial measurements. Tumor growth in response to gemcitabine was decreased by 24-48 ± 12.18 % in xenografts receiving a single injection of anti-miR-21 whereas it was only reduced by 1.34 ± 5.40 % in controls after 10 days. Expression of potential downstream targets of miR-21 was assessed by immunoblot analysis of tumor cell xenograft homogenates. An increase in expression of PTEN along with decreased phosphorylation of Akt was observed in tumors treated with anti-miR-21 compared to controls. Thus, targeting miR-21 dependent signaling pathways may be a useful strategy to improve therapeutic responses for highly treatment refractory tumors such as cholangiocarcinoma. Regulation of PTEN dependent cell survival pathways may represent an important mechanism by which miR-21 modulates tumorigenesis and chemoresistance in cholangiocarcinoma and other cancers.

Modulation of E-cadherin and Actin in Colon Cancer Cells

C. P. Bennett, G. S. Marchetti, A. F. Witts, K. Book, R. Tripathi, S. Parikh; University of the Witwatersrand, Johannesburg, South Africa

During the phase of epithelial to mesenchymal transition (EMT) cancer cells acquire migratory phenotypes and become invasive. Linked to EMTs are changes in cadherin expression and regulation of the actin cytoskeleton. In cell migration/wound assays we show that treatment of human adenocarcinoma HT29 cells with the immunomodulatory drug levamisole, results in the inhibition of cell migration in a dose dependent manner with an associated alteration of cell morphology. As levamisole concentration increased from 0.1 to 5 mM, migration declined. At 5 mM levamisole, the wound edge remained smooth with very little evidence of cell migration. In control cultures, cells migrated extensively and in such cells, confocal microscopy showed cytoplasmic-localisation of E-cadherin and actin in a punctate pattern. However, when cells were cultured with levamisole, E-cadherin was polarised to the cytoplasm to a distinct peri-nuclear cytoplasmic accumulation, with additional nuclear associated E-cadherin expression. In association with increasing concentrations of levamisole (ranging from 0.1 to 5 mM), cells began to lose their typical fibroblast-like morphology, displaying reduced cytoplasmic processes with cytoplasmically localised actin stress fibres. Actin was also associated with the peripheral edges of filopodia. At 5 mM levamisole, cells retracted their cytoplasmic processes and rounded-up, with the distinct formation of cytoplasmic actin stress fibres, and with an actin band around the cell periphery. In the absence of levamisole, control cultures lacked stress fibres and cells retained a fibroblast-like morphology with extensive cellular processes. The changes in cytosolic E-cadherin and cellular actin distribution suggest that levamisole may modulate small Rho-GTPase signalling, thus influencing migratory cell behaviour.

Measurement of Oncoproteins in Preclinical and Clinical Specimens Using a Nano-fluidic High Throughput Approach

Studying changes in oncogene protein expression and activation is increasingly important in the development of molecularly targeted therapeutics. Serial tumor sampling to assess biological endpoints is severely limited by the invasiveness of procedures required to acquire adequate numbers of cells for investigation. Here we demonstrate the use of an automated nano-fluidic system to measure changes in the expression of oncoproteins in preclinical and clinical tumor specimens. We measured the levels of MYC, BCL2, and AKT in serial fine needle aspirates of haematopoietic tumor cell populations obtained from patients with Burkitt’s lymphoma and chronic lymphocytic leukemia. We have previously shown that inactivation of MYC sustains tumor regression using our conditional model of MYC-induced lymphoma. Hence, targeting the inactivation of oncogenes may be useful for the treatment of cancer. Tumor-derived cell lines generated from conditional transgenic mouse models of BCL-2/MYC-induced lymphoma were injected subcutaneously into syngeneic mice. Upon BCL-2/MYC inactivation, serial fine needle aspirations (FNAs) of tumors were performed. Using this technology BCL-2/MYC protein levels were found to decrease in the serial FNAs. This approach was validated by measuring the levels of MYC, BCL2, ERK and AKT proteins in the lymph nodes obtained from patients with Burkitt’s, mantle cell and follicular lymphoma. MYC was overexpressed in Burkitt’s and BCL2 was overexpressed in mantle cell and follicular lymphoma patients. In parallel, traditional Western blots were performed to confirm BCL-2/MYC levels. Thus, we have developed a technique with the ability to quickly assess the levels of key signaling/onco proteins from small preclinical transgenic mouse models and human clinical lymphoma samples. This enables the possibility of monitoring tumor response to targetted therapies. Additionally, this approach has wide applications: (1) high throughput strategy for preclinical characterization of tumors (2) clinical analysis of tumor specimens and (3) for use in molecular diagnostic assays to improve the treatment of cancer.
2010
Caspase-6 in Alzheimer Disease
A. C. LeBlanc, S. Albrecht, T. Petzke; Pathology, McGill University, Montreal, PQ, Canada

While amyloid and neurofibrillar tangles have been widely investigated in Alzheimer disease, relatively little is known about the underlying molecular mechanisms of cell death and degeneration in these brains. Using neuropilhepros for the active p20 subunit of Caspase-6 and to Tau protein cleaved by Caspase-6, we have identified strong activity of Caspase-6 in senile plaques, neurulps and neurofibrillar tangles in hippocampal from mild, moderate, severe and very severe Alzheimer disease individuals. Interestingly, Caspase-6 activity is already present and strong in the entorhinal cortex of mildly cognitively impaired aged individuals. In contrast, there is no active Caspase-6 in the hippocampi from young individuals. The neurons that are affected do not display the morphological characteristics of apoptotic cells. A proteomic study of caspase-6-mediated cleavage of neuronal proteins indicated thirty-three proteins proteolysed by the addition of active Caspase-6 in cytosolic or membrane proteins from primary cultures of human neurons. Thirty percent of these proteins represent cytoskeleton or cytoskeleton-associated proteins. Drehem, an actin-binding protein of post-synaptic densities, and alpha-tubulin, are both directly cleaved by active Caspase-6 in vitro. These results indicate that Caspase-6 could alter learning and memory through the disruption of the neuronal cytoskeleton very early in Alzheimer disease.

2011
Tau Redistribution, Truncation and Colocalization with Tubulin Accompanies Dendritic Degeneration in an In Situ Cellular Model of Tauopathy
W. Kim, C. Jung, G. F. Hall; Biological Sciences, U. Mass. Lowell, Lowell, MA

Drosophila Giant neurons (ABCs) in the brain of the larval sea lamprey that have been microinjected with plasmids expressing human tau (htau) isoforms accumulate filamentous tau aggregates and undergo neurofibrillary degeneration in a manner similar to that seen in human familial tauopathies and Alzheimer's Disease. We have used this model to investigate the cellular mechanisms underlying the neurodegeneration induced by abnormal accumulation of htau. In particular, we have focused on the progressive distal to proximal dendritic degeneration that occurs with prolonged (10–40+ days) of htau expression. In this study, we expressed the longest htau isoform (tau40) containing the P301L mutation in ABCs for 10, 20 and 30 days post plasmid injection (ppi). Ten micron sections through htau-expressing cells were co-labeled with a mAb (tau 12) specific for the htau N terminal and a mAb (C3) specific for the tau species truncated at residue 420. Other sections were co-labeled with tau1 (the mAb specific alpha tubulin (D1M1A). We show that tubulin levels are progressively reduced over time in htau-expressing ABCs, while dendritic beading and fragmentation are accompanied by the co-localization of tubulin and htau in perineuronal aggregates. In addition, we found that 420-truncated htau (C3 tau) was generated in most htau-expressing cells by 20 days ppi. C3 tau was particularly prominent in high density htau deposits in ABC dendrites and axons. In summary, we identify changes in dendritic tubulin and htau distribution that are correlated with dendritic degeneration in an in situ cellular model of htau-induced neurofibrillary degeneration. We also show that these changes are associated with the C terminal truncation of overexpressed htau, which recent studies suggest may be a key event in the generation of filamentous htau. Further studies of this model thus appear likely to shed light on the cellular mechanisms underlying human tauopathies.

2012
Pre-fibrillar β-Amyloid Leads to Tau Dependent Microtubule Disassembly in Neuronal and Non-Neuronal Cells
M. E. King, H. Kan, P. Bazz, A. Eris, C. G. Gable, G. S. Bloom; Biology, University of Virginia, Charlottesville, VA, Neurobiology and Anatomy, Drexel University College of Medicine, Philadelphia, PA, Psychology, University of Virginia, Charlottesville, VA, Molecular Biology and Biochemistry, University of California at Irvine, Irvine, CA

Alzheimer’s Disease (AD) is defined histopathologically by extracellular β-amyloid (Aβ) fibrils plus intraneuronal tau filaments. Studies of transgenic mice indicate that AD is caused by a pathological cascade in which Aβ lies upstream of tau, but that the steps which connect Aβ to tau have remained undefined. To seek evidence for how Aβ signals to tau, various forms of Aβ were provided extracellulary to primary neurons that expressed endogenous tau or were treated with siRNA to suppress tau protein levels to ~5% of normal, or to non-neuronal cells that co-expressed tau-CFP plus GFP-tubulin. To assay effects of the Aβ, the neurons were analyzed by a quantitative biochemical assay for polymerized and unassembled tubulin, and the non-neuronal cells were monitored by live cell, time lapse fluorescence microscopy. For both cell types, we found that tau confers acute hypersensitivity of microtubules to pre-fibrillar Aβ, which comprises monomers and small oligomers of β-amyloid peptides. Pre-fibrillar Aβ42 was active at submicromolar concentrations, several-fold below those required for equivalent effects of pre-fibrillar Aβ40, and microtubules were insensitive to fibrillar Aβ. Microtubule disassembly typically occurred abruptly within 1.5 hours of exposing cells to pre-fibrillar Aβ, and transfection of non-neuronal cells with fluorescently tagged MAP2C, MAP2C-tau chimeras and tau fragments established that the active region of tau is localized to an N-terminal domain that does not bind microtubules and is not part of the region of tau that assembles into filaments. Surprisingly, tau-dependent microtubule disassembly induced by pre-fibrillar Aβ was not accompanied by AD-like phosphorylation of tau. Taken together, these results highlight the most dramatic, rapid and sensitive link between Aβ microtubules and is not part of the region of tau that assembles into filaments. Surprisingly, tau-dependent microtubule disassembly induced by pre-fibrillar Aβ was not accompanied by AD-like phosphorylation of tau. Taken together, these results highlight the most dramatic, rapid and sensitive link between Aβ microtubules and is not part of the region of tau that assembles into filaments. Surprisingly, tau-dependent microtubule disassembly induced by pre-fibrillar Aβ was not accompanied by AD-like phosphorylation of tau. Taken together, these results highlight the most dramatic, rapid and sensitive link between Aβ microtubules and is not part of the region of tau that assembles into filaments. Surprisingly, tau-dependent microtubule disassembly induced by pre-fibrillar Aβ was not accompanied by AD-like phosphorylation of tau. Taken together, these results highlight the most dramatic, rapid and sensitive link between Aβ microtubules and is not part of the region of tau that assembles into filaments. Alcadein, a Novel Cargo Receptor to Kinesin I, Regulates APP Metabolism
T. Suzuki, Y. Araki, T. Yamamoto, T. Kawano, M. Kinjo; Graduate School of Pharmaceutical Sciences, Laboratory of Neuroscience, Hokkaido University, Sapporo, Japan, *Research Institute for Electric Science, Hokkaido University, Sapporo, Japan

Amyloid b-protein (Ab) is generated by consecutive cleavages of APP with BACE and g-secretase complex, and aggregation and deposition of Ab are closely related to Alzheimer’s disease (AD) pathology. APP in neuron forms a tripartite complex with Alcadein (Alc), a type I membrane protein similar to APP, through their cytoplasmic interaction with the adaptor X11-like protein (X11L). Formation of a tripartite APP/X11L/Alc complex stabilizes intracellular metabolism of both APP and Alc. When X11L dissociates from the complex, APP and Alc are simultaneously cleaved in a coordinated fashion. Thus, naked APP generates Ab (or p3) and naked Alc generates b-Alc peptide. We therefore considered a possibility that Alc may be similar to APP in function as well as its metabolism. We found that Alc directly associates to KLC of kinesin I motor, assembles the motor complex, and drives cargo to neuron terminals functioning as a novel cargo receptor. The transport of Alc cargos compete with that of APP-containing vesicles for the kinesin I motor, and disruption of APP-containing vesicle transport increase Ab generation. It is known that APP interacts with kinesin I through JIP1b, but in vivo, Alc transport is largely independent of APP with different transport velocities. Thus, APP and Alc are separately transported to nerve-terminal, and then exposed on the plasma membrane. The three proteins, APP, X11L, and Alc may form a complex either prior to leaving the Golgi apparatus, at the plasma membrane, or during the endocytic process. Inappropriate connection of APP- and Alc-containing vesicles to kinesin I motor suggested in Alzheimer generation, suggesting vesicular transport system regulated by kinesin I motor with Alc and JIP1b is important for the physiologic metabolism of APP and Alc.

Involvement of Phosphatidyl Serine as a Surface Membrane Receptor for the Alzheimer’s Disease Aβ Peptide
O. Simakova, N. J. Arispe; Anatomy, Physiology and Genetics, Uniformed Services University, Bethesda, MD

The toxic effect of exogenous Aβ on cells is initiated when Aβ directly interacts with components in the plasma membrane resulting in disruption of the membrane permeability. The interaction of Aβ with the membrane is selective to some cells, and to cells on specific regions of the Alzheimer Disease brain, suggesting that membrane components may be acting as receptors for Aβ. The identity of a membrane receptor for Aβ has been a quest for many years. Several candidates cell surface receptors have been considered, but recent works and our own preliminary results, have provided information implying the phospholipids phosphatidylserine (PS) as one of the possible membrane surface receptors. To provide irrefutable data supporting this finding different types of cells lines and ex-vivo neurons were exposed to fluorescent annexin V and to Aβ and sorted with Facs/Aria/BD cell sorter on the basis of their surface membrane Aβ binding. We found that cells within the same cell line can successfully be grouped and sorted in subpopulations based in their affinity for Aβ. These subpopulations of cells showed distinct morphological and compositional characteristic. The degree of cell affinity for Aβ binding suffered of a much higher induction of apoptosis when exposed to Aβ. We concluded that these distinct cell indicators may be the basis for the selective attack of Aβ on some cells in culture, and also observed on cells in specific regions of the AD brain.

2018

Cellular Indicators Correlated with the Cell Specific Binding and Cytotoxic Levels of the Alzheimer’s Aβ Peptide
O. Simakova, N. J. Arispe; Anatomy, Physiology and Genetics, Uniformed Services University, Bethesda, MD

Despite the Aβ peptide normal existence in healthy individuals, abundant evidence has shown that external application of Aβ on cells, either in cell cultures or in animal brains, has toxic effects. However, in Alzheimer’s disease Aβ selectively attacks on specific regions of the brain, and experiments in vitro show that not all cells within the same cell line are equally affected by external addition of Aβ, and some cells are even found to be resistant. To study this phenomenon we characterized specific features and stages of the cells that make them exceptionally sensitive or resistant to the effect of Aβ. Different types of cells lines and ex-vivo neurons were exposed to Aβ conjugated to a fluorescent probe (Aβ-FITC), and sorted with Facs/Aria/BD cell sorter on the basis of their surface membrane Aβ binding. We found that cells within the same cell line can successfully be grouped and sorted in subpopulations based in their affinity for Aβ. These subpopulations of cells showed distinct morphological and compositional characteristic. The degree of cell affinity for Aβ correlated with the levels of phosphatidylserine on the cell membrane surface and the cell cycle stage. The sorted subpopulations of cells with higher affinity for Aβ binding observed after externalizing PS with the apoptosis inducer camptotecin, and by the increased Aβ-induced mortality and LDH release on sorted cells with higher surface PS. The selectivity of the Aβ binding to surface PS was confirmed with anti-PS antibody. Our data convincingly confirm the involvement of PS as a membrane receptor for Aβ.

Coordination with the Histidines Residues in the Aβ Molecule Affects Aβ Channel Activity and Cytotoxicity
J. C. Diaz, N. J. Arispe; Anatomy, Physiology and Genetics, Uniformed Services University, Bethesda, MD

The Aβ peptide associated with Alzheimer’s disease interacts with neurons to generate a potentially toxic increase in the intracellular calcium concentration. We have shown that the mechanism of the intracellular calcium increase is by the Aβ peptide itself forming an independent ion channel that conducts the calcium into the cell, disturbing the intracellular homeostasis. We recently showed that peptide segments, chosen from regions around the putative mouth of the polymeric membrane-bound Aβ channel model, effectively block the Aβ channel activity in planar lipid bilayers. We also showed that the presence of histidine residues in these peptides were essential for blocking the channel and for blocking Aβ cytotoxicity. We proposed that coordination between adjacent histidine-containing compounds and histidines in these peptides might have been established, thus blocking the entrance of the pore, the flow of current through the channel, and consequently blocking Aβ cytotoxicity. To test this proposition we studied the effect of compounds that potentially coordinate with the histidines in the Aβ molecule, on the activity of Aβ channels formed in the surface membrane of cells. Nickel ions, the histidine-reactive chain imidazole and a series of histidine-related compounds were studied on Aβ ion channels incorporated into planar lipid bilayers and on cells in culture exposed to Aβ. The results showed that the efficiency of these compounds to block the Aβ current activity in planar lipid bilayer was correlated with their capacity to react with the histidine residues in Aβ. This reactivity was also correlated with the magnitude of the prevention of cell surface membrane and mitochondrial disruption induced by Aβ. These data provide further evidence that not only the interaction with histidine residues are essential for blocking the Aβ channels, but that the Aβ ion channel activity contributes significantly to the cytoxic properties of exogenous Aβ.

In Situ Aβ Pores in Neurons in the Brain with Alzheimer’s Disease: Ultrastructural Demonstration
S. Inoue; Anatomy and Cell Biology, McGill University, Montreal, PQ, Canada

According to the amyloid pore hypothesis, pores formed in the membrane by small oligomers of misfolded amyloidogenic proteins cause unregulated rapid influx of ions such as calcium ions which interferes with intracellular ion homeostasis resulting in cell death. Pores of various amyloid proteins have been reconstituted in vitro in lipid bilayer membranes and their ultrastructural features were examined by transmission electron microscopy (TEM) or atomic force microscopy. However, the presence of in situ amyloid pores in amyloid tissues has not yet been ultrastructurally demonstrated. In this study the attempt was made to ultrastructurally identify in situ pores of β amyloid protein (Aβ) in vivo with TEM in the neuronal cell membrane in the brain of patients with Alzheimer’s disease. Within the tissue of β amyloid all unbound Aβ identified by immunolabeling, was localized in the form of 2-3 nm wide helices (“helical rods”) formed by the tight coiling of 1 nm wide Aβ filaments. In the cell membrane of neurons the pore-like structures were randomly distributed. They were round entities of the diameter of 16 nm with a rim of the thickness of 3 nm and a 10 nm wide lumen. The rim was made up of a cylindrical sheet of laterally associated Aβ helical rods 11 nm in length. Since no other pore-like structures were found in the membrane it is proposed that these 16 nm wide short columnar structures perforating the cell membrane are toxic Aβ pores. Also, since Aβ helical rods were the only conformation taken by unbound Aβ, it is proposed that this characteristic helical conformation is the ultrastructural representation of misfolded Aβ. Thus, the demonstration of the presence of in situ Aβ pores in this study in the amyloid tissue would further strengthens the amyloid pore hypothesis for the mechanism of β amyloid pathogenesis.

Seeding of Neuritic Plaques by Oligomeric Amyloid-β That Accumulates in Cortical and Hippocampal Projections of Brainstem Neurons: A Hypothesis
Z. Muresan, V. Muresan; Physiology and Biophysics, Case Western Reserve University, Cleveland, OH

2006 ASCB Annual Meeting Abstracts

371
Our goal is to understand the pathogenesis of amyloid-β (Aβ) deposition in the Alzheimer's disease (AD) brain. It is thought that neuritic plaques that form in the hippocampus and cerebral cortex are initiated by a “bad seed” of oligomized Aβ, but the origin of this seed is unknown. We established a cell culture system, where brainstem-derived, catecholaminergic, neuronal cells (CAD) produce and accumulate within their processes large amounts of Aβ peptide, similar to what is believed to occur in brain neurons, in the initial phases of AD. Using this system, we show that accumulation of Aβ begins within neurites, prior to any detectable signs of neurodegeneration. Neuritic accumulation of Aβ is restricted to a small population of neighboring cells that express normal levels of amyloid-β precursor protein (APP), but show redistribution of β-secretase to the processes, where it co-localizes with Aβ and markers of late endosomes and autophagic vacuoles. Invariably, cells that accumulate Aβ appear in isolated islets, suggesting their clonal origin from a few cells that show propensity to accumulate Aβ. We further show that, unlike cultured cortical and hippocampal neurons, the brainstem-derived CAD cells accumulate oligomized Aβ primarily at the terminals of their processes. Since brainstem neurons innervate many brain regions, including the cerebral cortex and the hippocampus, they could provide the “bad seed” that nucleates plaques. These results suggest that Aβ accumulation is initiated in a small number of brainstem neurons by intracellular determinants that alter APP metabolism. We propose that plaque formation in the cerebral cortex and hippocampus is seeded by oligomized Aβ that accumulates at the terminals of projections of such brainstem neurons. CAD cells appear to recapitulate the biochemical processes leading to Aβ deposition, thus providing an experimental in vitro system for studying the molecular pathobiology of AD.

Development of a Human Model System for the Study of Axonal Transport Defects
R. L. Nolan, J. D. Filippin, E. A. Davis, L. S. Goldstein; University of California—San Diego, La Jolla, CA
Recent work from our lab suggests that defects of individuals affected by Alzheimer's disease (AD) are likely to contain axonal defects. These defects are enhanced in Drosophila (Gunnawarden & Goldstein 2001) and mouse (Stokin et al 2003) AD models expressing reduced levels of the microtubule-based motor protein kinesin-1. To model these defects in human cells, we generated human embryonic stem cell (hESC) lines with Cre-regulatable RNA interference against the kinesin-1 subunit KLC1 (kinesin light chain 1). We transduced HUES9 hESC with lentivirus packaged to carry Cre-dependent expression of a small hairpin RNA sequence directed against KLC1. We then isolated and propagated individual colonies containing infected cells and characterized their progeny. We are now using these cell lines to reduce kinesin levels and to model cellular transport defects in human neurons differentiated in vitro.

Pathological Consequences of VCP-Mutations on Human Striated Muscle: Nuclear and Cytoplasmic Inclusions, a Distinct Form of Dilatative Cardiomyopathy, and a Novel Link to VCP-Glycoprotein Interactions
C. U. Hübers,1 A. Hofmann,2 A. Bödicker,1 D. R. Thal,4 R. Schröder,4 C. S. Clemen1; 1Institute of Biochemistry I, University of Cologne, Cologne, Germany, 2Institute of Structural and Molecular Biology, University of Edinburgh, Edinburgh, United Kingdom, 3Department of Neuroproteomics, Max-Delbrück-Center for Molecular Medicine, Berlin, Germany, 4Institute for Neuropathology, University Hospital Bonn, Bonn, Germany
Mutations in the valosin containing protein (VCP, p97) gene cause a late-onset form of autosomal dominant Inclusion Body Myopathy associated with Paget disease of the bone and Frontotemporal Dementia (BMPF/D). VCP is an ubiquitously expressed member of the AAA-ATPase family with a tripartite structure comprising an N-terminal (Cdc48) domain involved in ubiquitin-binding, and two central D1- and D2-domains which hydrolyse ATP. VCP assembles into functional hexamers with a central cylinder formed by the D-domains surrounded by the N-domains. VCP has been associated with a wide variety of essential cellular processes including the ubiquitin proteasome protein degradation system and along with its co-factors Ufd1, Npl4, and Derlin-1 with the endoplasmic reticulum associated protein degradation (ERAD). We report on the pathological consequences of three heterozygous VCP-mutations (R93C, R155H, R155C), located in the N-terminal Cdc48 domain of the VCP protein) on human striated muscle in vivo and in vitro. IBMPF/D skeletal muscle pathology is characterized by degenerative changes and filamentous VCP- and ubiquitin-positive cytoplasmic and nuclear protein aggregates. Furthermore, mutant VCP leads to a novel form of dilatative cardiomyopathy with inclusion bodies. In contrast to post-mitotic striated muscle cells aggregate proteinopathy was neither detected in primary IBMPF/D myoblasts nor in transiently and stably transfected cells using wildtype-VCP and the VCP mutants. Pull-down experiments showed that all three VCP mutations do not affect the binding to Ufd1, Npl4, and ataxin-3. Structural analysis demonstrated that R93 and R155 are both surface-accessible residues located in the center of cavities that may enable ligand binding. Mutations at R93 and R155 are predicted to induce changes in the tertiary structure of the VCP protein. The search for putative ligands to the R93 and R155 cavities resulted in the identification of cyclic sugar compounds providing a novel link to VCP carbohydrate interactions in the complex pathology of IBMPF/D.

CMT1A Neuropathies Caused by Partial Duplication of 17p11.2-p12 Region
J. S. Yu,1 J. K. Kim,1 B. O. Choi,2 K. Chung1; 1Biological Science, Kongju National University, Kongju, Republic of Korea, 2Neurology, Ewha Womans University, Seoul, Republic of Korea
Charcot-Marie-Tooth disease (CMT) is the most common motor and sensorimotor peripheral neuropathy. Tandem duplication of chromosome 17p11.2-p12 including PMP22 gene is the most frequent cause of CMT1A. It has been suggested that the mechanism of CMT1A duplication is remarkably uniform, however, two CMT1A families (FC85 and FC116) with partial duplication were identified as rare cases. The microsatellite genotyping analysis suggests that the proximal part of 17p11.2-p12 region which includes the PMP22 gene was partially duplicated in both families. These partial duplications were also confirmed by real-time PCR. It appears that this first (FC85 family) had a de novo mutation of paternal origin due to intrachromosomal rearrangement at meiosis. The other case was also regarded to be caused by intrachromosomal rearrangement between sister chromatids. Thus, it appears that the partial duplications might occur by a different mechanism from the general mechanism of duplication due to the interchromosomal unequal crossover during meiosis. The electrophysiological and MRI patterns of affected individuals with partial duplications were typical of CMT type 1 with somewhat mild tendency. The exact position of the duplication junction and the cytogenetic mechanism should be determined by further analysis.

In Vitro Efficacy and In Vivo Pharmacokinetic Studies with BLX-1060, a New Chemical Entity with Anti-IL-12 Activity
A. P. Sen, A. Mukherjee, A. Nag, D. Dey, P. Neogi, B. Nag; Bexel Pharmaceuticals, Union City, CA
BLX-1060 is a small molecule and hydroxamic acid derivative. It does not show any cytotoxicity in hepG2 and human peripheral blood mononuclear cells (hPBMC) at 100 μM concentration. Here we report on its anti-inflammatory property as an inhibitor of IL-12, a biomarker for inflammatory bowel disease (Ulcerative colitis and Crohn’s disease), in in vitro cell-based assays and in vivo pharmacokinetic studies in rats. In in vitro cell based assays, BLX-1060 inhibited IL-12p40 increase in hPBMC cells and in mouse peritoneal macrophages by 40%. BLX-1060 also inhibited anti-CD40L induced IL-12 mRNA by 20% and IFN-g by 40%. For the pharmacokinetic study, BLX-1060 was administered at 100 and 200 mg/kg, PO, and 10 mg/kg, IV to male rats. Blood was collected at predetermined time points for up to 24 hours. Plasma was obtained from blood and analyzed with LC-MS. The table below gives the pharmacokinetic parameters. BLX-1060 also inhibited anti-CD40L induced IL-12 mRNA by 20% and IFN-g by 40%. For the pharmacokinetic study, BLX-1060 was administered at 100 and 200 mg/kg, PO, and 10 mg/kg, IV to male rats. Blood was collected at predetermined time points for up to 24 hours. Plasma was obtained from blood and analyzed with LC-MS. The table below gives the pharmacokinetic parameters. Zebrafish, an In Vivo Model for Screening of Whitening Agents

T. Choi, J. Kim, E. Jeon, C. Kim, J. Lee, K. Kim, T. Yoon; 1Department of Dermatology, School of Medicine, Chungnam National University, Daejeon, Republic of Korea, 2Department of Dermatology, Gyeongsang National University College of Medicine, Jinju, Republic of Korea

Although it is an aquatic animal, zebrafish has most of organs and tissues that can be seen in human, such as heart, kidney, pancreas, bones and cartilage. Especially, it has pigments in the epidermal portion, giving colors on the surface of organism. Therefore, it can be used as a phenotype-based screening model for whitening agents. We tested the effect of several candidate materials on the pigmentation of zebrafish embryo, in a 96-well platform. The chemicals tested include arbutin, kojic acid, ascorbic acid, 2-mercaptobenzothiazole, salicylhydroxamic acid, and tranylcypromine. Our results showed that arbutin, kojic acid, 2-mercaptobenzothiazole decreased the pigmentation of zebrafish embryo. To identify molecular target modulated by whitening agents, we performed whole-mount in situ hybridization with various pigmentation markers, including nacre/mif and sox10. In addition, we determined the effects of whitening agents on the melanin content and tyrosinase activity. This study is the first approach to validate the feasibility of screening model for whitening agents using zebrafish.

Ultrastructure of Hepatoma Cells Following Administration of Orthovanadate

W. A. Dabros; Department of Pathomorphology, Jagiellonian University MC, Krakow, Poland

This study presents the investigation of the effect of sodium orthovanadate (V(IV)) - in the range of 0.5-20.0 mM - on the rat hepatoma cell line H35-19. The cells were tested with crystal violet and counted in a Bürker chamber to determine their rate of proliferation, while the survival level was established with neutral red and MTT [methylthiazolyltetrazo]. We found a progressive growth inhibition of rat hepatoma cell line H35-19 within the range of 0.5-20.0 mM Na3VO4. At the concentration of 5 mM Na3VO4 in the medium, the majority of the investigated cells showed approximately a 50% inhibition of proliferation and reduction of viability (c. 40%). As compared with metavanadate or vanadyl sulphate and especially organic vanadium derivatives previously studied by us in similar experimental conditions, the obtained effect was intermediate. The results were confirmed with electron microscopic examinations. For electron microscopy observation the cells were centrifuged at 400 rpm for 5 min and 4% solution of glutaraldehyde in incubation medium was added for fixation, next cell were processed in standard way. Cells exposed to sodium orthovanadate demonstrated different appearance than control hepatoma cell line H35-19. They become better differentiated. The vanadium compounds have toxic influence on the cells. Thus in groups with high concentration of orthovanadate only single cells survived. The cytoplasm of the surviving cells was rather scant, what may suggest that the cells were young, but they already contained numerous myelin-like structures originating from degraded membranous structures, pleomorphic condensed mitochondria and infrequent, narrow canaliculi of the rough endoplasmic reticulum. We can to conclude: Orthovanadate affects the rate of proliferation of rat hepatoma cells cultured in vitro. The compound seems to normalize the structure of liver hepatoma cell line H35-19. The structure of the orthovanadate treated cells is similar to the structure of control hepatoma cell line H35-19. However, orthovanadate is less toxic.

Inhibition of Platelet Aggregation by Anthrax Edema Toxin

S. Alam, M. Gupta, R. Bhatnagar; Center for Biotechnology, Jawaharlal Nehru University, New Delhi, India

Edema toxin is a key virulence determinant in anthrax pathogenesis that causes potentiation of cAMP inside host cells. This exotoxin has been implicated in facilitating bacterial invasion by impairing host defenses. Here, we report for the first time that edema toxin plays an important role in suppression of platelet aggregation; an effect that could be of vital significance in anthrax. We tested the effect of several candidate materials on the pigmentation of zebrafish embryo, in a 96-well platform. The chemicals tested include arbutin, kojic acid, ascorbic acid, 2-mercaptobenzothiazole, salicylhydroxamic acid, and tranylcypromine. Our results showed that arbutin, kojic acid, 2-mercaptobenzothiazole decreased the pigmentation of zebrafish embryo. To identify molecular target modulated by whitening agents, we performed whole-mount in situ hybridization with various pigmentation markers, including nacre/mif and sox10. In addition, we determined the effects of whitening agents on the melanin content and tyrosinase activity. This study is the first approach to validate the feasibility of screening model for whitening agents using zebrafish.

Characterization of Histidine 351 mutants of Bacillus anthracis Adenylate Cyclase

M. Gupta, S. Alam, R. Bhatnagar; Center for Biotechnology, Jawaharlal Nehru University, New Delhi, India

Edema factor (EF) is a calmodulin-dependent adenyl cyclase (AC) secreted as one of the primary exotoxins by Bacillus anthracis. We introduced mutations in histidine residue at position 351 of full-length EF. Various studies enunciate an indirect role of this residue in catalysis. Alanine (H351A), asparagine (H351N) and phenylalanine (H351F) variants of this residue were constructed with the objective of carrying out comprehensive biochemical, biophysical and toxicity studies. Spectral analysis of variants displayed no gross structural deformities. Kinetic analysis showed that AC activity of H351N and H351F decreased 34- and 40-fold respectively whereas H351A completely lost activity. Kinetic constants for ATP, pH activity profiles and especially organic vanadium derivatives previously studied by us in similar experimental conditions, the obtained effect was intermediate. The results were confirmed with electron microscopic examinations. For electron microscopy observation the cells were centrifuged at 400 rpm for 5 min and 4% solution of glutaraldehyde in incubation medium was added for fixation, next cell were processed in standard way. Cells exposed to sodium orthovanadate demonstrated different appearance than control hepatoma cell line H35-19. They become better differentiated. The vanadium compounds have toxic influence on the cells. Thus in groups with high concentration of orthovanadate only single cells survived. The cytoplasm of the surviving cells was rather scant, what may suggest that the cells were young, but they already contained numerous myelin-like structures originating from degraded membranous structures, pleomorphic condensed mitochondria and infrequent, narrow canaliculi of the rough endoplasmic reticulum. We can to conclude: Orthovanadate affects the rate of proliferation of rat hepatoma cells cultured in vitro. The compound seems to normalize the structure of liver hepatoma cell line H35-19. The structure of the orthovanadate treated cells is similar to the structure of control hepatoma cell line H35-19. However, orthovanadate is less toxic.

2034 The Cytosplasmic Tail of Polycystin-1 Functions as a Switch between the Stat1 and Stat6 Pathways to Regulate Proliferation in Renal Epithelial Cells

S. Mukherjee, S. Vasanth, S. Low, T. Obara, M. Kinter, T. Weimbs, 1Department of Molecular, Cellular, and Developmental Biology, University of California Santa Barbara, Santa Barbara, CA. 2Department of Medicine, MetroHealth Medical Center, Case Western Reserve University, Cleveland, OH. 3Department of Cell Biology, The Cleveland Clinic, Cleveland, OH.

Autosomal-dominant polycystic kidney disease (ADPKD) is caused by mutations in polycystin-1 (PC1), a large membrane protein of uncertain function. We show that polycystin-1 plays a major role as a regulatory switch between STAT1 and STAT6 pathways. The cytosplasmic tail of PC1 is proteolytically cleaved and undergoes nuclear translocation. The cleaved, complete tail or the C-terminal half alone stimulate STAT6 transcriptional activity in response to activation of IL-4 receptors. A fragment corresponding to the C-terminal half of the PC1 tail is highly expressed in ADPKD kidney tissues but not in normal tissues. Expression of the PC1 tail alone or activation with IL-4 stimulate proliferation in MDCK cells. The PC1 tail also regulates STAT1 activity but by two different modes. The membrane-anchored PC1 tail - but not the cleaved tail - directly activates STAT1. The cleaved tail, however, dramatically stimulates STAT1 activity in response to IFN-γ activation. This stimulation requires the full-length PC1 tail and does not occur with the C-terminal half. Inhibitor studies suggest that Jak3 is the major regulator of the PC1 mediated STAT1 and STAT6 pathways. These results suggest that PC1 acts as a switch between STAT1 and STAT6 activity. Uncloned PC1 provides a constitutive STAT1 signal. In contrast, the cleaved PC1 tail sensitizes renal epithelial cells to input from cytokines, providing a STAT6-mediated proliferative signal in response to IL-4 and a STAT1-mediated anti-proliferative signal response to IFN-γ. We propose that abberant proliferative signaling is involved in renal cyst growth in ADPKD.

2035 Activation of Polycystin-2 (or Pkd2) through Mammalian Diaphanous 1 (mdia1)-dependent Voltage Gating

C. Bai, S. Kim, L. Tsiokas; Cell Biology, University of Oklahoma, Oklahoma City, OK.

Autosomal dominant polycystic kidney disease (ADPKD) is one of the most common genetic diseases affecting 1 in every 400 to 1,000 individuals. Polycystin-2 or Pkd2 belongs to the transient receptor potential family of ion channels. Mutations of polycystin (PC) 1 or 2. However, the mechanisms that trigger cyst formation in ADPKD are still unclear. We have found that tumor necrosis factor-alpha (TNF-α), an inflammatory cytokine abundant in cyst fluid, plays an important role in promoting cystogenesis. TNF-α induces the production of a scaffold protein, FIP2, which interacts with the C-terminus of PC2 and recruits PC2 into an aberrant complex with a Rab GTPase. This prevents the correct localization of PC2 to the plasma membrane and the cilium and leads to disruption of the PC1-PC2 complex, a receptor-calcium channel complex in the primary cilia that responds to fluid flow stimulation. Directly supporting a role for TNF-α in cyst formation, we found that treatment of mouse embryonic kidney organ cultures with TNF-α results in formation of cysts, and this effect is enhanced with embryonic kidneys heterozygous for Pkd2, but not Pkd1 null mutations. Furthermore, analysis of human kidney cysts fluids revealed a correlation of TNF-α production with disease progression. Additionally, the levels of FIP2 and TNF-α receptor are significantly elevated in cystic kidney subtypes. These results indicate that TNF-α secreted in response to cyst-forming stimuli is a key factor in cyst formation in ADPKD.

2036 Alterations in Wnt/wg Gene Signaling in Cell Lines with Mutations in Polycystin-1

Department of Medicine/Nephrology, Indiana University School of Medicine, Indianapolis, IN.

Autosomal dominant polycystic kidney disease (ADPKD), a common hereditary disorder characterized by cystic dilation of the kidney tubules, results from heterozygous mutations affecting polycystin (PC) 1 or 2. However, the mechanisms that trigger cyst formation in ADPKD are still unclear. We have found that tumor necrosis factor-alpha (TNF-α), an inflammatory cytokine abundant in cyst fluid, plays an important role in promoting cystogenesis. TNF-α induces the production of a scaffold protein, FIP2, which interacts with the C-terminus of PC2 and recruits PC2 into an aberrant complex with a Rab GTPase. This prevents the correct localization of PC2 to the plasma membrane and the cilium and leads to disruption of the PC1-PC2 complex, a receptor-calcium channel complex in the primary cilia that responds to fluid flow stimulation. Directly supporting a role for TNF-α in cyst formation, we found that treatment of mouse embryonic kidney organ cultures with TNF-α results in formation of cysts, and this effect is enhanced with embryonic kidneys heterozygous for Pkd2, but not Pkd1 null mutations. Furthermore, analysis of human kidney cysts fluids revealed a correlation of TNF-α production with disease progression. Additionally, the levels of FIP2 and TNF-α receptor are significantly elevated in cystic kidney subtypes. These results indicate that TNF-α secreted in response to cyst-forming stimuli is a key factor in cyst formation in ADPKD. We propose that abberant proliferative signaling is involved in renal cyst growth in ADPKD.

2037 Control of Polycystin 2 Trafficking by Tumor Necrosis Factor-Alpha: A Potential Epigenetic Genetic Switch for Autosomal Dominant Polycystic Kidney Disease

X. Li, W. Bosi, B. S. Magenheimier, S. Xia, D. Wallace, J. Calvet, R. Li.

Stowers Institute for Medical Research, Kansas City, MO. 2Children's Hospital and Harvard Medical School, Boston, MA.

Autosomal dominant polycystic kidney disease (ADPKD), a common hereditary disorder characterized by cystic dilation of the kidney tubules, results from heterozygous mutations affecting polycystin (PC) 1 or 2. However, the mechanisms that trigger cyst formation in ADPKD are still unclear. We have found that tumor necrosis factor-alpha (TNF-α), an inflammatory cytokine abundant in cyst fluid, plays an important role in promoting cystogenesis. TNF-α induces the production of a scaffold protein, FIP2, which interacts with the C-terminus of PC2 and recruits PC2 into an aberrant complex with a Rab GTPase. This prevents the correct localization of PC2 to the plasma membrane and the cilium and leads to disruption of the PC1-PC2 complex, a receptor-calcium channel complex in the primary cilia that responds to fluid flow stimulation. Directly supporting a role for TNF-α in cyst formation, we found that treatment of mouse embryonic kidney organ cultures with TNF-α results in formation of cysts, and this effect is enhanced with embryonic kidneys heterozygous for Pkd2, but not Pkd1 null mutations. Furthermore, analysis of human kidney cysts fluids revealed a correlation of TNF-α production with disease progression. Additionally, the levels of FIP2 and TNF-α receptor are significantly elevated in cystic kidney subtypes. Based on these findings, we hypothesize that a regulatory circuit connecting TNF-α, PC2 localization and cystogenesis, which harbors two double negative feedback loops, could function as an epigenetic "second hit" promoting autosomal dominant disease progression. Unraveling epigenetic control pathways that potentially function as a "second hit" in ADPKD may provide hopeful targets for therapeutic intervention of disease initiation and progression.

2038 The Role of Ei3 in Diabetic Nephropathy

M. Matsoura, T. Tomonaga, H. Ahe, T. Doi.

Clinical Biology and Medicine, Course of Biological Medicine, Graduate School of Medicine University of Tokushima, Tokushima, Japan.

The purpose of this study is to elucidate the role of Ei3 in diabetic nephropathy in vitro and in vivo. We have recently demonstrated that TGFbeta-1 Smad signaling pathway played a key role for development of diabetic nephropathy. TGFbeta1 directly phosphorylates TGFbeta type II receptor (RII) and transduces the signal into intracellular factors. However, detailed mechanisms for the regulation of RII expression have been remained. Therefore, we focused on RII regulation in diabetic conditions. Ei3, a member of the Ets transcription factor family, is well known to transcriptionally regulate TGFbeta type II receptor (RII) expression. Ei3 expression was upregulated by advanced glycation end products (AGEs) stimulation in cultured mouse mesangial cells. Western blot and Northern blot analyses showed that AGEs increased both protein and mRNA levels of Smad1, type IV collagen, and type I collagen. Many reports have shown TGFbeta-1 plays a critical role in AGEs stimulation. However, TGFbeta-1 did not induce Ei3 in mouse mesangial cells. We have recently generated transgenic mice expressing inducible nitric oxide synthase (iNOS) under the control of insulin promoter (iNOS Tg mice), which showed both typical type1 diabetes and diabetic glomerulosclerosis. These mice show improved blood circulation and could be a good source of functional food development.
remarkable sclerotic region resembles human diabetic glomerulosclerosis. Immunohistochemical examination demonstrated manifest expression of type IV and type I collagen in sclerotic regions. Also, phosphorylated Smad1 (pSmad1), RII, and ElF3 were consistently observed in sclerotic glomeruli in iNOS Tg mice. On the other hand, these proteins (pSmad1, RII, ElF3) were hardly expressed in normal glomeruli. These results suggest that ElF3 involves in the progression of diabetic neuropathy through regulation of RII expression.

2039 Alterations of Uromodulin Biology: A Common Denominator of the Genetically Heterogeneous FJHN/MCKD Syndrome M. Kublova,1 P. Vyletel,1 M. Kalcbova,2 K. Hodanova,1 V. Barsova,2 B. Stibulkova,1 J. Sikora,2 H. Hulкова,2 J. Zivny,3 J. Majewski,1 A. Simmonds,4 J. Fryms,4 G. Venkat-Raman,4 M. Ellender,4 S. Knock,1 Institute for Inherited Metabolic Disorders, 1st School of Medicine, Charles University, Prague, Czech Republic, Department of Pathophysiology, 1st School of Medicine, Charles University, Prague, Czech Republic, Department of Human Genetics, McGill University and Genome Quebec Innovation Center, Montreal, PQ, Canada, Parina Research Unit, GKT, Guy’s Hospital, London, United Kingdom, 3Center for Human Genetics, University of Leuven, Leuven, Belgium, 4Renal Unit, Queen Alexandra Hospital, Portsmouth, United Kingdom Autosomal dominant hypertension, renal, and glomerular disease and progressive renal insufficiency are hallmarks of a disease complex comprising familial juvenile hyperuricicemic nephropathy (FJHN), medullary cystic kidney diseases type 1 (MCKD1) and type 2 (MCKD2). In some families the disease is associated with mutations of the gene encoding the cystic fibrosis transmembrane conductance regulator (CFTR), whereas in others no mutations in this gene have been found. Our results show that various genetic defects interfere with UMOD biology, which could lead to the development of the common FJHN/MCKD phenotype. "Uromodulin associated kidney diseases" (UAKD) may be a more appropriate term for the FJHN/MCKD syndrome. Urinary UMOD testing is a best method for identification of additional UAKD families and linkage mapping is a tool to reveal still unknown UAKD genes. Their identification may help to clarify the exact biological roles of UMOD, provide better diagnostic techniques and suggest potential therapeutic targets and therapeutic approaches.

2040 Aberrant Expression of laminin-γ3 with Congenital Autosomal-dominant Polycystic Kidney Disease in Mice H. Lin,1 S. Jiang,2 C. Lin,1 M. Tang,1 Y. Chou1; 1Department of Pediatrics, National Cheng Kung University Medical Center, Tainan, Taiwan, 2Institute of Molecular Biology, Academia Sinica, Taipei, Taiwan, 3Institute of Medical Research, Chang Jung Christian University, Tainan, Taiwan, 4Department of Physiology, College of Medicine National Cheng Kung University, Tainan, Taiwan. Autosomal dominant polycystic kidney disease (ADPKD) has an incidence of 1 in 1000 live births. It is the most common life-threatening inherited cystic kidney diseases characterized by the development of gradually enlarging renal cysts and a progressive loss of normal renal tissue that can lead to chronic renal failure and hemodialysis. Finding of PKD1 and PKD2 genes were major milestones in studying of this specific kidney disease. ADPKD is recognized as a monogenic disorder caused by mutation in two genes, PKD1, accounting for approximately 85% - 90% of cases, and PKD2, accounting for approximately 10% of cases. Polycystin-1 is a large (~460 KD) membrane protein of about 4300 amino acids with 11 transmembrane domains. Its extensive extracellular N terminus contains a number of adhesive domains that implicate polycystin-1 in cell-cell and matrix-cell reactions. Their functions include cell proliferation, regulation of cell survival, altered tubular cell polarity, fluid secretion, and reaction with extracellular matrix. In our preliminary data, renal tubular cystic epithelium was noted to have a tendency to detach from extracellular matrix. Meanwhile, in renal tissue of CDNA microarray analysis, laminin γ3 upregulated also was noted. About this reason, our purposes will focus on the role of laminin γ3, element of ECM, in the developmental process of renal cystic formation and the interaction between extracellular matrix abnormalities and PKD disease. That uses critical information gained from this genetically manipulated mouse models for the purpose of aberrant expression of laminin γ3. Overall, in homzygous mutant, the distribution aberrant of lamininγ3 translocated from basement to apical side at day 1 and the expression of lamininγ3 was increased at day 30. Meanwhile, the expression of laminin γ3 and polycystin-1 protein is colocalized in either cytoplasm or apical side of congenital ADPKD mice.

2041 Par-4 Is a Novel Mediator of Renal Injury J. Xie, Q. Guo; Department of Physiology, The University of Oklahoma Health Sciences Center, Oklahoma City, OK Ischemia/reperfusion-induced renal injury (IRI) is clinically important because it typically damages renal tubular epithelial cells and glomerular cells, and is the most common cause of acute renal failure (ARF). Par-4 (prostate apoptosis response-4) is a leucine zipper protein initially linked to apoptotic cell death in prostate cancer and neuronal tissues. RNA interference (RNAi) induces very effective sequence-specific silencing of gene expression when small interfering RNAs (siRNAs) enter a multimeric nuclease complex and induce targeted destruction of mRNAs. We now report that, in a well-characterized and widely used in vitro model of renal IRI, levels of Par-4 in human renal proximal tubule HK-2 cells started to increase within 4 hours following chemical ischemia-reperfusion. Mitochondrial dysfunction, caspase-3 activation, and significant amount of apoptotic cell death in HK-2 cells were observed following ischemia-reperfusion, which was significantly ameliorated by siRNAs targeted against Par-4 mRNA, while non-silencing control siRNAs were ineffective. These results identify Par-4 is an early critical link in the chain of events leading to the initiation of apoptosis in human kidney proximal tubular cells, and indicate that targeted knockdown of Par-4 expression by RNAi may provide a novel cytoprotective mechanism against ischemia/reperfusion-induced renal injury.

2042 AATF as a Cytoprotective Factor against Renal Injury Q. Guo, J. Xie; Department of Physiology, The University of Oklahoma Health Sciences Center, Oklahoma City, OK AATF (apoptosis antagonizing transcription factor) is a leucine zipper domain containing protein that has anti-apoptotic properties. Human AATF has an open reading frame of 560 amino acids, and is expressed in several organs and tissues including the kidney. AATF may participate in inhibition of pro-apoptotic pathways and/or activation of anti-apoptotic pathways. Ischemia/reperfusion-induced renal injury (IRI) is clinically important because it typically damages renal tubular epithelial cells and glomerular cells, and is the most common cause of acute renal failure. We now report that AATF is expressed in human kidney proximal tubule (HK-2) cells, and its levels of expression were significantly altered in these cells in a well-established in vitro model of ischemia-reperfusion induced renal injury. Overexpression of AATF in transfected HK-2 cells preserved mitochondrial function, suppressed accumulation of superoxide and peroxynitrite, and alleviated lipid peroxidation and oxidative damage induced by IRI. RNA-mediated silencing of AATF exacerbated, while overexpression of the full-length AATF ameliorated, caspase-3 activation and apoptotic death induced by IRI in proximal tubule cells. These results identify AATF as a novel cytoprotective factor against oxidative and apoptotic damage in renal tubular cells. AATF may represent a potential candidate for therapeutic application in ischemia/reperfusion-induced renal injury.

2043 Second-hand Cigarette Smoke Inhibits Wound Healing of the Cornea by Stimulating Inflammation and Delaying Corneal Re-epithelialization C. Ma, M. Martins-Green; Cell Biology and Neuroscience, University of California Riverside, Riverside, CA Environmental cigarette smoke is known to delay skin wound healing, but very little is known about its effects on healing of corneal wounds. Corneal re-epithelialization is a key process in preventing corneal corneal healing and immunosuppression. Identification of factors that promote re-epithelialization, and the mechanism of action, will provide insights into how to improve and accelerate corneal epithelial healing. To address this issue, we exposed mice to cigarette smoke in an established system that mimics second-hand cigarette smoking by humans. We injured the corneal epithelium using a trephine and a scalpel and exposed the mice to smoke during the healing process. We observed that the epithelium at the front edge of the wound did not adhere to the basal matrix and as a result epithelial cell migration was also inhibited. Immunohistological studies showed that in the mice exposed to smoke, many of the ECM molecules critical for epithelial cell migration were not present and that there was an accumulation of superficial basement membrane, inflammatory cytokines, such as IL-1, IL-6, TNF-α, and GRO-alpha increase in the corneal stroma and epithelium. Local treatment to the wounded cornea with dexamethasone (an anti-inflammatory agent) resulted in increased healing rate and infiltration of fewer neutrophils into the wounded area. In conclusion, second-hand cigarette smoke delays corneal re-epithelialization by attracting more neutrophils to the wound site,
which, in turn, produce enzymes that degrade the ECM and consequently inhibit corneal epithelial cell adhesion and migration. These findings have implications not only for the exposure to second hand smoke and its effects on the healing of injuries to the cornea but also for the treatment of the most common type of corneal wounds.

Proteomic Analysis of Lung Epithelial Cell Surface Molecules Recognized by Autoantibodies in SARS-associated Coronavirus Infection

Y. Fang,1 C. Lin,1 Y. Kuo,2 P. Liao,3 H. Lei,1 Y. Lin;1 Microbiology and Immunology, National Cheng Kung University Medical College, Tainan, Taiwan, 1Cell Biology and Anatomy, National Cheng Kung University Medical College, Tainan, Taiwan, 1Environmental and Occupational Health, National Cheng Kung University Medical College, Tainan, Taiwan

Severe acute respiratory syndrome (SARS) is a lower respiratory tract disease characterized by severe atypical pneumonia. Some of the patients have clinical worsening which is related to abnormal immune responses, such as the imbalance of immune cells and the production and dysregulation of cytokines and chemokines. In our study, we found the presence of antibodies (Abs) in SARS patient sera which cross-reacted with human lung epithelial cells A549 and caused cytotoxicity. By competitive binding assay, the cross-reactive Abs in SARS patient sera against SARS-CoV spike protein domain 2 (S2) were identified. By proteomic analysis using 2D gel electrophoresis and mass spectrometry, several candidate proteins, including annexin A2, glyceraldehyde-3-phosphate dehydrogenase, albumin, α-antitrypsin, aldo-keto reductase, and transferrin, recognized by SARS patient sera had been identified. Using immunofluorescence staining and ELISA analysis, we showed that annexin A2 proteins were recognized by anti-S2 Abs or SARS patient sera in A549 cells. Previous studies reported the high levels of inflammatory cytokines, such as IL-6 and IFN-γ, in SARS patient sera. We found that IL-6 and IFN-γ could increase annexin A2 expression in A549 cells. Interestingly, we also found the localization of annexin A2 on plasma membrane lipid-raft structure after IL-6 and IFN-γ stimulation. The elevated expression of annexin A2 by cytokine stimulation also increased the binding activity of anti-S2 Abs to A549 cells. Finally, these cross-reactive Abs could directly cause A549 cell cytotoxicity. Therefore, these results suggest that the regulation of annexin A2 expression by SARS-associated cytokines and the production of autoantibodies (anti-S2 and anti-annexin A2) may have implications in SARS pathogenesis.

2045

“Second-Hand” Cigarette Smoke Causes Lipid Accumulation in the Liver and in the Small Blood Vessels of the Heart

H. Yuan, L. S. Wong, M. Bhattacharya, C. Ma, M. Zafarani, M. Yao, M. Martins-Green; Cell Biology and Neurosciences, University of California, Riverside, Riverside, CA

Cigarette smoke, a mixture of more than 4,000 chemicals, is one of the major factors responsible for many diseases. Atherosclerosis, one of the pathological conditions severely affected by cigarette smoke, contributes to nearly 50% of the deaths in western societies. The early events in atherogenesis are stimulated, on the one hand by cytokines that chemotact attract leukocytes, and on the other hand, by decrease in circulation of molecules that protect endothelial cells (ECs) from injury. To study the effects of “second-hand” smoke on atherogenesis, we used a smoking machine that closely simulates exposure of humans to second-hand smoke, and mice transgenic for human ApoE<sup>−/−</sup>, a model system that closely mimics the human conditions that lead to atherosclerotic plaque formation. We found that smoke decreases the HDL level in the blood and also decreases the ratios between HDL and LDL, HDL and triglyceride (TG) and HDL and total cholesterol (TC). This change in lipid profiles causes not only lipid accumulation in the aortic walls, but also many of the smaller vessels of the heart are filled with lipids. In addition, mice exposed to smoke have decreased levels of an EC-protective protein called adiponectin. Furthermore, cytokine arrays revealed that smoking mice are in a permanent state of pro-inflammation. That is, the Th1 (pro-inflammatory) cytokine profile that develops when the mice are initially exposed to second-hand smoke does not switch to a Th2 (adaptive) response. In addition, TG levels increase significantly in the liver of smoke-exposed mice, thus leading to fatty liver disease. In conclusion, long-term exposure to second-hand smoke creates a state of permanent inflammation and an imbalance in the lipid profile that leads to lipid accumulation in the liver (potentially leading to non-alcoholic fatty liver disease) and in the blood vessels of the heart, potentially leading to heart attacks.

2047

Further Support for the Common Variants in Complement Factor H (Y402H) and LOC387715 (A69S) Genes as Major Risk Factors for the Exudative Age-related Macular Degeneration

B. S. Shastry, Biological Sciences, Oakland University, Rochester, MI

Age-related macular degeneration (AMD) is a progressive degenerative disorder of the retina. It causes changes in the macular region that is responsible for visualizing fine details clearly. The condition is the leading cause of irreversible visual loss in the elderly population in industrialized countries. The presence of large soft drusen (extracellular protein and/or lipid deposits) and retinal pigment epithelial abnormalities are considered to be early signs of the disease. When the disease progresses to an advanced stage, it is characterized by the presence of either geographic atrophy (dry AMD) or choroidal neovascularization (wet AMD). It is a clinically heterogeneous and epidemiologically complex disorder involving the interaction between genetic and environmental factors. Among environmental factors, age and smoking are consistently suggested to be the strongest risk factors. Much progress has been made previously in identifying a number of candidate genes. However, these can explain only a small proportion of AMD cases and none of them accounts for a substantial number of ARMD patients. Recently, several family-based whole genome linkage scans consistently identified two variants in two major susceptibility genes for this disorder. In order to replicate and to determine the overall prevalence of these variants, we have analyzed two unrelated families both having exudative ARMD. Our analysis has identified the same common polymorphism (Y402H) in the CFH gene in one family and the A69S polymorphism in the LOC387715 gene in the second family. These changes are heterozygous in both families, segregating in the LOC387715 gene in the second family. These changes are heterozygous in both families, segregating in the LOC387715 gene in the second family. The alternate localization of these proteins correlates with the dianged phenotype in present in infected mice. Mice that recover from the infection at 28-35 days post inoculum regain their normal membrane AQP localization. The altered localization of AQPs is partially dependent on the bacterial type III effector proteins EspF and EspG. We conclude that altered AQP localization may be a contributing factor to diarrhea during bacterial infection.

2048

Aquaporins Are Altered during Attacking and Effacing Pathogen-induced Diarrhea

J. A. Gutman, F. N. Samji, Y. Li, W. Deng, A. E. Lin, B. B. Finlay; Michael Smith Laboratories, University of British Columbia, Vancouver, BC, Canada

The attaching and effacing (A/E) pathogens, enterohemorrhagic E. coli (EHEC) and enteropathogenic E. coli (EPEC), cause serious global health problems. These bacteria colonize the gastrointestinal system, attach to intestinal epithelial cells, efface (collapse) infected cell microvilli and cause overt diarrhea that can result in host. Although pathogenically induced diarrhea is a significant global health issue, the molecular mechanisms that underlie this disease remain largely unknown. A natural murine infection model, using the A/E pathogen Citrobacter rodentium, has been helpful in studying the diseases in the mouse. As this disease progresses, infected mice develop a diarrhea phenotype. Aquaporin (AQP) water channels have been proposed to play a role in the normal dehydration of fecal contents. Here we examine whether C. rodentium infected mice may alter aquaporin localization in colonocytes. We demonstrate that during infection, AQP2 and AQP3 are mis-localized from their normal location along cell membranes to the cell cytoplasm. The change in localization of these proteins correlates with the diarrhea phenotype present in infected mice. Mice that recover from the infection at 28-35 days post inoculum regain their normal membrane AQP localization. The altered localization of AQPs is partially dependent on the bacterial type III effector proteins EspF and EspG. We conclude that altered AQP localization may be a contributing factor to diarrhea during bacterial infection.

2049

Overexpression of the E3 Ligase Rnf5 Is Associated with Early Onset of Muscular Disorders in Mice

A. Delaunay,1 K. D. Bromberg,2 C. Didier,1 S. A. Lira,1 Y. K. Hayashi,4 G. D. Shelton,4 Z. Romi1;1 Signal Transduction Program, The Burnham Institute for Medical Research, La Jolla, CA, 1Mount Sinai Hospital, New York, NY, 2Department of Immunobiology, Mount Sinai Hospital, New York, NY, 3Department of Neuroimmunology, National Institute of Neuroscience, Tokyo, Japan, 4Department of Pathology, UCSD, San Diego, CA

Rnf5 is a membrane anchored ubiquitin ligase conserved from C. elegans to humans. In C. elegans, Rnf5 localizes and participates to the organization of the dense bodies, a muscle structure similar to muscle Z-lines in mammals. To investigate the role of Rnf5 in mammals, we have constructed a mouse transgenic model to conditionally overexpress Rnf5 upon doxycyclin treatment. We have shown that Rnf5 overexpression leads to a very severe phenotype associated with early onset of kyphosis, muscle weakness, ultimately leading to death. Histopathological analysis of skeletal muscles from Rnf5 transgenic animals revealed a severe alteration of muscle structure with both occurrence of atrophic fibers and high level of regeneration. Analysis of Rnf5 expression in tissue samples from human dystrophic patients revealed Rnf5 expression is elevated in some unknown types of Limb-Girdle Muscular Dystrophy (LGMD), suggesting that Rnf5 is a new player in dystrophic diseases.
Glucoma-causing Mutations in Myocilin Lead to an Abnormal Association with Peroxisomal Targeting Signal Type 1 Receptor (PTSR1) and Elevated Intracellular Pressure (IOP)

T. Dechate1, 2, T. Shim1, S. A. Adam1, A. E. Goodman1, A. Rusinol3, M. S. Sinensky3, R. D. Goldman3, 2, Cell and Molecular Biology, Northwestern University, Feinberg Medical School, Chicago, IL, 1, Biochemistry and Molecular Biology, East Tennessee State University, JI Quillen College of Medicine, Johnson City, TN

IOP is most commonly caused by a point mutation in the lamin A (LA) gene generating a cryptic splice site. This results in the expression of a mutant LA (LAD50) lacking 50 amino acids within its C-terminal containing a proteolytic cleavage site necessary for the maturation of LA. This prevents the removal of the farnesylated/methylated C-terminus as demonstrated biochemically using base release and immunoblotting assays. Therefore LAD50 is permanently farnesylated/carboxymethylated, which has a negative impact on the properties of the mutant protein during mitosis. GBP-LAD50, when expressed in mitotic HeLa cells, abnormally colocalizes with the integral membrane protein emerin and with lamin B (LB), which is normally farnesylated and methylated, in membrane structures. In contrast the endogenous WT LA is found uniformly distributed throughout the cytoplasm during mitosis and cytokinesis until it begins to accumulate in daughter cell nuclei. As treatment of mitotic HeLa cells with a farnesyltransferase inhibitor leads to a uniform cytoplasmic localization of LAD50 identical to WT LA it can be assumed that the farnesyl group is responsible for the abnormal association of the mutant protein with membranes. Association of GBP-LAD50 with membranes during mitosis is also revealed in biochemical fractionation studies. FLIP experiments performed in late prometaphase to early anaphase show a clear difference in the dynamic behavior of GBP-LAD50 compared to GBP-LA. During nuclear reassembly GBP-LAD50 relocates exclusively to the nuclear periphery whereas GBP-LA and endogenous LA are concentrated within the nucleoplasm as revealed by live imaging. In addition, LAD50 is delayed with respect to completion of nuclear recolorization compared to GBP-LA. In fibroblasts derived from GBP patients LA together with LB and emerin are also abnormally structured in the cytoplasm in early G1. These delays in nuclear relocalization could explain some of the defects responsible for premature aging in HGPS.

Guanylate Binding Protein 5, a Novel Phagosomal Protein, Plays a Role in Salmonella Induced Cytotoxicity in Raw 264.7 Macrophages

A. Rupper1, D. Einhaus2, S. Donahoe3, A. Aderem1, J. Cardelli1, 1, Microbiology and Immunology, LSUHSC-Shreveport, Shreveport, LA, 2, The Institute for Systems Biology, Seattle, WA

In order to discover unknown proteins that might play a role against intracellular pathogens in macrophages, we performed a proteomic analysis of purified latex bead containing (LBC) phagosomes from interferon (IFN)-γ treated macrophages compared with purified LBC phagosomes from unstimulated macrophages. Both Lrg-47 and guanylate binding protein 5 (GBP-5) were found to be highly enriched on LBC phagosomes from IFN-γ stimulated cells. Lrg-47 and GBP-5 belong to a family of interferon induced large GTPases with structural similarity to dynamin. Lrg-47, a member of a p47 family, is required for resistance to intracellular pathogens in mice, while little is known about the function of GBP-5, a p67 family member (Taylor et al. Nat Rev Immunol, 2004). To determine if GBP-5 played a role in resistance to infection by S. typhimurium, Raw 264.7 cells were prepared that exhibit stabile expression of 3x Flag epitope tagged GBP-5 or mutant forms of this protein. 3x Flag-GBP-5 was found to rapidly localize with actin cups upon phagocytosis of ezymoan and was highly enriched in purified LBC phagosomes by western blot. Surprisingly, expression of tagged GBP-5 resulted in increased susceptibility of Raw 264.7 cells to S. typhimurium induced cytotoxicity as measured by release of lactate dehydrogenase from infected cell cultures. Expression of a putative slow cycling Gtpase mutant of GBP-5 (D183N) did not result in increased cytotoxicity from S. typhimurium, suggesting that wild type Gtpase activity was required for this function. GBP-5 might play a role in regulation caspase-1 activity in response to S. typhimurium infection and expression of GBP-5 might account for the increase in S. typhimurium induced cytotoxicity demonstrated in IFN-γ stimulated Raw 264.7 macrophages (Monack et al., PNAS, 1996).

Chemical Genetic Analysis of Protein and Lipid Kinases in Disease and Normal Physiology

K. Shokat; University of San Francisco, San Francisco, CA

Our laboratory has developed a systematic means to engineer each protein kinase to be inhibitable by a bio-orthogonal small molecule inhibitor that does not inhibit any wild-type protein kinases. Using this approach of combining chemistry and genetics we can analyze pathways with unparalleled specificity and rapidity revealing phenotypic effects often missed by traditional genetic studies. Using a more traditional pharmacological approach for the study of the much smaller lipid kinase family we synthesized a structurally diverse set of drug-like molecules based on their potential to serve as potent inhibitors of one or more enzymes involved in FfIP3 generation. Our goal was to produce different chemotypes with distinct target selectivities as probes of lipid kinase signaling. We have applied this matrix of inhibitors to both normal physiological pathways such as the insulin pathway and also disease pathways such as cancer.

Making and Shaping the Foregut

S. Mango; Huntsman Cancer Institute, University of Utah, Salt Lake City, UT

The goal of our research is to understand how the foregut is formed during development. Our focus is C. elegans, whose digestive tract is a simple, linear tube. We would like to understand how cells are specified to become one of seven cell types within the foregut and through aboral cell fates. Genetic studies have shown that the aboral cell has a deleterious gain-of-function. Depending on the mutation, glaucoma caused by mutant myocilin has a varying degree of onset and degree of severity of elevated IOP, a hallmark of primary open angle glaucoma (POAG). Yeast-two-hybrid studies showed myocilin associated with PTS1R, but only as the mutant form or if presented as a C-terminal fragment. Myocilin contains a cryptic peroxisomal targeting signal on the C-terminus, but is normally a secreted protein. Immunoprecipitation and fluorescent colocalization studies confirmed that only the mutant form of myocilin interacts with PTS1R and may cause a disruption in normal peroxisomal function of trabecular meshwork (TM) cells. Adenoviral vectors encoding wild-type and mutant myocilin were used to determine the effect of myocilin on IOP in mice. Wild-type adenoviral vectors did not cause elevated IOP when injected into mouse eyes, however, mutant myocilin adenoviral vectors caused elevated IOP which correlated with the severity of the mutation in humans. These data confirm the affinity of mutant myocilin for the PTS1R thus disrupting the normal function of myocilin as a secreted protein. As a result of the aberrant association for PTS1R, normal TM cellular function is compromised thus leading to a disease phenotype. This is the first demonstration of a disease resulting from mutation-induced exposure of a cryptic signaling site that causes mislocalization of mutant protein to peroxisomes and the first disease-gene based animal model of human POAG.

Decipher Mammalian Biology by Insertional Mutagenesis Screens in Mice

T. Xu1, 2; 1, Howard Hughes Medical Institute, Yale University School of Medicine, New Haven, CT, 2, Institute of Developmental Biology and Molecular Medicine, Fudan University, Shanghai, China

Forward genetic screens have played a pivotal role in our understanding of modern biology in lower organisms including bacteria, yeast, flies, worms, plants, and zebrafish. However, the lack of comparable genetic screens in mammals has impaired our ability to understand many aspects of human biology and disease. The current approaches of gene inactivation in the mouse, the piggyBac (PB), a DNA transposon from the cabbage looper moth, and showed that it can efficiently transpose in human cells and in the mouse germline, providing a powerful tool for transgenesis and insertional mutagenesis in mammals. We are in the process of producing the first genome-wide set of mouse insertional mutants, which will allow scientists around the world to utilize forward genetic screens to decipher the genetic basis of mammalian biology and disease.

Teaching Scientist Volunteers about K-12 Science Education, Pedagogy, and Partnership
P. Caldera, J. MacCormack; University of California, San Francisco, San Francisco, CA

Many scientists today are seeking opportunities to share their commitment to science in the wider community and are interested in lending their expertise to teachers and their students with a view to improving science education. Scientists are enthusiastic about sharing their science knowledge and skills, but they generally have had limited experience in K-12 classroom settings. Based on our experience with scientist volunteers working in K-12 classrooms, the Science and Health Education Partnership (SEP) at the University of California, San Francisco, developed a workshop series to support scientist volunteers in their teaching efforts. Utilizing hands-on, interactive science activities, this workshop series is designed to equip scientist volunteers with teaching strategies that will enable them to: focus on the concrete in their teaching; involve all students in classroom lessons; get to know learners through pre-assessment; incorporate inquiry-based methods in their approaches; consider all aspects of lesson-planning (e.g., setting specific lesson goals, managing materials, addressing language needs); and work in partnership with teachers by acknowledging and relying on teachers’ expertise in areas such as classroom management and cognitive development. First offered ten years ago, the workshop series has evolved over the years to better address the needs of scientist volunteers. Scientist volunteers who have taken part in the workshop series consistently rate the workshops very highly, report improvement in their teaching skills, and have integrated many of the ideas and strategies in their work in K-12 classrooms.

Modeling Hematopoietic Transplantation with ES Cells
G. Q. Daley1,2; 1Division of Pediatric Hematology/Oncology, Children's Hospital, Boston, MA, 2Department of Biological Chemistry and Molecular Pharmacology, Harvard Medical School, Boston, MA

Differentiation of embryonic stem (ES) cells in vitro yields abundant hematopoietic progenitors, but achieving stable blood engraftment of irradiated mice has proven difficult. ES cell differentiation chiefly recapitulates the earliest yolk sac stages of blood development, when progenitors have limited developmental potential and fail to productively engraft adults. In an effort to characterize factors that promote formation of definitive Hematopoietic Stem Cells (HSCs), we have shown that activation of a genetic pathway involving the homeodomain proteins cd46 and hesb4 promotes the differentiation of blood progenitors that engraft stable lymphoid-myeloid hematopoiesis in irradiated mice. Our studies in the blood forming system are aimed at establishing principles applicable to generating engraftable HSCs from human ES cells.

2058
Stem Cells and Their Lineages in Skin
E. Fuchs, C. Blanpain, H. Nguyen, V. Horsley, H. Rhee, M. Rendl, T. Lechler, G. Gudas, W. Lowry, J. Nowak; Howard Hughes Medical Institute, The Rockefeller University, New York, NY

The ability of stem cells (SCs) to maintain their growth and differentiation inhibited state while in the niche relies upon a balance of intrinsic and extrinsic factors. The niche must then be stimulated in order to mobilize SCs to their specialized microenvironment. A central issue in SC biology is the relation between SCs and their niche, and how these interactions govern self-renewal and SC activation. Skin is an excellent system for exploring these processes. In postnatal life, skin sets aside multipotent epithelial SCs within each hair follicle. In response to wounding, these SCs become activated and move upward to repair the epidermis. With each hair cycle, specialized mesenchymal-epithelial cross-talk activates SCs, producing rapidly dividing progeny that differentiate to regenerate the follicle to produce new hair. This growth phase is followed by destructive and resting phases, leading to loss of the old hair and completing the cycle. To understand the fascinating process by which multipotent skin SCs respond to these stimuli, change their transcriptional program and select specific cell fates, we developed strategies to isolate specialized mesenchyme and SCs in quiescent and activated states. Transcriptional profiling, biochemical studies and functional analyses have advanced the unraveling of key steps in SC lineage commitment. Questions that we now address include: 1) How does microenvironment render directionality to SC movement and permit SC replenishment within the niche? 2) How do follicle SCs change their gene expression program upon activation? 3) Do unipotent SCs reside within the specialized skin epithelial compartments? 4) How and when are different lineages fated? By addressing these questions, we hope to learn how external stimuli elicit transcriptional, cytoskeletal and adhesive changes that orchestrate the assembly of cells into a tissue. Our ultimate goal is to link the basic biology of our research to issues of human medicine.

Control of Stem Cell Fate by Oriented Mitotic Division through Asymmetric Centrosome Behavior
M. T. Fuller1, Y. Yamashita2; 1Departments of Developmental Biology and Genetics, Stanford University School of Medicine, Stanford, CA, 2Department of Developmental Biology, Stanford University School of Medicine, Stanford, CA

Adult stem cells divide to both renew stem cells and produce cells that initiate differentiation. This choice must be highly regulated to replenish the stem cell population throughout life, yet retain in stem cell proliferative capacity of stem cells. The Drosophila germ line provides a powerful system to study mechanisms that regulate stem cell self-renewal and differentiation. Drosophila male germ line stem cells (GSCs) attach to adherens junctions to somatic hub cells, which comprise the stem cell niche. Hub cells express Usp, which activates the JAK-STAT pathway in adjacent germ cells to specify GSC self-renewal. The normally asymmetric outcome of stem cell divisions in the Drosophila male germ line is specified by stereotyped orientation of the mitotic spindle perpendicular to the junctional complex that attaches the stem cell to the niche. As a result, one daughter inherits the adherens junctions, retains contact with the niche and self-renews, while the other daughter is displaced away and initiates differentiation. GSCs orient toward the niche throughout the cell cycle. The single centrosome in G1 is next to the niche. After duplication, one centrosome stays next to the niche while the other migrates to set up the oriented mitotic spindle. Strikingly, differences between mother and daughter centrosomes appear to underlie this stereotyped behavior: the mother centrosome remains next to the niche, while the daughter centrosome consistently migrates to the opposite side of the nucleus. This programmed asymmetric behavior of mother versus daughter centrosomes requires wild type function of the centromosomal protein cnn, suggesting that attachment to astral microtubules helps anchor the mother centrosome to the junction with the niche. Thus, adult male GSCs execute specialized cytoskeletal programs to govern centrosomal positioning so that the spindle is set up perpendicular to the niche. As a result, stem cells in the niche maintain a centrosomal Eve.

Dynamics of the Endocytic Coat Module in S. cerevisiae Regulated by an ArfGAP and Synaptotagmin
C. P. Toret, M. Kaksonen, Y. Sun, D. Drubin; Molecular and Cell Biology, University of California, Berkeley, Berkeley, CA

Recent studies have revealed a highly choreographed recruitment of endocytic proteins to sites of clathrin/actin-mediated endocytosis. How these precise dynamics are achieved remains unresolved. Earlier, we used quantitative live-cell imaging of budding yeast to uncover a modular organization of the endocytic machinery. Here, we investigated possible roles for candidate disassembly factors in regulation of the dynamics of the endocytic coat module proteins. Components of the coat module include clathrin, Slap2p, Enl1p, Enl2p, Slap1p, Pan1p, and Enl3p, each of which has a mammalian homologue. Live-cell imaging analysis revealed that the putative ArfGAP, Gts1p, and the synaptotagmin, Imp52p, arrive at endocytic sites late in the internalization pathway, consistent with a role in coat disassembly. ArfGAPs and synaptotagmins have been implicated as disassembly factors in other cellular trafficking pathways. Analysis of mutants of the genes encoding Gts1p, and the Arf6 homologue Arf3 that it is presumed to regulate, and Imp52p, implicate these proteins in disassembly of the endocytic coat module, with Gts1p/Arf3 and Imp52p each regulating a subset of the coat components. Loss of both Gts1p/Arf3p and Imp52p activities together results in pronounced uncoating defects. Our results implicate two cooperative pathways, one involving GTP hydrolysis stimulated by ArfGAP, and the other involving lipid turnover catalyzed by synaptotagmin, in separate pathways for the uncoating of endocytic vesicles.

Adaptors and Sorting Signals for Clathrin-coated Vesicles
M. S. Robinson; University of Cambridge, Cambridge, United Kingdom

Adaptors select cargo for transport in clathrin-coated vesicles (CCVs) between the TGN, endosomes, and the plasma membrane. We have investigated the functions of some of the binding sites and domains of the AP-2 adaptor complex, which acts at the plasma membrane, by stably transfecting cells with siRNA-resistant constructs and then knocking down the endogenous protein. These studies reveal a certain degree of functional redundancy, because no single mutation completely abolishes AP-2-dependent transferrin uptake; however, attaching a C-terminal GFP tag to the alpha subunit renders it non-functional. To investigate clathrin-mediated intracellular trafficking, we have been isolating CCVs from control and siRNA-treated HEla cells. Using a comparative proteomics approach, we have identified 63 bona fide CCV components. One of these proteins, CVAK104, is a novel regulator of AP-1-dependent trafficking, which is required for the sorting of two SNAREs, syntaxin 8 and vti1b, and for normal embryonic development in Xenopus tropicalis. EpisnR is another CCV component required for vti1b sorting, which acts as an alternative adaptor. We have mapped the binding site on vti1b for episnR to a folded domain, and we have solved the structure of this domain by X-ray crystallography.
Endocytosis is a key mechanism for plasma membrane protein downregulation, yet the intrinsic diversity of protein cargos and extracellular stimuli presents a challenge to achieving specificity. By lowering the abundance of specific plasma membrane proteins (e.g., sensors, receptors and channels), cells can reduce their sensitivity to certain environmental cues. Here we report a new family of proteins (ART, for Arrestin Related Trafficking adaptors) in *S. cerevisiae* that may play a pivotal role in cargo-specific endocytosis. Art proteins reside primarily in the cytoplasm, but they translocate to the plasma membrane in response to stress or extracellular nutrients. Two members (Art1p and Art2p) of the family were first discovered in our genome-wide chemical-genetic screens for yeast mutants defective in the endocytosis of specific 12-transmembrane amino acid transporters. Further screen analysis revealed seven additional homologs (Art3p to Art9p) in the yeast genome. The Art proteins are related to mammalian arrestins, and each additionally contains multiple Pro-X-Tyr (PY) motifs in the C-terminal region. We provide evidence that these PY motifs are required for recruiting the Nedd4-like Rsp5 ubiquitin ligase to the plasma membrane, where it ubiquitinates protein cargos as well as the Art proteins themselves. As a result, ubiquitinated protein cargos are targeted to the endocytic pathway followed by degradation in the vacuole/lysosome. Our data also suggest that a plasma membrane protein cargo can recruit distinct Art proteins in response to different extracellular signals. We propose that these Art proteins represent a new family of adaptors that target the Rsp5 ubiquitin ligase to specific membrane cargos in response to extracellular signals, resulting in their endocytosis and downregulation.

### 2063 Characterization of Yusunin, a Novel Component Required for TGN to Cell Surface Transport

C. Bossard, Y. Maceda, V. Malhotra; *Cell and Developmental Biology, UCSD, La Jolla, CA, Department of Immunoregulation, Osaka University, Osaka, Japan

Protein kinase D (PKD) is required to form trans-Golgi network (TGN) to cell surface transport carriers. PKD is recruited to the TGN by a specific pool of dicycloyglycerol (DAG) and activated by Gβγ and the Golgi apparatus-associated PKCγ. Inhibition of PKD inhibits membrane fission and resulting in the formation of large cargo filled tubules that remain attached to the TGN. Its overactivation, on the other hand, regulates tubules. PKD and its interactors therefore regulate events leading to separation, by fission, of the Golgi to cell surface transport carriers. We have identified a new downstream target of PKD and called it Yusunin. Our findings reveal that Yusunin - a cytosolic protein - is recruited to the TGN through binding to PKD. Yusunin interacts with inactive PKD and is released from PKD by phosphorylation. Inhibition of PKD-dependent phosphorylation of Yusunin abolishes Golgi to cell surface transport. Yusunin does not effect the recruitment of PKD to the TGN but inhibits TGN to cell surface transport. Yusunin, therefore, is a key component of the machinery involved in the formation of Golgi to cell surface transport carriers.

### 2064 Regulation of the Drs2p-dependent Flippase Activity in Golgi Membranes by Phosphatidylinositol 4-Phosphate

T. Graham, P. Natarajan, K. Liu; *Department of Biomedical Sciences, Vanderbilt University, Nashville, TN*

Phospholipid translocases (PLTs) flip fluorescent or spin-labeled derivatives of phospholipids from the exoplasmic leaflet of a membrane bilayer to the cytosolic leaflet, and are thought to establish asymmetry of endogenous phospholipid in biological membranes. The best candidates for PLTs are the Drs2p/ATPase II (ATP7A) subfamily of P-type ATPases (P4 ATPases). Drs2p from budding yeast localizes to the trans-Golgi network (TGN) and is required for a flippase activity measured with purified TGN membranes using a 7-nitro-2,1,3-benzoazadiazol-4-yl (NBD) phosphatidylinositol (PS) domain of Npt3p to destroy phosphoinositides markedly reduced Drs2p flippase activity. In contrast, Wortmannin, a PI 3-kinase inhibitor, had no effect. Moreover, Drs2p activity is substantially reduced in TGN membranes from pik1ts and 1p3p and stimulated the Drs2p-dependent NBD-PS flippase activity in these membranes. Further addition of the Sac1p (phosphoinositol phosphate) domain of Inp53p to destroy phosphoinositides markedly reduced Drs2p activity. In contrast, Wortmannin, a PI 3-kinase inhibitor, had no effect. Moreover, Drs2p activity is substantially reduced in TGN membranes from pik1ts incubated at the nonpermissive temperature (37°C). These results indicate that PI4P stimulates Drs2p-dependent NBD-PS translocase activity in TGN membranes. Therefore, we propose that Drs2p is a critical effector of PI4P at the yeast TGN.

### 2065 Golgin-160 Is Required for the Golgi Membrane Sorting of the Insulin-responsive Glucose Transporter GLUT4 in Adipocytes

D. Williams, S. W. Hicks, E. M. Madam, J. E. Fessin; *Department of Pharmacological Sciences, Stony Brook University, Stony Brook, NY, Department of Cell Biology, Johns Hopkins University, Baltimore, MD, Department of Microbial Pathogenesis, Yale University, New Haven, CT*

The peripheral Golgi protein golgin-160 is induced during 3T3L1 adipogenesis and is primarily localized to the Golgi cisternae distinct from the TGN in a general distribution similar to p115. siRNA mediated reduction in golgin-160 protein in an increase accumulation of the insulin-responsive aminopeptidase (IRAP) and GLUT4 protein (both endogenous and transfected) at the plasma membrane and enhanced glucose uptake in the basal state. The redistribution of GLUT4 was rescued by expression of a siRNA resistant golgin-160 cDNA. The basal state accumulation of plasma membrane GLUT4 occurred due to an increased rate of exocytosis without any significant effect on the rate of endocytosis. This GLUT4 trafficking to the plasma membrane in the absence of golgin-160 was independent of GLUT4 sorting, as it was no longer inhibited by the expression of a dominant-interfering GGA mutant. Moreover, expression of the amino terminal head domain (amino acids 1-393) had no significant effect on the distribution or insulin-regulated trafficking of GLUT4 or IRAP. In contrast, expression of carbonyl alpha helical region (393-1498) inhibited insulin-stimulated GLUT4 and IRAP trafficking but had no effect on the sorting of constitutive membrane trafficking proteins, the transferrin receptor or vesicular stomatitis virus G (VSV-G) protein. Taken together these data demonstrate that golgin-160 plays an important role in directing insulin-regulated trafficking proteins toward the insulin-responsive compartment in adipocytes.

### 2066 Direct Visualization of Prokaryotic Cytoskeletal Filaments and Other Ultrastructural Elements in Intact Cells by Electron Cryotomography

G. Jensen; *Division of Biology, California Institute of Technology, Pasadena, CA*

Using state-of-the-art electron cryotomography, we have now directly visualized ~10 distinct cytoskeletal filament types in the bacterial species Caulobacter crescentus, Magnetospirillum magnetcum, Mycoplasma pneumoniae, and Mesoplasma florum. Thus while the absence of any cytoskeleton was once thought to be a distinguishing characteristic of prokaryotes, it is now clear that the cytoskeleton is an important, complex, and widespread component of bacterial cell biology. In the case of *C. crescentus*, six distinct filament bundles have been characterized and efforts are underway to identify each through structural signatures, mutational analysis, and correlated fluorescence and electron microscopy. FtsZ2 in particular was seen to form half-rings and stacked helices with characteristic spacings. In the case of Magneticum, MamK was identified as a new actin-like protein filament used by the cell to organize the organelle-like magnetosome chain. In *M. pneumoniae*, the filamentous "attachment organelle" has been characterized in detail, prompting new hypotheses about its role in motility and infectivity. In *M. florum*, a cellular process known as "nuring" occurs as the cell porks across the cytoplasm. In addition to revealing novel cytoskeletal filaments, this work has also allowed us to visualize complete, unperturbed flagellar motors, chemoreceptor bundles, and polysomes in-situ, albeit at only medium resolution (~5 nm). This work has been a mixture of technology development and biological and, illustrates how electron cryomicroscopy is opening a new window into prokaryotic ultrastructure.

### 2067 Tension-dependent Regulation of Microtubule Dynamics at Kinetochores Can Explain Metaphase Congression in Yeast

M. K. Gardner, C. G. Pearson, B. L. Sprague, T. R. Zarzar, K. Bloom, E. D. Salmon, D. J. Odde; *Department of Biomedical Engineering, University of Minnesota, Minneapolis, MN, Division of Biological Sciences, University of California, San Diego, School of Medicine, La Jolla, CA, Department of Biomedical Sciences, University of California, San Diego, School of Medicine, La Jolla, CA, Bunting and Best Department of Medical Research and Department of Medical Genetics and Microbiology, University of Toronto, Toronto, ON, Canada*

Magnetosome chain. In clear that the cytoskeleton is an important, complex, and widespread component of bacterial cell biology. In the case of *M. K. Gardner, 1 C. G. Pearson, 2 B. L. Sprague, 3 T. R. Zarzar, 4 K. Bloom, 4 E. D. Salmon, 4 D. J. Odde 1; 1Department of Biomedical Engineering, University of Minnesota, Minneapolis, MN, 2Department of Biological Sciences, University of California, San Diego, School of Medicine, La Jolla, CA, 3Bunting and Best Department of Medical Research and Department of Medical Genetics and Microbiology, University of Toronto, Toronto, ON, Canada*
During mitosis, dynamic kinetochore-attached microtubules (kMTs) mediate the proper segregation of chromosomes into nascent daughter cells. In budding yeast, kinetochore-bearing microtubules play a significant role in the separation of chromosomes. As a result, the intervening chromatin is stretched and the chromosomes are centered at the spindle equator, a process known as congression. To understand how kMT plus end self-assembly dynamics are regulated to achieve congression, we used quantitative fluorescence microscopy combined with computational modeling to simulate (1) the extent of kinetochore-stabilized plus-end attachment during metaphase as measured via fluorescence recovery after photobleaching (FRAP) of Cse4-GFP; (2) kinetochore-associated fluorescence distribution during metaphase; (3) kMT plus-end self-assembly dynamics as measured via FRAP of GFP-Tubulin, and (4) kinetochore-associated fluorescence distribution during metaphase in a replication deficient mutant lacking tension generated from chromatin stretch. The only model that explained all four experiments was one in which kMT plus-end dynamics are regulated both by a spatial catastrophe gradient leading to kMT depolymerization at the spindle equator, and by attachment site tension that promotes net kMT assembly with increasing chromatin stretch. In this model, the catastrophe gradient establishes rudimentary bi-orientation, and tension between sister kinetochores corrects remaining errors to robustly achieve congression. Many other models were tested and failed to explain at least one experiment, establishing a method for systematic hypothesis testing via computational modeling.

2068 Structure of the Kinetochore Dam1 Complex and Its Assembly on Microtubules
1Pathology and Immunology, Washington University School of Medicine, St. Louis, MO, 2Microbiology and Immunology, Hamamatsu University School of Medicine, Hamamatsu, Japan

Multi-photon microscopy is providing crucial insight into the cell dynamics that underlie antigen presentation and T cell activation. However, published studies have used model systems that elicited immune responses with protein immunizations or peptide-pulsed dendritic cells (DCs). During an infection, host-pathogen interactions are likely to impact antigen recognition and it is unclear how well model systems can recapitulate physiological levels of inflammation, antigen abundance or peptide-MHC processing. Using multi-photon microscopy and immunofluorescence of thin spleen sections, we examined the fate of GFP-expressing Listeria monocytogenes (Lm), the distribution of macrophages and DCs and the kinetics of Lm-specific antigen presentation during infection. After i.v. challenge, bacteria were captured rapidly (~1h) by sessile marginal zone macrophages (MZM) and cleared from the marginal zone by 6h. In contrast, bacteria that infected DCs avoided destruction and were carried into the T cell area or periarteriolar lymphoid sheath (PALS). Paradoxically, the replication of Lm in the PALS induced the widespread apoptosis of lymphocytes and DCs at 24h-48h, yet Lm entry into PALS has been shown to be required for long-lived immunity. To understand how antigen recognition occurs in the face of pathogen counter measures, we imaged adoptively transferred TCR transgenic T cells as a probe for the presentation of Lm-derived antigens in situ. The CD8 T cell response was remarkably rapid and efficient; 9h after challenge large clusters of Lm-specific cells were seen on DCs and by 24h many lymphoblasts were visible migrating through the PALS. Strikingly, CD4 T cell activation occurred after CD8 activation, was comparably weak and occurred within a wider distribution in the PALS. Our studies suggest that during infection, Lm-induced tissue-remodeling transports pathogen-derived antigens to specific tissue microenvironments and that initial CD8 and CD4 T cell responses show distinct spatiotemporal dynamics.

2069 Spleen Remodeling and Antigen Presentation Dynamics during Listeria monocytogenes Infection
M. J. Millie, T. Aoshi, Y. Koide, F. F. Ruegg, E. B. Unanue

Near-molecular Resolution of Intracellular Fluorescent Proteins Using Photoactivated Localization Microscopy (PALM)
E. Betzig, G. Patterson, R. Sougrat, M. Davidson, S. Olender, W. Lindwasser, J. Bonifacino, J. Lippincott-Schwartz, H. Hess, Janelia Farm Research Campus, Howard Hughes Medical Institute, Ashburn, VA, 2Cell Biology and Metabolism Branch, National Institute of Child Health and Human Development, Bethesda, MD, 3National High Magnetic Field Laboratory, Florida State University, Tallahassee, FL

In conventional biological imaging, diffraction places a limit on the minimal xy distance that two marked objects can be discerned. Consequently, imaging of target proteins within cells is typically coarser by two orders of magnitude than the molecular scale at which the proteins are spatially distributed. Here, we introduce a method capable of optically resolving selected subsets of fluorescently-tagged proteins within cells at mean separations of a few nanometers, overcoming the diffraction barrier in fluorescence microscopy. Terned photoactivated localization microscopy (PALM), the method involves serial photoactivation and subsequent bleaching of numerous sparse subsets of photoactivated fluorescent protein molecules. Individual molecules are localized at near molecular resolution by determining their centers of fluorescent emission via a statistical fit of their point-spread-function. The aggregate position information from all subsets is then assembled into a super-resolution image, in which individual fluorescent molecules are isolated at high molecular densities (up to 10^10 molecules per micron^3). PALM imaging of intracellular structures (including lysosome, Golgi apparatus and mitochondria) in cryo-prepared thin sections is presented. In addition, imaging of vinculin and actin by PALM in fixed cells with TIRF excitation is shown. Finally, correlative PALM/transmission electron microscopy images are presented of a mitochondrial marker protein, illustrating the feasibility of relating the nanometer scale distribution of a specified protein at high molecular density (i.e., 5500 molecules per mitochondrion) to cellular ultrastructure.

2070 Electron Tomography of Cells
R. McIntosh; Department of Molecular/Cell/Developmental Biology, University of Colorado, Boulder, CO

Improvements in electron microscopes, digital cameras, computers, and software have made electron tomography (ET) a powerful method for structural cell biologists. Specimen details can be visualized in 3-D with 4 - 6nm resolution and the volumes reconstructed can be big enough to include the entirety of an organelle or even a small cell. Large volume work is best accomplished with rapidly frozen, freeze-substitution fixed, stained, and plastic-embedded material, which facilitates the accumulation of montaged images from adjacent areas and the construction of serial tomograms from successive thick sections. The resulting evidence about the connectivity of cytoplasmic membranes and cytoskeletal elements is important. High-resolution work on fixed, stained samples is, however, hampered by the possibility of fixation artifacts and by the imaging of stain, rather than the macromolecules themselves. Cryo-ET of frozen-hydrated samples solves these problems, but resolution is now limited by poor image signal-to-noise, due to low contrast and the low electron dose that is tolerated by these radiation sensitive specimens. Image signal-to-noise can be improved when tomograms contain multiple copies of a given object; these 3-D structures can be excised, aligned, and averaged, essentially as in high-resolution cryo-EM of other kinds. Now signal-to-noise can be good enough that molecular shapes are distinct and informative, allowing atomic or other high-resolution structures to be docked into their cellular location. Examples of both kinds of data will be shown and discussed, along with evidence about the key outstanding problem in cellular ET, the identification and localization of specific macromolecules.
Neuromuscular transmission defects and muscle weakness are common in desminopathy, a disease caused by mutations in the intermediate filament (IF) protein desmin. These mutations can affect various muscle types, including skeletal, cardiac, and smooth muscle. The number of identified pathogenic mutations in the IF protein desmin, which lead to desminopathy of skeletal, cardiac, as well as smooth muscle, has grown considerably in the last few years. We have investigated, both in vitro and in vivo, 25 disease-causing mutations in order to obtain insight into the molecular and structural characteristics of desmin IFs accompanying tissue pathogenesis. In comparison to the wild-type protein, many of the mutant desmins variants exhibited distinct assembly defects at various stages of assembly. In particular, both tetramer and unit-length filament formation as well as filament elongation and IF maturation were affected. For further characterization of the viscoelastic properties of desmin IFs, we performed nanomechanical techniques employing the scanning force microscope. Thereby we demonstrated that IFs from mutated desmins were on average not mechanically weaker than wild-type IFs. In parallel, we expressed the proteins both in cellulo of cytokinetic intermediate filaments (human SW13) and into those containing an extensive vimentin network (mouse 3T3). The in vivo assembly properties matched - and by large - those determined in vitro. In summary, despite the ability to form apparently normal IFs by about half of the mutant desmins, in the tissue the mutated residues obviously interfere negatively with intrinsic cellular factors engaged in the establishment and maintenance of a functional myocyte architecture.

**2073 Assembly Competence, Biomechanical Properties, and Network Forming Ability of Desmin Disease Mutants**

H. Herrmann, S. Sharma, L. Kreplak, H. A. Katus, U. Aebi, H. Bär; Molecular Genetics, German Cancer Research Center, Heidelberg, Germany, M. E. Müller Institute, Biozentrum, Basel, Switzerland, Department of Cardiology, University of Heidelberg, Heidelberg, Germany

We have discovered a spontaneous mutation in the Sprague Dawley rat with a novel and unusual eye phenotype that we have named Nuc1. Nuc1 is inherited as a single Mendelian locus with viable homozygotes and with an intermediate phenotype in the heterozygotes. Heterozygotes exhibit nuclear cataracts, while homozygotes have microphthalmia, retinal abnormalities and rupture of the lens capsule shortly before birth. The Nuc1 locus was mapped to rat chromosome 10; a 27 nucleotide insertion in a beta-crystallin gene results in the Nuc1 phenotype. In Nuc1 homozygotes, the secondary lens fibers elongating from opposite directions exhibit abnormal migration and orientation and fail to iterdigitate to form normal sutures. We have observed a marked decrease in filensin in developing fiber cells of Nuc1 homozygotes both by immunohistochemical and confocal microscopy starting at embryonic day 19. Western blots using anti-filensin polyclonal antibody demonstrate decreased filensin in Nuc1 heterozygotes and homogygotes relative to wild-type lenses. Filensin is a constituent of the beaded filament, a lens-specific cytoskeletal element. Our yeast two-hybrid studies do indicate physical interactions between beta/crystallins and cytoskeletal proteins suggesting that crystallins may have a stabilizing function on the cytoskeletal structure. Finally, metabolic labeling studies with 35S amino acids in organ cultured lenses indicated that filensin synthesis was decreased in mutant lenses. Our results clearly demonstrate that the programmed remodeling of the lens fibers that is essential to maintain transparency is dependent on crystallins. We also provide evidence that crystallins are not merely structural proteins but have important regulatory functions in maintaining the cytoskeletal structure and thereby serve an important role in health and disease.

**2074 A Spontaneous Mutation in a Beta-Crystallin Gene Affects the Remodeling of Lens Fibers Cells**

D. Sinha, S. Kisse, S. Schubert, P. K. Ho, M. Can, O. Sandin, E. Ratovitski, P. Zelenka, K. W. Bromman, J. S. Zigler; Ophthalmo, Wilmer Eye Institute, The Johns Hopkins University School of Medicine, Baltimore, MD, The National Eye Institute, National Institutes of Health, Bethesda, MD, Otolaryngology-Head and Neck Surgery, The Johns Hopkins University School of Medicine, Baltimore, MD, Bios-statistics, The Johns Hopkins University, Baltimore, MD

We have discovered a spontaneous mutation in the Sprague Dawley rat with a novel and unusual eye phenotype that we have named Nuc1. Nuc1 is inherited as a single Mendelian locus with viable homozygotes and with an intermediate phenotype in the heterozygotes. Heterozygotes exhibit nuclear cataracts, while homozygotes have microphthalmia, retinal abnormalities and rupture of the lens capsule shortly before birth. The Nuc1 locus was mapped to rat chromosome 10; a 27 nucleotide insertion in a beta-crystallin gene results in the Nuc1 phenotype. In Nuc1 homozygotes, the secondary lens fibers elongating from opposite directions exhibit abnormal migration and orientation and fail to iterdigitate to form normal sutures. We have observed a marked decrease in filensin in developing fiber cells of Nuc1 homozygotes both by immunohistochemical and confocal microscopy starting at embryonic day 19. Western blots using anti-filensin polyclonal antibody demonstrate decreased filensin in Nuc1 heterozygotes and homogygotes relative to wild-type lenses. Filensin is a constituent of the beaded filament, a lens-specific cytoskeletal element. Our yeast two-hybrid studies do indicate physical interactions between beta/crystallins and cytoskeletal proteins suggesting that crystallins may have a stabilizing function on the cytoskeletal structure. Finally, metabolic labeling studies with 35S amino acids in organ cultured lenses indicated that filensin synthesis was decreased in mutant lenses. Our results clearly demonstrate that the programmed remodeling of the lens fibers that is essential to maintain transparency is dependent on crystallins. We also provide evidence that crystallins are not merely structural proteins but have important regulatory functions in maintaining the cytoskeletal structure and thereby serve an important role in health and disease.

**2075 Normalization of Differentially Expressed Genes in Keratin 8-null Colonoocytes in Response to Antibiotic Treatment**

D. A. D. Brooks, E. C. Butcher, M. B. Omary; Medicine, VA Palo Alto Health Care System and Stanford University Digestive Disease Center, Palo Alto, CA, Applied Biosystems, Foster City, CA, Pathology, VA Palo Alto Health Care System and Stanford University Digestive Disease Center, Palo Alto, CA

Keratin 8 (K8) is the major type II intermediate filament protein present in colonic epithelial cells. K8-null mice develop colonic hyperplasia, diarrhea, and chronic spontaneous Th2-type colitis amenable to broad-spectrum antibiotic treatment. The aim of this study was to identify genes that are differentially expressed as a result of K8 absence in colonic epithelial cells. Microarray analysis was used to examine differences in gene expression between colonocytes freshly isolated from K8 wild-type and K8-null mice. We also examined whether the differentially expressed genes were related to the presence of luminal bacteria by examining the gene expression profile following antibiotic treatment. The majority of the highly altered genes in untreated K8-null versus wild-type colonoocytes were related to apoptosis, growth and differentiation. Among these genes, we confirmed which were recognized by RT-PCR, tranquillatine-3 (14.4-fold by RT-PCR), clusterin (3.4-fold), and peroxiredoxin (2.2-fold) were highly down-regulated whereas survivin (5.7-fold) was up-regulated in K8-null colonoocytes. These alterations provide a mechanistic insight regarding the colon hyperplasia of K8-null mice and the involvement of keratin in modulating epithelial cell susceptibility to apoptosis. Notably, nearly all of the differentially regulated genes in K8-null versus wild-type colonoocytes were normalized following antibiotic treatment, thereby supporting the importance of colonoocyte interaction with the luminal bacterial milieu in manifesting the intestinal phenotype of K8-null mice.

**2076 Insights into the Role of Nuclear Laminas in DNA Replication: lamin Interactions with PCNA**

D. K. Shumaker, T. Shimi, L. Solimando, M. Cardoso, R. D. Goldman; Cell Molecular Biology, The Feinberg School of Medicine, Northwestern University, Chicago, IL, Max Delbruck Center for Molecular Medicine, Berlin, Germany

When nuclei are exposed to mutant laminas lacking their N-terminus, the nuclear lamin network is disassembled and DNA replication is blocked. Under these conditions, laminas are present in nuclear foci with the DNA replication elongation factors, PCNA and RFC, which normally associate with chromatin during S-phase. Based upon these observations, we have examined the relationship between laminas, B2, C and PCNA in more detail using S-phase HeLa cells and in vitro assembled Xenopus nuclei. The overall organization of Lamin A (LA), LB2 and LC is similar, but not identical. We have found that during S-phase in HeLa cells, PCNA foci are either associated with nucleoplastic lamin foci or the lamin at all stages of replication. The relationship between PCNA and lamin was further examined in live cells using EGFP and mCherry tagged proteins. Under these conditions, PCNA foci were also associated either with the nucleoplastic laminas or the nuclear lamin. Our results suggest that laminas play a role in regulating DNA replication through its interactions with PCNA. To determine the nature of the interactions between PCNA and laminas, various fragments of Xenopus LB3 and human LA were expressed and purified. Using affinity chromatography, we find that the C-terminal domain of both Xenopus LB3 and human LA bind PCNA in Xenopus egg and HeLa cell extracts. Further analyses show that this binding involves the highly conserved Ig-fold of the lamin C-terminus. To determine whether PCNA interacts directly with lamin fragments, immunoprecipitation assays using purified proteins and gel overlays with radioactively labeled PCNA were performed. The results show that PCNA can directly interact with the lamin Ig-fold domain. Supported by the NCI, The Ellison Foundation and the Progeria Research Foundation.
A Farnesylated Mutant Lamin A Affects the Extracellular Matrix and Cell Proliferation in a Model of Hutchinson-Gilford Progeria

K. Roux,1 L. Hernandez,2 B. Burke,2 C. L. Stewart1; 1Anatomy and Cell Biology, University of Florida, Gainesville, FL, 2UCBL, National Cancer Institute, Frederick, MD

The laminopathies is a group of diseases caused by mutations in the LMNA gene that encodes the A-type lamins. One of the most striking laminopathies is the premature aging disease Hutchinson-Gilford Progeria Syndrome (HGPS). The most prevalent mutation associated with HGPS is a base change in codon 608 that introduces a premature splice donor site into LMNA resulting in a 50 amino acid deletion within the C-terminal nonhelical domain of lamin A. Posttranslational modification of lamin A includes farnesylation of a terminal CaaX motif, followed by proteolytic processing that removes the terminal 18 amino acids. The HGPS deletion eliminates the cleavage site within lamin A, resulting in a truncated yet permanently farnesylated form of the molecule (Progerin). How Progerin causes HGPS is an area of intense investigation. Previously we described a mouse line in which Exon 9 of Lmna was deleted (Δ9 mice, Mounkes et al Nature 2003 423; p298). These mice exhibited phenotypes similar to many of the pathologies associated with HGPS. Here we show that the Exon 9 deletion results in a truncated form of lamin A that remains farnesylated suggesting that this mouse line may provide a model to uncover the etiology of HGPS. To this end we find that embryonic fibroblasts from the Δ9 mice, despite abnormally shaped nuclei, show normal growth parameters and gene expression. In contrast postnatal fibroblasts exhibit severe growth retardation associated with reduced expression of many extracellular matrix (ECM) proteins, as well as components in the FGF and TGFβ signaling pathways. Growth can be rescued by maintaining the Δ9 cells on ECM from normal cells or by treatment with FGF18. Our results support the notion HGPS maybe caused by developmentally regulated defects in ECM production that affects cell proliferation/maintenance in specific tissues such as cartilage, skeleton, and cardiovascular system.

Molecular Details of Tubulin Assembly Measured with Optical Tweezers

E. Munteanu,1 J. W. J. Kerssemakers,2 T. Nötzel,1 M. Dogterom1; 1Bio-Assembly and Organization, FOM Institute AMOLF, Amsterdam, The Netherlands, 2MPI-CBG, Dresden, Germany

Although microtubules are known to self-assemble from tubulin dimers both in vivo and in vitro, the underlying sequence of molecular events remains poorly understood. We perform in vitro experiments aimed at understanding the molecular details of the assembly process of microtubules and the molecular mechanism by which microtubule associated proteins regulate microtubule dynamics. We use a combination of micro-fabrication techniques and optical tweezers to observe the growth process of individual microtubules at molecular resolution. We find that microtubules can near-instantaneously increase their overall length by amounts exceeding the size of single dimers (8 nanometers). When the microtubule-associated protein XMAP215 is added, this effect is markedly enhanced and fast length increases up to 60 nanometers are observed, which corresponds to the size of the XMAP215 protein itself. These observations show that small tubulin oligomers can add directly to growing microtubules and that XMAP215 speeds up microtubule growth by facilitating the addition of long oligomers.

Structural Basis for the Activation Mechanism of Microtubule Assembly by Plus-End Tracking Proteins

I. Hayashi, M. Ikura; Department of Medical Biophysics, University of Toronto, Ontario Cancer Institute, Toronto, ON, Canada

A group of proteins, such as EB1, CLIP-170 and the dynein/dynactin complex, has been found to associate specifically with the microtubule growing ends in vivo. These proteins, termed “plus-tracking proteins (+TIPs)”, are thought to form a plus-end complex and guide microtubule growth toward specialized destinations by local influences on microtubule assembly. Despite much recent progress in the field, many key mechanistic questions remain unanswered. Previously we determined the crystal structure of EB1 and the dynactin subunit p150Glued, and demonstrated that EB1 alone has an activity to assemble microtubules whereas p150Glued plays a role as an allometric activator of EB1. CLIP-170 is structurally related to p150Glued. They both have the CAP-Gly domains in their N-terminal region which can interact with EB1. Furthermore, CLIP-170 has two putative zinc-binding motifs at the C terminus to control its intramolecular interaction by binding to the N-terminal CAP-Gly domains. In the present study, we have investigated the crystallographic, NMR and mutational analyses of EB1, p150Glued and CLIP-170. Our data reveal that EB1 and CLIP-170 recognize the same elements of p150Glued, and that these interactions are critical for the activation of EB1 and CLIP-170. We further show the regulatory interplays between these three +TIPs by in vitro binding analysis. Taken together, we propose a possible activation mechanism of microtubule assembly by EB1, CLIP-170 and p150Glued.

Coordination of Microtubule Plus-End Binding Proteins

M. Raycroft, L. Casaletti, K. T. Vaughan; Department of Biological Sciences, University of Notre Dame, Notre Dame, IN

A growing number of microtubule binding proteins display some preference for the plus-ends of growing microtubules. Because these proteins are implicated in different functions, it remains unclear if plus-end localization reveals overlapping function or regulated microtubule binding. Focusing on the p150Glued subunit of dynactin, we used three approaches to perturb plus-end binding proteins and tested the impact on other members of this family. First we depleted p150Glued using siRNA and assessed the effect on EB1 and CLIP-170. Loss of p150Glued resulted in the loss of EB1 at plus-ends. Expression of p150Glued rescue constructs re-established plus-end labeling of both dynactin and EB1. This suggests that EB1 is somewhat dependent on dynactin for plus-end localization. To determine the order of plus-end binding, we coexpressed combinations of EB1, p150Glued and CLIP-170 and visualized GFP these proteins by live-cell imaging. Dual imaging during time-lapse microscopy revealed initial localization of EB1 to plus-ends, followed by p150Glued, followed by CLIP-170. This suggests an order of loading inconsistent with EB1 depending on p150Glued for binding. Finally we utilized mTOR manipulation to test for phosphorylation effects on plus-end binding. Inhibition of mTOR with rapamycin led to dramatic decoration of microtubules with EB1, but a loss of p150Glued from plus-ends. No effects on CLIP-170 were detected. Overexpression of active mTOR had the opposite effect; EB1 was lost from plus-ends, but p150Glued decorated microtubules along their lengths. To assess the basis of p150Glued modulation, we performed 2-D gel analysis on rapamycin-treated cells. Rapamycin increased the phosphorylation complexity of p150Glued consistent with phosphorylation at two sites. Together these results suggest that several key plus-end binding proteins influence each other and that phosphorylation is at the root of plus-end function.

2081

Microtubule Plus End Attachment to the Cell Cortex: Mechanisms and the Role in Vesicular Traffic

A. Akhmakova,1 I. Grigoriev,1 G. Lansbergen,1 S. Spangler,2 C. C. Hoogenraad,1 N. Galjart,1 F. Grosveld1; 1Department of Cell Biology and Genetics, Erasmus Medical Center, Rotterdam, The Netherlands, 2Department of Neuroscience, Erasmus Medical Center, Rotterdam, The Netherlands, 1KAN Research Institute, Kyoto, Japan

The organization of the microtubule network strongly depends on the interaction of microtubule tips with the cell cortex. In many types of mammalian cells, microtubule plus ends face the cell periphery and can be linked to the actin cytoskeleton or the plasma membrane by different plus end tracking proteins (+TIPs). One such microtubule-cortex attachment is formed by CLASPs - evolutionary conserved +TIPs - and the proteins LL5β and ELKS, which form relatively stable clusters at the cortex of HeLa cells and the leading edges of motile fibroblasts. Using RNA interference-mediated protein depletion we show that CLASPs, LL5β and ELKS are necessary to maintain the high density and stability of the microtubule network. We isolated additional protein components essential for the formation of LL5β-ELKS clusters with the aid of mass spectrometry-based approaches. We also investigated the function of the identified cortical complexes in vesicular transport. Since ELKS (also known as Rab6 Interacting Protein 2) binds directly to the small GTPase Rab6 (Monier et al., 2002, Traffic 3 (4), 289-97), we have focused our attention on the trafficking of Rab6-positive vesicles and found that ELKS is involved in catalysing the fusion of stable microtubules, suggesting Kif4 is necessary for microtubule stabilization. Endogenous Kif4 localized to the ends of stable microtubules while GFP-tagged Kif4 tracked the plus-ends of microtubules and accumulated at the
cell periphery where it might form part of a capping complex. Ki67 interacted with EB1 both by endogenous co-immunoprecipitation and directly by pull-down using recombinant proteins showing Ki67 interacts with other factors involved in microtubule stabilization. Together our results show that Ki67 contributes to microtubule stabilization and has properties consistent with it being part of a plus-end capping complex.

2083 Interactions between Microtubule Plus Ends and Dynein Cortical Receptor Numl in Budding Yeast

W. Lee; Biology Department, University of Massachusetts, Amherst, MA

Mitotic spindle positioning plays an essential role in determining where replicated chromosomes are deposited at the end of cell division. In the budding yeast S. cerevisiae, the site of division is at the bud neck, and a protein Num1 accumulates in patches along the membrane and this protein correlates with the point of attachment of microtubules that anchors the mitotic spindle. Genetic interactions and localization studies have indicated that Num1 functions as a receptor protein for dynein to mediate cortical sliding of microtubules in the dynein pathway of spindle positioning. Here, we have used one- and two-color time-lapse analyses to investigate microtubules and Num1 interactions during spindle movements. We observed that the plus end of a single cytoplasmic microtubule can stably attach to a Num1 patch at the cortex. Speckle analysis showed that microtubules can elongate at the plus end while remaining attached to Num1. To investigate components mediating microtubule attachment at Num1 patches, we used a split-ubiquitin two-hybrid assay to test for interactions between Num1 and dynein pathway candidates. We found that Num1 interacts with dynein HC/Dyn1, dynein LIC/Dyn3, dynactin Arp1, and a recently identified dynein pathway candidate Y1049w (Ye et al., 2005, Mol Syst Biol 1: 2005.0026). These results revealed a novel role for Num1 patches in microtubule capture, which may be a prerequisite step for cortical sliding of microtubules along the cortex.

2084 How Is Cell Polarity Intrinsically Acquired in Bacteria?

C. Jacobs-Wagner, H. Lam, W. Schofield, G. Ebersbach; Molecular, Cellular & Developmental Biology, Yale University, New Haven, CT

Cell polarity is one of the most fundamental principles in biology. It is now abundantly clear that even primitive organisms such as bacteria exhibit cell polarity. How bacterial cell polarity is acquired, translated into polarized cell functions, and transmitted to progeny remains largely unknown. The bacterium Caulobacter crescentus provide a good model system to address these questions because in this organism, cell polarity is readily apparent by the presence of polar organelles and by the asymmetric cell division which produces two daughter cells of different size, morphology and fate. Cell polarity is also important for regulatory proteins that couple development to the cell cycle. We have recently identified a cell polarity determinant (TipN) that serves as a spatial cue from the preceding cell cycle to set up the correct polarity of C. crescentus. Our findings suggest that TipN specifies the site of the most recent division by identifying the new pole. In the absence of the landmark protein TipN, the cells often misorient their polarity axis, resulting in misplacement of polarity markers. In addition, the division apparatus is often mispolarized in the absence of TipN, yielding progeny cells of reversed size asymmetry. Ectopic localization of TipN along the lateral side of the cell creates new axes of polarity as manifested by cell branch formation and occupation of competent cell poles at the ectopic TipN sites. Evidence suggests that TipN acts upstream of the bacterial actin homolog MreB in regulating cell polarity.

2085 Spatial Regulation of Exocytosis by Rho GTPases

P. Brennwald, O. Roumanie, H. Wu; Department of Cell and Developmental Biology, University of North Carolina, Chapel Hill, NC

Rho3 and Cdc42 are members of the Rho family of small GTPases in yeast and both proteins play important but distinct roles in regulating polarized growth. We have suggested a model by which these two GTPases function in exocytosis by locally activating the Exocyst complex at sites of polarized growth. We have previously shown that Cdc42 is critical to exocytic function during early bud emergence, when Cdc42 itself is highly polarized. In contrast, Rho3 appears to continue to function in regulation of exocytosis throughout bud growth. Consistent with its distinct function in exocytosis, we find that the localization of Rho3 is quite distinct from that of Cdc42; utilizing a novel mAb against Rho3, we find that Rho3 localization appears as dispersed plasma membrane staining which is not concentrated at bud tips of small budded cells. In order to understand the molecular basis for the specific functions and localization of these proteins in polarized exocytosis, we created chimeric forms of Rho3 and Cdc42 by exchanging specific regions within each GTPase. Surprisingly, we find that exchange of the N-terminal domain of Cdc42 with that of Rho3 will convert Cdc42 into a protein which fully complements a rho3 deletion. Localization studies on the chimeric proteins suggest that the N-terminal domain of Rho3 is both necessary and sufficient for the Rho3-like staining pattern strongly suggesting that the specific localization of Rho3 is critical to its function in exocytosis. Recent genetic analyses from our laboratory strongly support the notion that Rho3/Cdc42 engagement results in “activation” of the Exocyst complex in a manner that is similar to other well-characterized Rho-effector interactions. This suggests that the exocytic machinery has evolved in such a way that its intrinsic activity is highly sensitive to regulation by external spatial cues such as those generated by Rho/Cdc42 GTPases.

2086 Asymmetric Cell Division of Drosophila Neuroblasts

C. Q. Doe; Institute of Neuroscience, HHMI/University of Oregon, Eugene, OR

Drosophila neuroblasts have become an attractive system to investigate the establishment of cell polarity, the mechanism of spindle orientation, and the process of asymmetric cell division. I will first summarize work from many labs on neuroblast cell polarity and asymmetric cell division, and then focus on recent work from our lab on one or more of the following topics: (1) microtubule-induced cortical polarity via the kinesin heavy chain 73 (KHC73) pathway; (2) the role of a NuMA-like protein in aligning the mitotic spindle with the axis of cortical polarity; or (3) asymmetric cortical proteins such as Brain tumor (Brat), Prospero (Pros) and newly identified proteins that regulate neuroblast self-renewal.
Chromatin-based Signals Control Cortical Polarity during Mammalian Oocyte Meliotic Divisions

M. Deng, S. Praveen, R. Li; Stowers Institute for Medical Research, Kansas City, MO

Cortical polarity is critical for many developmental processes, such as directional cell migration and asymmetric cell division. Although in most systems, extra-cellular signals provide the cue for the establishment of cortical polarity, in mouse oocytes undergoing asymmetric meiotic divisions, the cue appears to come from the maternal chromosomes. Symmetry breaking occurs through migration of the chromosomes from the cell center to a subcortical region where significant cortical reassortments in preparation for polar body extrusion. We report here that the chromatin cues induce assembly of a cortical domain that is enriched in actin and Par3/aPKC polarity complex and surrounded by an actomyosin contractile ring during the metaphases of meiotic divisions. Remarkably, the chromatin-induced cortical fission can be fully reconstituted by cortical injection of DNA-coated beads into metaphase II-arrested eggs. The DNA beads induce polar actomyosin structure is dependent on the proximity of the beads to the cortex and number of beads injected. Microtubules are neither necessary nor sufficient for the DNA bead-induced cortical assembly. Instead, a Ran GTPase dependent pathway is required for the chromatin-cortex communication, as both the dominant negative and constitutively active Ran blocked the DNA-induced cortical response. Interestingly, myosin-II appears to be a critical effector of this signaling pathway, since blocking myosin-II assembly prevented the accumulation of actin filaments and Par3 at the polar cortex. Inhibition of myosin-II contractility, on the other hand, did not affect establishment of cortical polarity but prevented contractile ring formation. These results suggest that cortical polarity during mammalian oocyte maturation is governed by a unique chromatin-based signaling pathway that directly controls actomyosin cytoskeleton organization at the plasma membrane.

Myosin 19 (Myo19) Is a Novel Unconventional Myosin Involved in Mitochondrial Movements

O. A. Quinteiro,1 M. B. Kortan,1 K. M. Denefy,1 L. B. Case,1 A. J. Lier,2 R. E. Cheney2; Biology Department, Franklin and Marshall College, Lancaster, PA, 1Department of Cell and Molecular Physiology, University of North Carolina-Chapel Hill, Chapel Hill, NC

Mitochondria are central to many cellular functions. Though alterations in mitochondrial function have been implicated in a number diseases, little is known about the mechanisms by which vertebrate mitochondria are properly localized. Previous studies have shown that mitochondria move on both actin and microtubules in neuronal cells (R. Morris and PJ Hellenbeck, JCB, 1995), thus, until recently only microtubule motors have been identified in association with vertebrate mitochondria. We have identified a novel myosin, myosin 19 (Myo19), that we hypothesize is involved in mitochondrial motility. Antibodies against human Myo19 detect a protein of ~110kD in multiple cell lines, and also colocalize with MitoTracker via immunohistochemistry. Amino acids 866-912 are necessary but insufficient for mitochondrial localization, as GFP constructs that contain this region localize to mitochondria, but a GFP construct of this region alone fails to label mitochondria. Placement of the GFP tag at the c-terminus of the Myo19 tail construct fails to block localization to mitochondria, suggesting that Myo19 is not a tail-anchored mitochondrial outer membrane protein. However, FRAP suggests that Myo19 is tightly associated with mitochondria, as GFP-Myo19 constructs require several minutes to recover. In A549 cells, overexpression of full length GFP-Myo19 leads to a striking phenotype, resulting in cells where the majority of mitochondria are moving at velocities of approximately 80 μm/s, and these mitochondria taper with the leading end of the organelle wider than the trailing end. These movements were insensitive to 15μM nocodazole, but in the presence of 1μM cytochalasin D, the movements ceased, and the mitochondria lost their "tailpole" shape. In unindifferentiated CAD cells overexpressing GFP-Myo19, mitochondria could also be seen to move in the actin-rich lamella. These data suggest that Myo19 is an unconventional myosin involved in mitochondrial movements. Supported by a SRE postdoctoral training grant NIH/GM06078 to OAQ, and NIH/NIDCD DC03299 to REC.

Function of the C1 Inserted Isoform of Nonmuscle Myosin II-C in Tumor Cell Lines and Mice

S. S. Jana, R. S. Adelstein; Laboratory of Molecular Cardiology, National Institutes of Health, Bethesda, MD

Nonmuscle myosins IIIs play an important role during cytokinesis, cell migration and in establishing cellular polarity. Three isoforms of nonmuscle myosin heavy chain II (NMHC) have been identified in vertebrates, NMHC II-A, II-B and II-C. We report here on the role of an alternatively-spliced isoform, NMHC II-C1, which includes an α amino acid insertion in loop1 of NMHC II-C. We recently reported that expression of this isoform is markedly increased in a number of tumor cell lines and that inhibiting expression leads to a delay in cytokinesis, resulting in a decrease in cell proliferation in the A549 human lung tumor cell line (Jana et al. J. Biol. Chem. 2006 PMID: 16790446). We now report on a second tumor cell line showing increased expression of NMHC II-C1, the human breast cell line MCF-7. Unlike A549 cells which are adhesive to the underlying matrix, MCF-7 cells retain a rounded shape during cytokinesis and appear to be loosely attached to the surface. Decreasing NMHC II-C1 expression in MCF-7 cells leads to marked prolongation in a late stage of cytokinesis, from 3.5 to 5.5 h for control siRNA treated cells to 15-17 h for the NMHC II-C1 depleted cells, similar to our findings with A549 cells. This prolongation results in a 6-8 fold decrease in cell number at 120 h. Although A549 and MCF-7 cells differ morphologically during cytokinesis, in both cases inhibition of NMHC II-C1 leads to a delay in cell division. For in vivo studies of nonmuscle myosin II-C1 function we generated hypomorphic knockout mice using homologous recombination. These mice expressed decreased amounts of myosin II-C1 all of which lacked the C1-insert. Some of these mice show evidence for a cardiomyopathy as determined by echocardiography and histopathologic analysis. Of note is that expression of NMHC II-C1 in the heart is restricted to the embryonic stage.

Molecular and Functional Analysis on the Role of Myosin VI in Exocytic Membrane Trafficking Pathways

J. Au, C. Thut, D. Abraham, N. D. Ardell, J. Kendrich-Jones, F. Buss; MRC Laboratory of Molecular Biology, Cambridge, United Kingdom, 1Cambridge Institute of Medical Research, University of Cambridge, Cambridge, United Kingdom

The actin cytoskeleton and myosin motor proteins are essential for the efficient functioning of vesicular traffic and membrane dynamics. Myosin VI, the focus of our research, is a unique motor that moves backwards towards the minus end of actin filaments. We have localised myosin VI in a variety of different intracellular compartments including the Golgi complex and vesicles concentrating in the perinuclear area on the trans side of the Golgi. Our functional studies using siRNA knock down approaches, over expression of dominant negative myosin VI deletion constructs as well as stable cell lines derived from the myosin VI knock out mouse (Snell’s waltzer mouse) have established that myosin VI plays an important role in exocytic membrane trafficking pathways. In Snell’s waltzer fibroblasts myosin VI is required for efficient secretion of alkaline phosphatase (SEAP) to the plasma membrane and for the maintenance of Golgi morphology. In these non-polarised cells myosin VI is linked to the Golgi complex and to the secretory pathway by binding to optimin, which also binds the small GTPase Rab8. Myosin VI and Rab8 colocalise around the Golgi complex and in vesicles at the plasma membrane. Overexpression of constitutively active Rab8Q67L recruits myosin VI onto Rab8 positive structures. Therefore since we have shown that myosin VI in non-polarised cells is involved in the secretory pathway and is linked via optimin to Rab8, which is known to regulate basolateral transport in polarised epithelial cells, we are currently investigating the role of myosin VI in the sorting and delivery of newly synthesised proteins to the apical and basolateral domains in polarised MDCK cells.

A α-helical Domain of Melanophilin Is Essential for Myosin Va Recruitment and Melanosome Transport in Melanocytes

A. N. Hume,1 A. K. Taraldter,3 J. S. Ramalho,2 E. V. Sviderskaya,1 M. C. Seabra; 1Molecular and Cellular Medicine, Imperial College London, London, United Kingdom, 2Centre of Ophthalmology, University of Coimbra, Coimbra, Portugal, 3Department of Basic Medical Sciences, St. George’s, University of London, London, United Kingdom

Melanophilin (Mlp) regulates retention of melanosomes at the peripheral actin cytoskeleton of melanocytes, a process essential for normal mammalian pigmentation. Mlp has been proposed to be a modular protein the binding melanosome-associated protein Rab27a, Myosin Va (MyoVa), actin and microtubule end-binding protein (EB1), via distinct N-terminal Rab27a binding domain. The α-helical region together with R27BD and EFBD regions of Mlp play an important role during cytokinesis, cell migration and in establishing cell polarity. Three isoforms of nonmuscle myosin heavy chain II (NMHC) have been identified in vertebrates, NMHC II-A, II-B and II-C. Here we report on the role of an alternatively-spliced isoform, NMHC II-C1, which includes an α amino acid insertion in loop1 of NMHC II-C. We recently reported that expression of this isoform is markedly increased in a number of tumor cell lines and that inhibiting expression leads to a delay in cytokinesis, resulting in a decrease in cell proliferation in the A549 human lung tumor cell line (Jana et al. J. Biol. Chem. 2006 PMID: 16790446). We now report on a second tumor cell line showing increased expression of NMHC II-C1, the human breast cell line MCF-7. Unlike A549 cells which are adhesive to the underlying matrix, MCF-7 cells retain a rounded shape during cytokinesis and appear to be loosely attached to the surface. Decreasing NMHC II-C1 expression in MCF-7 cells leads to marked prolongation in a late stage of cytokinesis, from 3.5 to 5.5 h for control siRNA treated cells to 15-17 h for the NMHC II-C1 depleted cells, similar to our findings with A549 cells. This prolongation results in a 6-8 fold decrease in cell number at 120 h. Although A549 and MCF-7 cells differ morphologically during cytokinesis, in both cases inhibition of NMHC II-C1 leads to a delay in cell division. For in vivo studies of nonmuscle myosin II-C1 function we generated hypomorphic knockout mice using homologous recombination. These mice expressed decreased amounts of myosin II-C1 all of which lacked the C1-insert. Some of these mice show evidence for a cardiomyopathy as determined by echocardiography and histopathologic analysis. Of note is that expression of NMHC II-C1 in the heart is restricted to the embryonic stage.

Localization of Myosin to the Cleavage Furrow of Drosophila S2 Cells in the Absence of Cortical Flow

R. Vale, M. Zuccollo, M. Bettencourt-Dias, G. Goshima, J. Spudich; Physiology Course 2006, Marine Biological Laboratory, Woods Hole, MA
The localization of myosin to the cleavage furrow establishes the contractile machinery for cell division. The most widely cited hypothesis for how myosin relocates during the metaphase-anaphase transition is that cortical flow drives myosin filaments from the poles to the equatorial region. Here, we have investigated the mechanism of myosin localization during cytokinesis by visualizing myosin (regulatory light chain fused to GFP) in *Drosophila* S2 cells spread on concanavalin A coated surfaces using total internal reflection microscopy. By this method, single myosin filaments on the cortex can be imaged and tracked with time. During interphase, prominent actin-mediated retrograde flow of myosin filaments is observed. However, when myosin is accumulating at the cleavage furrow during anaphase, we find that cortical myosin filaments are largely stationary and do not flow towards the equatorial region. Instead, the accumulation of myosin at the cleavage furrow results from two processes. First, cortical myosin filaments rapidly disappear from beneath the centrosomes as they separate during anaphase B, causing the depletion of myosin from the poles. This process does not require conventional asters, as centrosomal poles (created by centrosomin RNAi) separating during anaphase also caused the disappearance of myosin filaments, resulting in a normal timing of cytokinesis. A similar result was observed with 3-D sectioning of dividing S2 cells by spinning disk confocal microscopy. Second, after the depletion of myosin filaments at the poles had begun, new myosin filaments appeared at the equator, a process that was correlated with the appearance of stable microtubules at the equatorial cortex (observed by TIRF microscopy of Cherry-tubulin). Our observations suggest that high densities of dynamic microtubules cause the disassembly of myosin filaments, while low densities of dynamic microtubules coupled with the formation of stable microtubules promote the stabilization and potentially active transport of myosin filaments to the equatorial cortex.
An essential aspect of nervous system development is the extension of axons, which find their correct partners and form synapses, enabling neurons to communicate. Although the actin and microtubule cytoskeletons are crucial to nervous system development and stability, their roles in axon growth and maintenance are not fully understood. Another class of cytoskeletal filament-forming proteins, the septin family of GTP-binding proteins, is demonstrated to interact with both the actin and microtubule cytoskeletons. Furthermore, septins are implicated in neurodegenerative diseases, including Parkinson's and Alzheimer's diseases. Understanding how septins function in neurons is therefore critical to understanding axonal dynamics in the developing nervous system and in disease. We recently described a novel role for the only two worm septins, UNC-59 and UNC-61, in ventral cord motor neuron axon migration. To further define the role of septins in the nervous system, we are using primary cultures of C. elegans embryonic neurons as a system where cell biological analysis can be combined with the powerful genetics of this model system. Additionally, the simplicity of the worm septin system gives C. elegans a clear advantage over other animal systems for the dissection of basic, conserved septin functions in animals. We find that neurons cultured from septin mutant embryos are defective in extension of processes, and that they display abnormalities in both their actin and microtubule cytoskeletons, suggesting that septins may regulate neuronal cytoskeleton assembly. Using RNAi directed against each septin, we observe defects in process outgrowth and maintenance. Furthermore, a drug reported to affect septin organization causes a rapid, reversible loss of neuronal processes in cultured neurons, and results in uncoordinated locomotion of treated worms. We hypothesize that septins are involved in establishment and maintenance of the axonal cytoskeleton, which is necessary for axon outgrowth and stability.

Inhibition of Integrin Signaling by Amino-Nogo
F. Hu, S. Siritrimitr; Neuroscience, Yale University School of Medicine, New Haven, CT

Nogo is a myelin-derived protein that limits axonal regeneration after CNS injury. A short hydrophilic Nogo-66 loop between two hydrophobic domains of Nogo binds to NgR to inhibit axon outgrowth. A second Nogo domain, termed Amino-Nogo, inhibits axon outgrowth and cell adhesion through unknown mechanisms. Here we present evidence indicating that Amino-Nogo inhibits integrin signaling. Adhesion of COS-7 cells to fibronectin but not laminin or collagen is inhibited by Amino-Nogo, suggesting that Amino-Nogo affects the function of a certain subset of integrins. Amino-Nogo inhibition can be partially overcome by antibodies that activate integrin β1. Furthermore, FAK activation in response to fibronectin dependent adhesion is reduced in the presence of Amino-Nogo. Analysis of responses of various cell lines to Amino-Nogo revealed that αvβ3, αvβ5 and αvβ integrins are inhibited by Amino-Nogo. The inhibition of neuronal outgrowth by Amino-Nogo is modulated by the ECM substrates, suggesting that Amino-Nogo inhibition of axon outgrowth also involves inhibition of integrin signaling. Amino-Nogo inhibition of both cell adhesion and axon outgrowth can be overcome by the addition of Mn2+, a known activator of integrins. All these data indicate that perturbation of integrin signaling is a crucial aspect of Amino-Nogo inhibition.

TGFβ Signaling Suppresses Axon Growth Ability in Sensory Neurons
Y. Chen,1 K. Liu,2 G. Yiu,1 H. Hasegawa,3 A. K. Wagner,3 S. Kaneko,1 K. Kuwako,1 M. Kaneko,1 Y. Zhang,5 F. Wang,2 Z. He,1 Division of Neuroscience, Children's Hospital, Harvard Medical School, Boston, MA, 2Department of Cell Biology, Duke University Medical Center, Durham, NC, 3Laboratory of Cellular and Molecular Biology, Center for Cancer Research, NCI, National Institutes of Health, Bethesda, MD

The failure of injured axons to regenerate in the adult central nervous system (CNS) has been partly attributed to the diminished ability of mature axons to regrow after injury. The mechanisms responsible for this decline in intrinsic regenerative capacity over the course of development, however, remain largely unknown. In this study, we find that dorsal root ganglion (DRG) sensory neurons exhibit a gradual age-dependent decrease in axonal elongation ability after their peripheral branches have established contacts with targets such as the skin. We further show that activation of FAK that are expressed in skin tissues could reduce axon elongation ability in both embryonic and adult DRG neurons through a canonical Smad signaling pathway. Interruption of the retrograde transport of target-derived signals by a signal from peripheral axons, which can promote axonal regeneration in axotomized neurons, also inactivates this pathway in the adult. Furthermore, local administration of a TGFβ inhibitor increases the axonal growth ability of the adult DRG neurons. Thus, our results suggest that the age-dependent loss of intrinsic axonal growth capacity is at least in part triggered by target-derived activin/TGFβ signaling, pointing to a novel direction for designing therapeutic strategies to promote axonal regeneration after neural injury.

Deriving Insulin-producing Cells from the Embryonic Progenitor for Treatment of Type 1 Diabetes
G. Li,1 R. Luo,1 F. Xie,1 J. Zhang,1 O. L. Kon,2 M. Salto-Tellez,2 S. K. Lim,3 1National University Medical Institutes, National University of Singapore, NUS, Singapore, 2Division of Medical Sciences, National Cancer Centre, Singapore, Singapore, 3Dept of Pathology, National University of Singapore, NUS, Singapore, 4Stem Cell Biology, Genomic Institute of Singapore, Singapore, Singapore

Limited supply of cadaveric pancreata has restricted the therapeutic application of transplantation of human pancreatic islets for treatment of type 1 diabetes. Therefore, alternative sources and concomitantly the LacZ reporter gene. Neural-derived, LacZ-positive cells expressed mammary-specific functions including milk protein synthesis in secretory acini. Some adopted epithelial outgrowths suggests the following scenario: mammary epithelial cells recombine to assemble growth-competent cellular microenvironments, chimeras are formed which include neural stem cells; development proceeds. The neural cells not only contribute significantly to mammary growth but also facilitate during pregnancy activating the WAP-Cre gene and concomitantly the LacZ reporter gene. Neural-derived, LacZ-positive cells expressed mammary-specific functions including milk protein synthesis in secretory acini. Some adopted

MicroRNA-mediated Control of Stem Cell Specification and Function in Arabidopsis thaliana
M. Barton; Carnegie Institution of Washington, Stanford, CA

Land plants rely heavily on stem cells for the generation of new leaf, stem and root segments. The stem cells are principally found within apical meristems located at the tips of roots and shoots. In the shoot apical meristem, stem cell descendants are pushed outward, where they participate in leaf primordium formation, or downward, where they participate in stem formation. The PINHEAD gene is required for efficient meristem formation and, when its expression is artificially shifted within the shoot apex, can cause the formation of extra, ectopic meristems. PINHEAD is a member of the ARBOGATA family of genes and therefore acts to mediate microRNA-directed regulation of target RNAs. Enhancers of the pinhead mutant phenotype have profound effects on meristem formation but these effects vary. Some enhancers cause scores of new meristems to develop from the stem surface while others cause the main shoot apical meristem to become greatly enlarged. The molecular identification of these enhancers and studies of their effects on targeted RNAs will be discussed.

The Mammary Stem Cell Niche Modifies Neural Stem Cell Repertoire
C. A. Boulanger,1 A. Androutsellis-Theotokis,2 B. W. Booth,1 D. L. Mack,1 R. McKay,2 G. H. Smith,1 NCI, NIH, Bethesda, MD, 2NINDS, NIH, Bethesda, MD

Evidence for somatic stem cell niches has been clearly defined in several biological systems. To determine if stem cells from other organs would conform to signals from the mouse mammary gland environment, we mixed wild type mammary epithelial cells with bona fide neural stem cells isolated from a WAP-Cre/R26R embryo at a 1:1 ratio and inoculated them into the cleared inguinal fat pads of immune-compromised Nu/Nu female hosts. The host mice were bred 6-8 weeks later and examined 20-30 days post inoculation. This approach allowed for growth of mammary tissue, transient activation of the WAP-Cre gene, recombination and constitutive expression of LacZ from the Rosa 26 promoter. Whole mount analysis was done on the inguinal glands from the injected mice. Neural-derived cells were LacZ-positive in chimeric mammary glands and contributed robustly to the outgrowth. No LacZ-positive cells were observed in epithelial outgrowths collected from non-breeding hosts indicating that pregnancy was essential for activation. The presence of neural-derived cells in significant numbers throughout mammary glands from the injected mice. Neural-derived cells were LacZ-positive in chimeric mammary glands and contributed robustly to the outgrowth. No LacZ-positive cells were observed in
myoepithelial cell fates. We conclude that neural stem cells capable of self-renewal and multiple cell fates, enter mammary epithelium-specific niches and adopt the function of similarly endowed mammary cells. These results imply the tissue-dominance of stem cell niches.

A Role for esgarcot in Stem Cell Niche Maintenance
J. Voog, 1 G. Hime, 2 M. Rocha, 1 M. Boyle, 1 M. T. Fuller, 1 L. Jones; 1 Laboratory of Genetics, The Salk Institute for Biological Studies, La Jolla, CA, 2 Department of Anatomy and Cell Biology/ARC Centre for Excellence in Biotechnology and Development, University of Queensland, Melbourne, Australia, 3 Departments of Developmental Biology and Genetics, Stanford University School of Medicine, Stanford, CA

Upon cell division, adult stem cells can generate both daughter stem cells (self-renewal) and cells that differentiate along a specific lineage. Removal of stem cells from their regulatory microenvironment, or niche, often results in loss of the capacity to self-renew, suggesting that niches play a major role in regulating stem cell fate. The somatic apical hub at the tip of the Drosophila testis is a primary component of the male germ-line stem cell niche. Hub cells secrete the ligand Unpaired (Upd), which activates the JAK-STAT pathway in adjacent germine stem cells (GSCs) to specify stem cell self-renewal. We have characterized an allele of the Snail family transcriptional repressor esgarcot called shutoff (sho). In adult esgarcot males we observe a loss of multiple hub cell markers, GSCs, and somatic cyst progenitor cells (PCPs). Loss of expression of upd and shothor (sho), the gene that encodes DE-cadherin, was observed in esgarcot testes from larval (L3) males. These findings suggest that hub cells may be lost and niche function compromised during development in esgarcot males. Previous work has demonstrated DE-cadherin expression is necessary for stem cell maintenance and anchorage to niche support cells. We hypothesize that stem cell loss in esgarcot males is due to loss of DE-cadherin expression between hub cells and between hub cells and stem cells. Germ-line stem cell clones homozygous mutant for sho were not capable of long-term self-renewal, supporting the thought that DE-cadherin expression is necessary for stem cell maintenance. In Drosophila, esgarcot has been shown to act genetically upstream of sho in the trachea. Mammalian Snail family members have also been shown to directly regulate E-cadherin expression. We then hypothesize that esg regulates sho expression within hub cells. This work suggests a genetic program exists which regulates maintenance of the Drosophila germ-line stem cell niche.

Live Cell Imaging of Interactions between Hematopoietic Progenitor Cells and Osteoblastic Cells
J. M. Gillette, 1 F. Pruefer, 2 J. Zhou, 2 J. Lippincott-Schwartz; 1 Laboratory of Genetics, The Salk Institute for Biological Studies, La Jolla, CA

Hematopoietic stem cells localize to a complex niche within the bone marrow where they interact specifically with the bone forming osteoblasts. Despite knowledge of the importance of osteoblast contact for hematopoietic stem cell maintenance, how hematopoietic progenitor cells find osteoblasts within this microenvironment and what role the ensuing interaction between these cells plays in hematopoietic stem cell renewal and differentiation is not well understood. Here, we investigate the cellular and molecular interactions that occur between hematopoietic progenitor and osteoblastic cells using live-cell imaging techniques. KG1a and primary CD34+ hematopoietic progenitor cells were used in co-cultured experiments with osteoblastic cells. Through microscopy techniques, we observed a dynamic, amoeboid motility by the progenitor cells that was directed to the osteoblastic cells. The progenitor cells formed a specialized uropod domain that was enriched in lipid raft molecules (GPI-GFP and the cholera toxin B subunit) and served as the contact point between the progenitor and osteoblastic cells. Additionally, stem cell markers CD34 and CD133 were found to coalesce at the uropod contact site along with quantum dot nanocrystals. The quantum dots localized specifically at the cell surface of the progenitor cell uropod and could be disrupted by cholesterol sequestration. Remarkably, the quantum dot loaded uropod appeared to transfer and be taken up by the osteoblasts and preliminary interaction and may implicate a potential signaling mechanism mediated by the release and/or up-take of specific proteins within the hematopoietic/osteoblastic niche. Future studies will be directed at determining the mechanism of this molecular transfer and the potential downstream functions of this cell-cell interaction.

Transcriptional Regulation of Cxcl12 and Stem Cell Engraftment during Wound Repair
K. A. Mace, N. Boudreau, D. M. Young; University of California San Francisco, San Francisco, CA

Adult stem cell migration, engrafment and differentiation in response to injury, is a tightly regulated process, although the mechanisms controlling the role of stem cells in wound repair and regeneration are largely unknown. Previously we have demonstrated that the HOXA3 transcription factor functions during wound repair to promote cell migration and angiogenesis, in part by regulating genes such as urokinase plasminogen activator receptor (upAR), which mediates extra cellular matrix remodeling. Microarray analysis of genes expressed during HOXA3-mediated wound repair revealed that Cxcl12 is also regulated by HOX A3. Cxcl12 is a cytokine that mediates incorporation of bone marrow derived cells (BMDCs) into injured tissue. In particular, Cxcl12 has been shown to recruit endothelial cell precursors to sites of angiogenesis. Our preliminary data suggests that HOX A3 function may enhance BMDC incorporation into injured tissue. Analysis of GFP bone marrow chimeras will be presented to evaluate the role of HOX A3 in the wound microenvironment and its impact on recruitment and engrafment of circulating BMDCs.

The EphB4 Receptor Tyrosine Kinase as an Inhibitor of Breast Cancer Cell Tumorigenicity
N. K. Noren, G. Foss, C. A. Hauser, E. B. Pasquale; Burnham Institute for Medical Research, La Jolla, CA

Recent evidence suggests that EphB receptor tyrosine kinases have a tumor suppressor role in colorectal and prostate cancer. This is an activity that is unlike other families of receptor tyrosine kinases, which generally promote tumorigenesis. Here we report that the EphB4 receptor can act as a tumor suppressor in breast cancer when activated by its ligand, ephrin-B2. Activation of EphB4 in vivo by soluble ephrin-B2 Fc inhibits the growth of tumors in a mouse xenograft model of breast cancer. Furthermore, we have identified a novel Eph receptor signaling pathway involving the Abl family of tyrosine kinases. Through Abl-mediated phosphorylation and inactivation of the adaptor protein Crk, ligand-activated EphB4 inhibits cell viability and growth as well as cell migration and invasion. Additionally, EphB4 downregulates expression of the pro-invasive matrix metalloprotease MMP-2, which is a metalloprotease that has been correlated with a poor breast cancer prognosis. Consistent with these effects, in non-transformed mammary epithelial cells EphB4-ephrin-B2 interaction maintains high Abl activity and Crk phosphorylation. In these cells, EphB4 and ephrin-B2 are localized to cell-cell junctions and disruption of their interaction disturbs EphB4 and ephrin-B2 localization and the integrity of cell-cell junctions. Furthermore, reduced EphB4 signaling induces some characteristics of cell transformation. These data suggest that the EphB4-Abl-Crk pathway promotes an epithelial phenotype in normal cells and suppresses tumorigenesis in breast cancer cells.

Ezrin Promotes Src-dependent Functions Associated with Malignancy
L. Heisku, 1 F. Zhao, 1 I. Saotome, 2 A. I. McClatchey, 3 O. Carpen; 1 Department of Pathology, University of Helsinki, Helsinki, Finland, 2 MGH Cancer Center and Harvard Medical School of Pathology, Charlestown, MA, 3 Department of Pathology, University of Turku and Turku University Hospital, Turku, Finland

Ezrin, a linker molecule between plasma membrane and actin cytoskeleton, has been associated to tumorigenesis and metastatic processes with unknown mechanisms. It is implicated e.g. in PTEN and Rho signalling pathways. Ezrin is a known target for oncogenic Src kinase, and both proteins are elevated or activated particularly in advanced cancers and metastases. To elucidate ezrin’s role in oncogenesis, we employed embryonic fibroblasts (MEFs) from the ezrin knock-out mouse to take advantage of a model without endogenous ezrin expression. To dissect Src-dependent functions, constitutively active Src was expressed. While the introduction of wild-type ezrin to ezrin-/MEFs expressing active Src had no effect on cell behaviour in normal growth conditions, it promoted malignant phenotype in three-dimensional growth conditions, i.e. cell growth and invasion in Matrigel. In addition, wild-type ezrin promoted cell growth in suspension. Upon reversion of the Src target amino acid on ezrin was mutated to phenylalanine, expression of the mutant ezrin protein did not provide cells any selective advantage compared to the parent MEFs. Moreover, when the cells were grown inside Matrigel, wild-type ezrin was locally concentrated to patches or specific regions on the membrane, whereas mutated ezrin was diffusely distributed. The data indicate that Src-dependent ezrin phosphorylation has a specific role in three-dimensional environment which is possibly linked to tumorigenesis and metastasis formation.
Activation of Hepatocyte Growth Factor/c-Met Signaling Contributes to Genomic Instability via Centrosome Hyperamplification and/or Changes in Mitotic Kinases

H. Nam,1,2 Y. Park,1,2 L. Min-woo,1,2 J. Lee1,2; 1Biochemistry and Molecular Biology, Ajou University School of Medicine, Suwon, Republic of Korea, 2Chronic Inflammatory Disease Research Center, Ajou Research Institute, Suwon, Republic of Korea

Genomic instability is accepted as one of the main pathways in human carcinogenesis. Since aberrant HGF/c-Met signaling has been known to cause human cancers, we have examined whether activation of HGF/c-Met signaling causes genomic instability. In order to address this question, we have established cells with constitutive HGF/c-Met signaling by transfection with M1268T mutant of Met. Indeed, in both stably and transiently M1268T expressing cells, increase in the cell population showing too few or too many chromosomes was observed. In addition, centrosome hyperamplification and increase in multinucleated cells were observed, evidencing positive effect of HGF/c-Met signaling in causing genomic instability. Among the possible down-stream signaling molecules, phospho-Erk and phospho-Akt levels were elevated in M1268T expressing cells compared to mock-transfected cells. LY294002, a PI3K inhibitor, but not U0126, an MEK inhibitor, could abolish both centrosome hyperamplification and multinucleated cell generation. Moreover, transfection with either dominant-negative Akt mutant or pTEN clearly inhibited both phenotypes whereas those were increased by WT-Akt overexpression, suggesting that activation of PI3K-Akt axis is both necessary and sufficient. Therefore, it is demonstrated that constitutive HGF/c-Met signaling induces the centrosome hyperamplification and the increase of aneuploidy cells via PI3K pathway. Interestingly, constitutive activation of HGF/c-Met signaling also resulted in the changes in expression and/or activity of some mitotic kinases. In M1268T expressing cells, the amount and activity of Aurora-A kinase increased while activity of Aurora-B kinase decreased. The changes in these kinases might induce genomic instability through aberrant mitosis via centrosome hyperamplification and/or obliteration of check point activity based on previous reports. In conclusion, abnormal HGF/c-Met signaling induces genomic instability through means of centrosome hyperamplification via PI3K pathway as well as changes in expression and activity of Aurora-A and Aurora-B kinases.

Identification of Statmin as a Novel Substrate of Aurora-A

J. D. Wu; Division of Cancer Research, National Health Research Institutes, Taipei, Taiwan

Identification of the downstream substrate of a protein kinase is an essential step to provide better understanding of its uncharted functions. We have previously identified several potential substrates for Aurora-A protein kinase via small pool screening. By using alanine-scanning mutagenesis of three peptides substrates of Aurora-A, we demonstrate that [K/R]-X-[S/T]-[I/L/V] are the substrate specificity determinants for Aurora-A, similar to PKA. This finding raises the possibility that Aurora-A and PKA might phosphorylate a subset of common mitotic targets. Moreover, phosphorylation sites of centrosome proteins were identified at two different criteria, overexpression in cancer cells and location in centrosome and mitotic spindle, were used to prioritize the potential targets, resulting in the identification of statmin as one of the potential substrates of Aurora-A. In vitro kinase assay reveal that both Aurora-A and PKA phosphorylate statmin at the same sites. Overexpression or knockdown Aurora-A affects the phosphorylation status of statmin-Ser13 at mitotic phase. Finally, Aurora-A might cooperate with Statmin to against Taxol-induced alpha-tubulin polymerization. Together, this systematic search for the downstream substrates and substrate specificity determinants of Aurora-A protein kinase may provide novel insights toward the functionality study of Aurora-A.

The Ring Finger Domain of MDM2 Is Essential for MDM2 Mediated TGF-β Resistance

C. Kannemeier, R. Liao, P. Sun; Molecular Biology, The Scripps Research Institute, La Jolla, CA

TGF-β is a multifunctional cytokine that inhibits the proliferation of normal and early-stage tumor cells. TGF-β induced growth inhibition is frequently evaded in late-stage, metastatic tumors with increased production of TGF-β, resulting in enhanced malignancy due to the pro-metastatic functions of TGF-β. We have shown previously that increased expression of MDM2 is a potential genetic alteration that leads to resistance to TGF-β induced growth arrest in tumor cells. In the current study, we attempted to gain insights into the molecular mechanism underlying MDM2 mediated TGF-β resistance. Our results demonstrated that MDM2 rendered cells refractory to TGF-β by overcoming a TGF-β induced G1 cell cycle arrest. In addition, since the TGF-β resistant phenotype was reversible upon the removal of MDM2, MDM2 was likely to confer TGF-β resistance by directly targeting the cellular machinery involved in the growth inhibition by TGF-β, rather than by promoting secondary mutations that in turn cause the resistance. Investigation of the structure-function relationship of MDM2 revealed three elements that were essential for MDM2 to confer TGF-β resistance, the C-terminal half of the p53 binding domain, the nuclear localization of MDM2 and the zinc coordination residues involved in the E3 ubiquitin protein ligase activity of the RING finger domain. In contrast, the interaction of MDM2 with B5, p21/WAF1, p19/p14ARF and ribosomal protein L5 was not required for TGF-β resistance. The ability of MDM2 to bind to nucleotides and RNA was also dispensable. Furthermore, MDM2 mediated TGF-β resistance could be uncoupled with its ability to inactivate p53, suggesting that MDM2 might confer TGF-β resistance through a p53 independent mechanism.

Mdm2/p53 Interaction Studied Using a Novel Self-labeling Protein Tag

K. Muenter,1 S. Roesti,1 L. Gedge,1 A. Brecht,2 T. Gibbs1; 1Marketing, Covalys Biosciences AG, Witterswil, Switzerland, 2R and D, Covalys Biosciences AG, Witterswil, Switzerland

In living cells DNA damage causes an increase in p53 levels and stabilizes the protein which contributes to cessation of cell growth, senescence and apoptosis. Inactivation of p53 is a common feature of transformed cells leading to unregulated cell proliferation, thus it presents a pharmaceutical target of considerable interest. Mdm2 (p53 specific E3 ubiquitin ligase) is the chief cellular antagonist of p53. Monoubiquitination of p53 by mdm2 targets p53 for degradation by the proteasome. In its turn p53 activation also induces mdm2 expression. We present the use of a novel protein-tag, the SNAP-tag, to study p53/mdm2 localization and interactions. This protein tag labels itself covalently and stably with a wide range of benzyl guanine-derived substrates carrying fluorescent or affinity labels. Using this approach, SNAP-mdm2 could be labeled with a cell-permeable fluorescent substrate and was shown to localize to the nucleus. The ability to decouple expression of the fusion protein and labeling permits approaches such as pulse chase imaging to follow successive generations of the fusion protein population using a sequential labeling approach. Elucidation of interacting protein complexes allows candidate interacting proteins to be evaluated in downstream functional assays. Recombinant SNAP-p53 could be rapidly covalently coupled to benzyl guanine coated Sepharose resin in physiological conditions for use as a bait to pull down Mdm2. Having confirmed interaction by pull down, the p53/Mdm2 interaction could then be characterized further using a TR-FRET interaction assay. This self-labeling SNAP-tag approach permits a whole program of experiments using labeled p53 ranging from localization to interaction studies. This should facilitate identification of potential modulators of the p53/mdm2 interaction.

Cyclin-dependent Kinase p16/INK4A Rescue of Neoplastic Phenotype in Canine Mammary Tumor Cells

R. Bird, P. Delmonocete, P. Agarwall; Pathobiology, Auburn University, Auburn, AL

Spontaneous canine mammary cancer (CMC) is the most common malignancy of dogs and a highly homologous model of human breast cancer. We developed a well characterized panel of cell lines independently derived from neoplastic canine mammary carcinomas. Analysis of gene expression associated with neoplastic potential and loss of proliferative control revealed frequent defects in 2 tumor suppressor genes: p16/INK4A and p53. p16/INK4A expression is defective in 2 CMT cell lines (no mRNA detected by rt-PCR), with or without concomitant p53 defects, and abundant in a third CMT cell line. Phenotype rescue was attempted by transfecting human p16/INK4A cDNA, in expression constructs (3 Modiano), into CMT cell lines followed by

2006 ASCB Annual Meeting Abstracts
G418/neo selection, single cell cloning by cell sorting into 96-well plates and p16/INK4A expression analysis. Transfected cell clones (3-5 per parental CMT cell line) were selected for analysis of characteristics typical of neoplastic transformation. Clones with reduced growth rates were recovered only from CMT cells lacking p16/INK4A. Cell cycle phase distribution was only slightly altered including some reduction in G1 phase fraction in p16/INK4A-transfected cells with reduced growth rates. Many of the clones with reduced growth rates also reacquired substrate-dependent growth as assayed on soft-agar plates. At least 1 CMT clone also became senescent/post-proliferative by ~25 passages post-transfection. Changes in morphology were also observed consistent with rescue of the transformed phenotype. This data suggests multiple mechanisms by which p16/INK4A expression influences exit/entry pathways and kinetic rate of the cell cycle, promotion of the differentiated phenotype and cellular senescence. Data suggests that each of these characteristics strongly influences neoplastic transformation and many characteristics can be rescued independently. Thus, p16/INK4A offers a promising therapeutic target that contributes to multiple pathways promoting the transformed and immortalized phenotype in this spontaneous model of breast cancer. (Supported by NIH & Scott-Ritchey Research Center)

Comparative Analysis of In Situ DNA Binding Sites of p53 and p73 in Response to Hydroxyurea

V. Huang, Y. Kwon, Y. Jiang, X. Fu, Y. J. Wang; Division of Biological Sciences and Moores Cancer Center, University of California, San Diego, La Jolla, CA, 2School of Medicine, University of California, San Diego, La Jolla, CA

The p53 gene family regulates DNA repair, cell cycle checkpoints and apoptosis in response to stress signals. The three members of the p53-family - p53, p63 and p73 encode sequence-specific transcription factors which share significant identity in their DNA binding domains. However, phenotypic defects of the p53, p63 and p73 knockout mice suggest that they may regulate similar and distinct sets of genes. In this study, we have compared the promoter occupancy profiles of p53 and p73 in a human colorectal cancer cell line that does not express p53. The in situ binding sites of p53 and p73 were examined in response to hydroxyurea (HU) using a modified chromatin immunoprecipitation (ChIP) and oligonucleotide-based microarray analysis, or ChIP-DNA Selection and Ligation (DSL) technology. The ChIP-DSL technology has significantly improved the conventional ChIP-chip assay in terms of sensitivity and specificity. Analysis was performed under steady state conditions and after exposure to HU, which caused a three-fold increase in the levels of p53 and p73 protein. Of the ~2000 human promoters surveyed, we found 166 and 148 binding sites constitutively occupied by p53 and p73, respectively. ~50% of these binding sites are occupied by both p53 and p73. Our current results suggest that p53 and p73 constitutively co-occupy a large number of promoters in the absence of DNA damage. Following HU treatment, we found no significant change in the overall promoter occupancy profiles where ~80% of the binding sites remained bound by either p53 or p73. Functional studies by siRNA-mediated knockdown of p53 or p73 suggest that constitutive transcriptional activity of promoters co-occupied by p53 and p73 is regulated mostly by p53. Taken together, these findings support the mouse genetic studies to suggest that p53 and p73 have overlapping as well as non-redundant functions.

2117

Identification of a Novel p53 Target Gene Rad

B. Hsiao, T. Chang, F. Wang; Institute of Biochemistry and Molecular Biology, Yang-Ming University, Taipei City, Taiwan

The tumor suppressor p53 is a guardian of genome that elicits cell cycle arrest, apoptosis and DNA repair in stressed cells. The ability of p53 to prevent tumorigenesis is primarily mediated by many of its transcriptional target genes. To identify novel p53-regulated genes, we have established H1299 human lung cancer cells stably expressing a temperature-sensitive p53 gene. By conducting p53 ChIP DNA microarrays at permissive temperature, we have identified the Rad GTPase as a novel p53-activated gene. Rad belongs to the superfamily of Ras GTase and was first identified as a protein overexpressed in the muscle of type II diabetic patients. Expression of Rad has been reported to inhibit insulin-stimulated glucose uptake in cells and reduce plasma triglyceride levels in mice. It has been shown that Rad associates with Rho kinase ROCK and negatively influence Rho signaling. Here we show that ectopic expression of p53 increased Rad mRNA levels, elevation of Rad expression was also found in cells harboring wild type p53 exposed to DNA damaging agents, such as UV and mitomycin C. By transfection luciferase assay, we identified that nucleotides -2934 to -2904 relative to the translation start site of the Rad promoter conferred the responsiveness, this region was further shown to complex with p53 in the gel mobility shift assay. Chromatin immunoprecipitation assay (Chip) verified the binding of p53 to Rad promoter in cells overexpressing p53 or treated with adriamycin. Together our results clearly show that Rad is a direct transcriptional target of p53.

2118

SUMO-specific Protease SUSP4 Positively Regulates p53 by Promoting Self-Ubiquitination of Mdm2

M. H. Lee, Y. J. Jeon, J. E. Kwon, G. R. Kim, O. S. Bang, C. H. Chung; School of Biological Sciences, Seoul National University, Seoul, Republic of Korea

Tight regulation of the p53 protein level is essential for its activity in controlling cell growth, maintaining genome integrity, and responding to stresses. Mdm2 is an ubiquitin ligase that targets p53 for degradation by the proteasome. Here we isolate a new SUMO-specific protease SUSP4 that specifically removes SUMO-1 from Mdm2 and identified a novel cascade for the increase in p53 level by UV damage. Desumoylation of Mdm2 by SUSP4 has enhanced its self-ubiquitination and subsequent degradation by the proteasome, leading to stabilization of p53 and promotion of its transcriptional activity. Overexpression of SUSP4 caused cell growth inhibition, while knockdown of SUSP4 by RNA interference led to promotion of cell growth. Intriguingly, UV damage induced SUSP4 expression, leading to an increase in p53 level in parallel with a decrease in Mdm2 level. These findings establish a new mechanism for the elevation of cellular p53 level in response to UV damage.

2119

Nucleostemin, a Stem Cell-expressed Protein, Localizes with the TumorSuppressor Arf in the Nucleolus and Modulates p53 in the Nucleoplasm

H. Ma, T. Pederson; Biochemistry and Molecular Pharmacology, UMass Medical School, Worcester, MA

Nucleostemin (NS) is highly expressed in adult and embryo-derived stem cells, as well as in some tumor cell lines. NS is concentrated in nucleoli but dynamically exchanges with the nucleoplasm where it binds the tumor suppressor p53. Within the nucleolus, NS occupies regions distinct from those where nascent ribosomes are located (Pollitz et al., Mol. Biol. Cell 16, 3401-3410, 2005). In the present study, we found that NS is co-localized in the nucleolus with the tumor suppressor Arf. When Arf was over-expressed, the nucleolar level of NS decreased, suggesting that the two proteins may compete for common binding sites in the nucleolus. Additional results revealed that the nucleolar protein B23, already implicated in localizing Arf to the nucleolus (Korgoanaker et al., Mol. Cell. Biol. 25, 1258-1271, 2005), also plays a role in the nucleolar localization of NS. siRNA knockdown of NS resulted in an increase of p53 in the nucleoplasm and, conversely, when p53 was elevated following DNA damage, the level of NS decreased. These results suggest that NS has roles in controlling both Arf in the nucleolus and p53 in the nucleoplasm.

2120

Effects of GSK-3B Inhibitors on Stabilization of p53 and B-Catenin

S. R. Mudreddy, R. K. Gary; Chemistry, University of Nevada, Las Vegas, Las Vegas, NV

B-catenin is a bifunctional protein. It associates with cadherins as part of a membrane-cytoskeletal linkage in cell-cell adhesions, and it acts as a transcription factor for cell proliferation in the Wnt signaling pathway. Levels of B-catenin are controlled mainly by glycogen synthase kinase 3B (GSK-3B), a constitutively active kinase that suppresses B-catenin. There appears to be a regulatory feedback mechanism that connects GSK-3B activity and B-catenin to changes in the p53 tumor suppressor protein. Increases in B-catenin cause p53 to increase, which in turn inhibits the expression of the target gene Sestrin2 (Levina et al., Oncogene 24: 4444-4453). Here we report the use of BeS04 to investigate the relationships among these factors. In vitro, BeS04 was much more potent as a GSK-3B inhibitor than the classical inhibitor LiCl. Cells treated with BeS04 expressed increased levels of B-catenin, and showed morphological signs of defective cell-cell adhesions. BeS04-treated cells also exhibited increased levels of p53. Subcellular fractionation showed that most of the accumulated p53 was in the nucleus. Inhibition of GSK-3B causes stabilization of B-catenin by reducing the phosphorylated form of B-catenin, which is targeted for degradation. Likewise, inhibition of GSK-3B stabilizes p53 by reducing the phosphorylation of Mdm2, which needs to be phosphorylated to serve as an efficient E3 ubiquitin ligase for p53. However, these two outcomes of GSK-3B inhibition (elevated B-catenin and elevated p53) are potentially incompatible in the negative feedback model of B-catenin-p53 regulation. In BeS04-treated cells, we observed increased p53 in the absence of increased B-catenin, but never the converse, suggesting that the ability of p53 to suppress B-catenin may be dominant when both proteins are stabilized via GSK-3B inhibition. The p53 gene is frequently mutated in tumors. Such cells can be expected to lack an important check on B-catenin-mediated proliferation.
Investigating the Chromatin Regulatory Domain (CRD) of the INGI Tumor Suppressors

X. Han, K. Riabowol; Department of Biochemistry & Molecular Biology, Faculty of Medicine, University of Calgary, Calgary, AB, Canada.

Since the discovery of the INGI (Inhibitor of Growth) gene in 1996, five ING genes named ING1-5 and several different splicing forms of ING1 and ING2 have been identified. All the ING family members share a conserved plant homedomain zinc finger motif and a nuclear localization sequence. Numerous studies demonstrate that human ING proteins are involved in epigenetic regulation of gene expression through chromatin remodeling by physical interaction with protein complexes possessing histone acetyltransferase (HAT) or histone deacetylase (HDAC) activities. Through comparative sequence analyses, a novel conserved motif among all ING family members has been identified, and our hypothesis is that this unique region may play a critical role in binding HAT/HDAC complexes during chromatin remodeling and the subsequent regulation of gene expression. Our first aim was to determine whether the CRD defines a new protein motif and if it is ING-specific. By using the Basic Local Alignment Search Tool (BLAST), we got 140 matches of the query sequence, among which most were members of ING family in human and mouse, and their distant homologs in Xenopus and Drosophila melanogaster. In order to determine whether the CRD has any sequence similarity with those proteins already identified as chromatin remodeling proteins, multiple sequence alignments were performed and we found that the CRD was surprisingly unique to the ING protein family. Following the sequence searches, INGI constructs with various mutations within the CRD and multimers of this domain have been made and their interactions with HAT/HDAC complexes in cultured mammalian cells are currently being analyzed. As a conclusion, this study suggests a potential role of the CRD in ING-mediated chromatin remodeling and will help to clarify the biochemical mechanisms used by the class II tumor suppressor ING1 in proliferation, DNA repair, apoptosis, and senescence.

Loss of APC Induces Polyploidy Due to a Combination of Mitotic and Apoptotic Defects

D. Nikuradze, T. Scherthan, A. Boguski, K. Kitagawa; Molecular Pharmacology, St. Jude Children's Research Hospital, Memphis, TN, National Center for Microscopy and Imaging Research, Center for Research on Biological Structure, School of Medicine, University of California, San Diego, La Jolla, CA.

We report a novel type of mitotic cell death, caspase-independent mitotic cell death (CIMCD), which is modulated by BUB1. The spindle checkpoint prevents apoptosis by monitoring the kinetochore-microtubule attachment. When defects arise in the spindle checkpoint pathway and in the kinetochore-microtubule attachment, substantial aneuploidy results, and cell death follows. When MAD2-depleted cells had defects in the kinetochore-microtubule attachment, premature mitotic exit occurred and resulted in abnormal nuclei. Although substantial BUB1 depletion did not cause premature mitotic exit, substantial synthetic lethality occurred between BUB1 depletion and treatment with paclitaxel or 17-AAG. This finding raises the provoking question: Why does simultaneous BUB1 siRNA and paclitaxel or 17-AAG treatment cause substantial synthetic lethality, although the spindle checkpoint appeared to be active? We found that in BUB1 (partly, but not completely) deficient cells, the conditions that activate the spindle checkpoint, treatment with nocodazole, paclitaxel, or 17-AAG, or cold shock induced DNA fragmentation during early mitosis, which can explain the substantial synthetic lethality. CIMCD appeared to be independent of caspase activation or p53. Apoptosis-inducing factor (AIF) and endonuclease G (EndoG), which are effectors of the caspase-independent cell-death pathway, were released from mitochondria during the activation of CIMCD. Moreover, double depletion of EndoG and AIF abolished DNA fragmentation and suppressed the lethality. These results indicate that CIMCD is a type of programmed cell death. Many tumor cells have a diminished, but not absent, spindle checkpoint response. Further, we found that BUB1 expression levels in CIN (chromosome instability) tumors were lower than those in MIN (microsatellite instability) tumors, and that treatment with drugs (nocodazole, paclitaxel, or 17-AAG) induced CIMCD in CIN tumors but not in MIN tumors. Furthermore, ectopic expression of BUB1 suppresses CIMCD in these CIN tumors. These results suggest that CIMCD protects cells from aneuploidy by inducing the death of cells prone to substantial chromosome mis segregation.

Regulation of the Discs Large Tumour Suppressor Protein by Phosphorylation during the Cell Cycle

N. Narayan, P. Massimi, L. Banks; Tumour Virology, ICGEB, Trieste, Italy.

The Discs Large (Dlg) tumour suppressor protein along with Scribble (Scrib) and Lethal giant larva (Lgl), is known to link cell polarity and cell proliferation of epithelial cells in Drosophila. In higher eukaryotic cells less is known about its growth suppressive function, although Dlg has been shown to induce growth arrest and retard proliferation in mouse fibroblasts (Ishidate et al., 2000). A Dlg truncation mutant results in impaired morphogenesis and perinatal death during marine development (Caruana and Bernstein, 2001). Mammalian Dlg is targeted by viral oncoproteins such as the high-risk Human Papillomavirus (HPV) E6 proteins for proteasome-mediated degradation and is also sequestered by HTLV-1 Tax and Adenovirus E4 ORF1. It has been previously shown by our group that phosphorylation of Dlg is a very important post-translational mechanism of regulating the protein and that hyperphosphorylation of Dlg renders it more susceptible to degradation induced by the HPV E6 oncoprotein. Several kinases have been implicated in phosphorylation of Dlg, including the p38 MAPKs and JNK. We have now extended these studies to investigate post-translational modification of Dlg during different phases of the cell cycle. We show that Dlg is hyperphosphorylated during S phase as well as in M phase, either following Apgc6l2l5p release or Nocodazole arrest. Further, we demonstrate both in vitro and in vivo that Dlg associates with, and is phosphorylated by, the cyclinB-cdk1 complex during the M phase, and most likely by cyclinA-cdk2 during the S phase. The specificity of the kinase complex for Dlg was confirmed by treating cells with a specific inhibitor. Finally, site directed mutagenesis of the putative kinase consensus site that lies between PDZ regions 2 and 3 on Dlg also abolishes the M-phase phosphorylation of Dlg. In conclusion, we show a novel mechanism by which the Dlg tumour suppressor is regulated during normal cell proliferation in mammalian tissue.

Human DNA Topoisomerase III Alpha Serves as a Potential Anti-Cancer Block

M. Y. Hsieh, J. R. Fang, H. W. Chang, H. C. Chen, T. L. Shen, S. C. Feng, T. K. Li; 1Department and Graduate Institute of Microbiology, College of Medicine, National Taiwan University, Taipei, Taiwan. 2Department of Plan Pathology and Microbiology, National Taiwan University, Taipei, Taiwan.

Genomic instability, especially chromosome instability (CIN), and checkpoint abnormalities have been closely related to the initiation and/or progression of tumor development. Here, we showed that tumor cells are generally deficient in expression of DNA human topoisomerase III alpha (hTOP3alpha) suggesting a potential anti-tumorigenic activity for h TOP3α. Consistently, hTOP3α-deficient cell lines generated by RNA interference (siRNA-hTOP3α cells) induced/promoted tumor formation in SCID tumorigenesis model compared to parental cell lines. Conversely, tumor cells with overexpression of hTOP3α lost its ability to form tumor on SCID mice. Moreover, siRNA-hTOP3α cell lines exhibited elongated cellular morphology, less serum dependence, enriched stretch fibers, greater sensitivity to cell cycle drugs, CIN, enhanced ability in anchorage-independent growth on soft agar and greater invasiveness compared to control cell lines. Our results suggest a potential role of hTOP3α as a potential anti-cancer block functioning in maintaining genomic stability and possibly in cell cycle checkpoints. The fact that deletion of TOP3 in yeast resulted in checkpoint deficiency and hyperrecombination phenotype also support such a possibility.

Functions of ZNF217, a Gene Amplified during Neoplastic Progression

L. E. Littlepage, P. Yaswen, Z. Werb; 1Anatomy, University of California, San Francisco, San Francisco, CA, 2Lawrence Berkeley National Laboratory, Berkeley, CA.
The 20q13.1 region of the human genome is highly amplified in 20-30% of early stage human breast cancers, and this amplification correlates with poor prognosis. ZNF217, a candidate oncogene in 20q13.1, is a putative transcription factor that is a component of the co-repressor of transcription associated with the human histone deacetylase complex (CoREST-HDAC), as well as in a complex with the transcriptional co-repressor C-terminal binding protein (CBP). Overexpression of ZNF217 in human mammary epithelial cell lines leads to their immortalization. To investigate its effect on neoplastic progression in epithelial cells, we cloned mouse Zn217. We characterized the role of Znf217 as a putative transcription factor. Using Gal4-fusion constructs in transcription assays, we found that Zn217 is a strong transcriptional repressor. We then infected mouse epithelial MC2 cells with vector or mouse Zn217 in a retroviral vector. Using an antibody raised against human ZNF217 that we found cross-reacts with mouse Zn217, we found that the cells expressed the Zn217 protein when induced, as determined by western blot analysis. Cells overexpressing Zn217 had altered cell and nuclear morphology and showed increased motility in scratch assays. Taken together, our data suggest that repression of a transcriptional target by ZNF217 may lead to increased motility of epithelial cells in culture. Supported by Ruth L. Kirschstein National Research Service Award, American Cancer Society Postdoctoral Fellowship, and grant CA058207 from NCI.

2127 Interaction between the HERC1 Ubiquitin Ligase and the TSC1/TSC2 Complex

E. Casas-Terradellas, O. Hadjebi, F. Gaucin-Gonzalo, R. Bartoms, F. Ventura, J. Rosa; Ciencies Fisiològiques IL, IDIBELL-Universitat Barcelona, Hospitalitat, Spain

Tuberous Sclerosis complex is an autosomal dominant disease characterized by benign tumor formation (hamartoma) in various organs and tissues. Mutations in either of these two genes, TSC1 (or hamartin) and TSC2 (or tuberin), can cause this disease. These proteins have been shown to regulate cell growth through inhibition of the mTOR pathway. TSC1 stabilizes TSC2 forming a physical and functional complex which regulates to the Rheb small GTPase through its GAP activity. HERC1 is a giant protein containing an HECT domain in its carboxyl-terminal. Proteins containing HECT domains function as a subtype of E3 ubiquitin ligases participating in protein ubiquitination through the transfer of ubiquitin from E2 ubiquitin conjugating enzymes to specific substrates. Recently, HERC1 has been identified as a TSC2 interacting protein (Chong-Kopera et al., 2006). These initial studies, using C-terminal regions of HERC1 and overexpressed TSC1/TSC2 proteins, suggested that TSC1 stabilized TSC2 by excluding HERC1 from the TSC1/TSC2 complex. We have analyzed this interaction between endogenous proteins finding that HERC1 can interact with TSC1/TSC2 complex. This interaction is constitutive and it is not regulated by insulin or amino acids. Knock-down experiments of HERC1 seem to indicate that the stability of the TSC1/TSC2 complex is not affected. Interestingly, expression of truncation mutants of HERC1 regulated overexpressed TSC1 and TSC2 proteins. Altogether these data show the participation of HERC1 in a complex with TSC1/TSC2 and a possible role in its stability.

2128 Growth Stimulation of Prostate Cancer by Androgen Receptor Cofactor ARA70β

Y. Peng1, C. Li, F. Chen, Z. Wang, W. Gerald, L. Peng2; 1Pathology, New York University School of Medicine, New York, NY, 2Cancer Biology, The University of Texas, M. D. Anderson Cancer Center, Houston, TX

ARA70/ERl/ELE1/RFG was first identified as a gene fused to the ret oncogene in thyroid carcinoma and subsequently as an androgen receptor (AR)coactivator. Two isoforms of ARA70, full length 70 kDa ARA70α and internally spliced 35 kDa ARA70β have been identified. ARA70α can activate AR mediated transcription activation in a ligand dependent manner, possibly through its interaction with general transcription factors TFII B and pCAF. We have shown that ARA70α is decreased in prostate cancer and its overexpression inhibits prostate cancer growth in androgen dependent LNCaP cells. To elucidate the function and role of ARA70β in prostate cancer, we examined the regulatory effects of transcription, prostate cancer cell growth and invasion of ARA70β. In contrast to ARA70α function as a transcriptional coactivator of AR, ARA70β can function as an AR corepressor in androgen free condition in transient transfection assays. ARA70β promotes prostate cell growth in cell proliferation and anchorage independent growth assays. ARA70β also enhanced the ability of cell invasion in in vitro Matrigel assays. In concert to above findings, genome wide expression profiling by Affymetric DNA microarray revealed parallel changes in the upregulation of genes involved in proliferation and cell adhesion. Collectively, the above data indicates that ARA70β plays an important role in androgen dependent prostate cancer growth and invasion.

2129 Modeling Human Brain Cancer in Drosophila

R. D. Read, J. B. Thomas; Salk Institute for Biological Studies, La Jolla, CA

Gliomas, neoplasms of glial cells and their precursors, are among the most common and deadly malignant tumors of the central nervous system (CNS). These tumors diffusely infiltrate the brain and grow rapidly, properties that render them largely incurable. Formation of these tumors is a complex process involving accumulation of mutations in many genes, only some of which are known. In particular, constitutive activation of the EGFR-Ras and PI-3 kinase signaling pathways is a common feature in gliomas and is sufficient to cause glioma in mouse models. Yet, how these pathways specifically regulate glioma pathogenesis is unknown. To understand the molecular basis for this disease, we have developed a novel model in Drosophila for the purpose of carrying out large-scale genetic analyses to identify genes involved in glioma invasion and proliferation. The Drosophila CNS contains multiple glial cell types that are strikingly similar to their vertebrate counterparts in terms of function, development, and gene expression. We have developed techniques that target glia and glial precursors to allow spatial and temporal control of gene expression in the fly CNS with single cell resolution. Using these tools we found that co-activation of both the EGFR-Ras and PI-3 kinase pathways in Drosophila glia gives rise to proliferative, invasive cells that create tumor-like growths in the fly brain, mimicking the human disease. We are now performing a genetic screen for enhancers and suppressors of the EGFR-Ras-PI-3 kinase phenotype in order to identify new regulators of glial neoplasia. Furthermore, we are performing misexpression screens for additional loci that cause glioma-like phenotypes in the fly brain. The genes identified in these two screens represent excellent candidates for genes directly involved in pathogenesis.

2130 Identification of Transcripts with Altered Translational Efficiency in Human Mammary Epithelial Cells Overexpressing eIF4E

S. Li, O. Larsson, M. Peterson, S. Avdalov, P. Bitterman, V. Polansky; Pulmonary Medicine, University of Minnesota, Minneapolis, MN

Purpose: Ectopic over expression of eIF4E in human mammary epithelial cells (HMECs) harboring active telomerase (hTERT) conferred these cells with autonomy, fundamentally altering cell cycle control and apoptosis regulation. When eIF4E is aberrantly activated, it increased the translational efficiency of a subset of transcripts encoding regulators of the cell cycle and viability. Here we intend to examine the mechanism on a genome-wide scale. Methods: We combined translational efficiency estimates derived from polyribosome preparations of RNA - which stratifies RNA based on the number of bound ribosomes - with a quantitative abundance measure obtained from microarray analysis of the polyribosome associated mRNA. Briefly, HMEC/hTERT and HMEC/hTERT/eIF4E: cells were studied 18 hours after growth factor deprivation. After polyribosome fractionation, we combined those transcripts associated with the translational efficiency of transcripts governing key life cycle events.

2131 E-cadherin Promotes the Anti-proliferative Role of Caveolin-1 as Well as Down-regulation of Survivin

V. A. Torres, J. Tapia, A. Lladser, D. Rodriguez, L. Leyton, A. F. G. Quest; FONDAP Center for Molecular Studies of the Cell, ICBM, University of Chile, Santiago, Chile

Caveolin-1 is a lipid raft-enriched membrane protein that suppressor or promotes events associated with tumour progression and metastasis. These distinct roles are attributed to cell-specific variations; however, mechanistically, these differences are not understood. In HT29 colon cancer cells, caveolin-1 expression decreased survivin mRNA and protein levels via a transcriptional mechanism involving the b-catenin-Tcf/Lef pathway. Also, proliferation was reduced upon caveolin-1 expression. Surprisingly, this was not the case in metastatic HT29(US) cells. Survivin down-regulation was paralleled by co-immunoprecipitation and co-localisation of caveolin-1 and b-catenin from HT29, but not HT29(US) cells. Metastasis is often associated with loss of E-cadherin. Indeed, E-cadherin was expressed in HT29, but not HT29(US) cells and re-expression of E-cadherin in HT29(US) cells restored co-immunoprecipitation and co-localisation with b-catenin, as well as survivin down-regulation and inhibition of cell proliferation by caveolin-1. These findings provide a first mechanistic insight as to how caveolin-1 function may vary in a cell context dependent fashion and suggest that the absence of E-cadherin severely compromises caveolin-1 in this respect.
2132

Estrogen Mediates the Growth of Human Thyroid Carcinoma Cells via an Estrogen Receptor-ERK Pathway

Q. Zeng,1 G. G. Chen,1 A. C. Vlantis,1 C. A. van Hasselt3; 1Department of Surgery, R417, Cancer Centre, Hong Kong,2 Department of Surgery, Prince of Wales Hospital, Hong Kong There is strong evidence to show that thyroid tumors occur more frequently in females, suggesting a role of sex hormones in thyroid carcinogenesis. However, few studies have investigated the molecular mechanism responsible for this. Our previous study demonstrated that estrogen receptors (ERs) exist in thyroid papillary carcinoma (Kat5) cells. Our present study investigated how 7β-estradiol (E2) influences the proliferation of Kat5 cells. Two estrogen receptor agonists, a selective ERα agonist, PPT, and a selective ERβ agonist, DPN, were employed to selectively regulate the ER levels by MTT assay and DNA fragmentation ELISA. The response of ERK1/2 and Bcl-2 family members to E2 and ER agonists was examined by Western blot. We showed that E2 significantly promoted the proliferation of Kat5 cells. The proliferation-promoting effect of E2 was related positively to ERα but negatively to ERβ, as PPT enhanced cell proliferation whereas DPN inhibited cell proliferation. Furthermore, PPT increased Bcl-2 protein levels while DPN decreased them in Kat5 cells. DPN also elevated the expression of pro-apoptotic Bax protein. PPT markedly induced the level of phosphorylated ERK1/2, suggesting that ERK1/2 may be positively involved in the proliferation of cells induced by E2. We also demonstrated that estrogen was able to stimulate the proliferation of cancer thyroid cells and that ERα and ERβ expression had opposite effects on cell proliferation. The action of estrogen appears to be associated with an increase in Bcl-2 and a decrease in Bax levels in an ERα/ERK1/2-related pathway. Our data suggest that an imbalance between ERα and ERβ may contribute to the development of thyroid cancer.

Structural Transitions That Regulate the Apoptotic Activity of BAX Are Dependent on Its C-terminal Alpha-9 Helix

N. Tscharmer,1 G. Zhang,1 A. Pande,1 S. Qin,1 L. L. Sechy,2 S. A. Tatulian,3 A. R. Khaled1; 1Biomolecular Science Center, University of Central Florida, Orlando, Florida, FL, 2Chemistry, University of Central Florida, Orlando, FL

A balance between processes that control life and death or homeostasis is essential for normal tissue development and the maintenance of cell population size. Activation of death proteins, such as those of the BCL-2 family, figure prominently in the homoeostatic process. Previously, we showed that loss of cytokine signaling perturbed the activation of the BCL-2 family of apoptotic mediators in lymphocytes, resulting in induction of the death activity of BAX. Hence BAX is a critical mediator of cytokine-withdrawal induced death; yet, how this lethal protein is activated is poorly understood. In the healthy cells, BAX is a cytosolic protein, with its C-terminal alpha-9 helix folded in a deep hydrophobic groove. Under apoptotic stress BAX translocates to mitochondria, causing membrane destabilization and the release of death-inducing factors. To explain this transitional behavior of BAX, we tested the hypothesis that the alpha-9 helix of BAX is an essential regulatory domain that governs its intracellular localization. Using a multi-disciplinary approach, we demonstrated that (1) the alpha-9 helix BAX is a membrane-binding domain that enables mitochondrialochondrial integration, (2) Two lysines located at the distal end of the alpha-9 helix are essential for membrane binding, and (3) Apoptotic stimuli induce a transient alkalinization that alters mitochondrial lipid dynamics, facilitating the mitochondrial integration of BAX. From these studies, we have shown that the C-terminal of BAX is responsive to apoptotic stimuli and, thereby, is an ideal molecular target for manipulation of the activity of BAX in a manner that has therapeutic application.

2134

Targeted Destruction of Prostate Cancer Cells with Genetically Altered Salmonella

H. Schatten,1 A. Eisenstadt,2 R. Kazmierzak,2 Z. Zhong,1 D. Newman,2 A. Fear; 1Veterinary Pathobiology, University of Missouri-Columbia, Columbia, Missouri, MO

Recently, genetically engineered non-toxic Salmonella Typhimurium strains have become attractive for cancer treatment because Salmonella preferentially infect and replicate within tumor cells and destroy solid tumors. We have engineered a Typhimurium strain (CRC1674) that is superior to previously engineered strains in the ability to attach, invade and alter cellular components in PC-3 prostate cancer cells. However, the mechanisms underlying the preferential tumor cell infection and destruction are not clear. Here we investigated the specific mechanisms that are used by the bacteria for cancer cell destruction with the goal to exploit these mechanisms for destruction of subpopulations in cancer tissue and increase therapeutic efficiency. We employed fluorescence and immunofluorescence microscopy as well as transmission electron microscopy (TEM) on S. typhimurium-infected PC-3M human prostate cancer cells fixed at 20 min, 4 hrs, and 8 hrs after inoculation. Rhodamine-phalloidin was employed to stain microfilaments, FITC-conjugated anti-tubulin antibody to stain microtubules and DAPI to stain DNA. Double and triple immunofluorescence staining was performed to determine the effects of Salmonella on the tumor cell's cytoskeleton. Our results show that the bacteria tightly attach and modify the infected PC-3M cell's microfilament system for incorporation into host cells. Ultrastructural analysis with TEM revealed Salmonella containing vacuoles (SCVs) that are formed within the host cells and connect with the host cells by tubular extensions between the vacuole and the host cell's cytoplasm. The rims of the vacuoles are stained with rhodamine-phalloidin indicating microfilament participation in the formation of the SCVs. Host cell mitochondria show deterioration and loss of cristae. These studies demonstrate that genetically modified S. typhimurium (strain CRC1674) [1] interact with PC-3 prostate cancer cells [2] and accumulate within the tumor cells in membrane-bounded SCVs. Further experiments are needed to determine the nature of the SCV-host cell interactions. Supported by Cancer Research Center.

2135

Essential Role of Death Domain Kinase RIP in DNA Damage-induced, p53 Independent Cell Death

G. Huh,1 M. Won,1 H. Byun,1 K. Park,1 Y. Kim,2 Z. Liu; 1Department of Pharmacology, Chungnam National University, College of Medicine, Daejeon, Republic of Korea, 2Cancer Research Institute, Daejeon, Republic of Korea

The hormonal stimulation of luteinizing hormone (LH) is an essential process in reproduction in starfish oocytes. Without fertilization, spontaneous inactivation of ERK and activation of caspase-3, which is the key enzyme to execute apoptosis, occur about 10 h after 1-MA stimulation. Also, immediately after the inactivation of MAPK, p38MAPK, which is generally considered as a death factor, is activated. When we treated eggs with p38MAPK inhibitor SB203580, apoptotic body formation was inhibited, but it did not affect activation of caspase-3. Thus, in starfish apoptosis, activation of p38MAPK and caspase-3 occur independently after ERK inactivation, and both of these cascades are needed for apoptotic body formation.

2136

Involvement of p38MAPK in Apoptotic Body Formation in Starfish Eggs

K. Usui,1 K. Chiba, Biology, Ochanomizu University, Tokyo, Japan

The hormonal stimulation of luteinizing hormone (LH) is an essential process in reproduction in starfish oocytes. Without fertilization, spontaneous inactivation of ERK and activation of caspase-3, which is the key enzyme to execute apoptosis, occur about 10 h after 1-MA stimulation. Also, immediately after the inactivation of MAPK, p38MAPK, which is generally considered as a death factor, is activated. When we treated eggs with p38MAPK inhibitor SB203580, apoptotic body formation was inhibited, but it did not affect activation of caspase-3. Thus, in starfish apoptosis, activation of p38MAPK and caspase-3 occur independently after ERK inactivation, and both of these cascades are needed for apoptotic body formation.

Regulatory Role of Protein Kinase C on the Death Receptor Mediated Necrotic Cell Death

H. Byun,1 K. Park,1 M. Won,1 K. Yang,1 S. Shin,1 L. Paz,1 J. Kwak,1 J. Park,1 J. Seok,1 Z. Liu,1 G. Hur1; 1Department of Pharmacology, Chungnam National University, College of Medicine, Daejeon, Republic of Korea, 2Cell and Cellular Biology Branch, Center for Cancer Research, National Cancer Institute, NIH, Bethesda, MD, 3Cancer Research Institute, Daejeon, Republic of Korea

Protein kinase C (PKC) triggers cellular signals that regulate proliferation or death in a cell- and stimulus-specific manner. Although previous studies have demonstrated that activation of PKC with phorbol 12-myristate 13-acetate (PMA) protects cells from apoptosis induced by a number of mechanisms, including death receptor ligation, little is known about the effect or mechanism of PMA in the necrotic cell death. Here we demonstrate that PMA-mediated activation of PKC protects against TNF-induced necrosis by disrupting formation of the TNF receptor 1 (TNFR1) signaling complex. Pretreatment with PMA protected L929 cells from TNF-induced necrotic cell death in a PKC dependent manner, but did not protect against DNA damaging agents,
including adriamycin and campothecin. Analysis of the upstream signaling events affected by PMA showed that it markedly inhibited TNF-induced recruitment of TNFR1-associated death domain protein (TRADD) and receptor interacting protein (RIP) into TNFR1, subsequently inhibiting TNF-induced activation of NF-κB and JNK. However, JNK inhibitors did not significantly affect TNF-induced necrosis, suggesting that the inhibition of JNK activation by PMA is not part of anti-necrotic mechanism. In addition, PMA acted as an antagonist of TNF-induced reactive oxygen species (ROS) production, thereby suppressing activation of the ROS-mediated poly(ADP-ribose) polymerase (PARP), and thus inhibiting necrotic cell death. Furthermore, during TNF-induced necrosis, PARP was significantly activated in wild-type MEF cells but not in RIP-/- or TRAF2-/- MEF cells. Together, these results suggest that PKC activation ensures effective shutdown of the death receptor-mediated necrotic cell death pathway by modulating formation of the death receptor signaling complex. This work was supported by grant R01-2005-000-10240-0 from the Basic Research Program of the Korea Science & Engineering Foundation.

Rottlerin Plays as a Functional Dichotomy between Apoptotic and Necrotic Modes in Response to Death Receptor Ligation by Uncoupling of Mitochondria

M. Won,1 H. Byun,2 K. Park,3 K. Yang,1 S. Shin,1 L. Piao,3 J. Park,3 J. Seok,1 G. Hur,2,3 1Department of Pharmacology, Chumgnam National University, College of Medicine, Daejeon, Republic of Korea, 2Cancer Research Institute, Daejeon, Republic of Korea, 3Department of Pathology, Chumgnam National University, College of Medicine, Daejeon, Republic of Korea.

Tumor necrosis factor (TNF)-induced cell death can be induced by apoptosis and necrosis. Our recent studies have shown that rottlerin, a potent and specific PKC-δ inhibitor, sensitizes cells from apoptosis induced by death receptor ligation, little is known about the effect or mechanisms in the necrotic cell death. To dissect the pathways of apoptosis and necrosis during death receptor ligandation in the same cell line, we used geldanamycin (GA)-induced apoptotic model in L929 murine fibroblasts, which is predominantly triggered by necrosis upon TNF treatment. Treatment with GA plus TNF caused a shift from necrosis to apoptosis characterized by caspase activation and plasma membrane blebbing, whereas TNF triggered necrosis in L929 cells. Surprisingly, whereas rottlerin sensitized apoptotic cell death induced by GA plus TNF, it protected necrotic cell death induced by TNF alone in a manner independent of its ability to inhibit PKC-δ. This protection against TNF-induced necrosis was achieved through suppressing the TNF-induced reactive oxygen species (ROS) production as well as the activation ROS-mediated poly(ADP-ribose) polymerase (PARP) leading to profound ATP depletion and subsequent necrosis. In understanding the underlying mechanisms, we found that rottlerin did not protect against H2O2-induced cell death. Furthermore, pretreatment with mitochondrial uncoupler FCCP or CCCP resulted in protection against TNF- but not H2O2-induced cell death and PARP activation. Therefore, the data from this study provide novel evidence that rottlerin regulates mitochondria-derived ROS production by uncoupling of mitochondria and thus inhibits necrotic modes of TNF-induced cell death. This work was supported by grant R01-2005-000-10240-0 from the Basic Research Program of the Korea Science & Engineering Foundation.

2139

Role of Protein Kinase C on the Nuclear Factor-κB signaling via Dissociation of IKK-γ and Hsp90 Complex in Human Colonic Epithelial Cells

K. Park,1 H. Byun,2 K. Yang,1 S. Shin,1 L. Piao,3 J. Kim,1 E. Junn,1 J. Park,3 J. Seok,1 G. Hur,2,1 1Department of Pharmacology, Chumgnam National University, College of Medicine, Daejeon, Republic of Korea, 2Department of Pathology, Chumgnam National University, College of Medicine, Daejeon, Republic of Korea, 3Department of Neurology, University of Medicine and Dentistry of New Jersey-Robert Wood Johnson Medical School, Piscataway, NJ, 4Cancer Research Institute, Daejeon, Republic of Korea.

Activation of protein kinase C (PKC) by phorbol 12-myristate 13-acetate (PMA) triggers cellular signals that lead to the activation of the transcription factor NF-kB. In various cell types. In addition to NF-κB activation by short-time PMA treatment, here we report that the prolonged exposure of human colonic cancer epithelial cells treated with PMA can also lead to a persistent inhibition of NF-κB activation. PMA selectively causes the degradation of IkB kinases (IKKs) including IKK-γ and IKK-β, and subsequent inhibition of TNF-induced IKK-γ and NF-κB activation in human colon cancer cell line HCT-116, but not in other gastrointestinal tract cells. The use of Ro31-8220 and GSK-6983, general PKC inhibitors as well as MG-132, a proteasome specific inhibitor, abrogated PMA-induced degradation of IKK-γ, and recovered the activation of IKK by TNF, suggesting that IKK complex is predominantly degraded by the proteasome pathway in PKC dependent manner. We also found that IKK-γ strongly associates with heat shock protein 90 (Hsp90) in HCT-116 cells, and that this interaction was dramatically reduced after following exposure to PMA. Furthermore, high levels of Hsp90 expression were observed in human colon cancer tissues. Taken together, these results suggest that long term activation of PKC by PMA inhibits NF-κB system in case of colon cancer cells by disrupting the interaction of IKK-γ with Hsp90 which may represent a novel regulatory mechanism of PKC-dependent cellular differentiation and limiting proliferation of colonic epithelial cells. This work was supported by grant R01-2005-000-10240-0 from the Basic Research Program of the Korea Science & Engineering Foundation.

Mitochondrial DNA Mutations Modulate ER Stress Induced Apoptosis

J. Q. Kwong,1 A. A. Starkov,2 G. Manfredi,3 1Neuroscience, Weill Medical College of Cornell University, New York, NY, 2Neurology, Weill Medical College of Cornell University, New York, NY.

Mitochondria are responsible for aerobic respiration and ATP synthesis. They have a complex biosignature, as respiratory chain subunits are encoded by both nuclear and mitochondrial (mtDNA) genomes. Mitochondria are also a major source of reactive oxygen species and are central to apoptosis. Mutations in the mtDNA have been associated with mitochondrial diseases, cancer, and aging. Although it is has been shown that mtDNA mutations cause respiratory chain distress leading to mitochondrial dysfunction, permeability transition, and apoptosis, the exact mechanisms whereby mtDNA mutations lead to cell death have yet to be determined. We have investigated the role of mtDNA mutations in apoptotic cell death. We have studied three types of pathogenic mtDNA abnormalities, in human cybrid cells: the first affects global mitochondrial protein synthesis, the second abrogates the function of individual respiratory chain complexes, and the third impairs specifically the mitochondrial ATP synthase. Since mitochondria sequester calcium and dysregulation of calcium storages has been shown to induce apoptosis, we have studied the role of mtDNA mutations in apoptosis induced by thapsigargin, an irreversible inhibitor of the endoplasmic reticulum (ER) calcium-ATPase. We have found that, although all the mtDNA abnormalities share bioenergetic similarities resulting in reduced mitochondrial ATP synthesis, the three groups exhibit different responses to ER stress- mediated apoptosis: as compared to normal cells, the first group prevented apoptosis, the second promoted it, and the third did not change it. We have investigated the mechanisms underlying these different responses and found that they can be associated with different capacities in uptaking calcium released from the ER in mitochondria. Our findings suggest that mtDNA abnormalities either inherited or acquired, such as those accumulated in aging and cancer cells, may affect apoptosis differently, depending on their effect on mitochondrial membrane potential and mitochondrial calcium uptake in response to ER stress.

Elucidation of the Mechanism by Which the Lim Protein Zyxin Promotes Apoptosis

M. Herry, M. C. Beckerle; Huntsman Cancer Institute, University of Utah, Salt Lake City, UT

Exposure of Ewing sarcoma cells to anti-CDD99 antibody promotes apoptosis and provides a potential targeted therapy (1). Recent evidence has implicated the LIM protein, zyxin, as a key mediator of apoptotic signaling induced by CD99 engagement (2). Zyxin is a focal adhesion protein implicated in integrin-dependent signaling and actin dynamics (3). We have determined that exposure of wildtype fibroblasts to UV-C irradiation results in apoptotic cell death, whereas cells harboring a homologous disruption of the zyxin gene display a statistically significant survival advantage. Reintroduction of a wildtype zyxin transgene restores sensitivity to UV-C irradiation illustrating that zyxin is pro-apoptotic. To explore the molecular mechanism by which zyxin contributes to apoptotic signaling, we introduced an affinity tagged version of zyxin into zyxin null fibroblasts and isolated zyxin and associated proteins from cell lysates under physiological conditions. A 130kDa protein that was co-isolated with zyxin was identified as the Cell Cycle and Apoptosis Regulator 1 (CARP-1) protein by microsequence analysis. CARP-1 was first characterized as a key protein in apoptotic signaling in breast cancer cells treated with a novel retinoid, CD437 (4). CARP-1 binds directly to zyxin, associated with its C-terminal LIM region. Zyxin that lacks the CARP-1 binding region fails to promote apoptosis in response to UV-C irradiation, thus suggesting that zyxin and CARP-1 cooperate to stimulate apoptosis. Zyxin and CARP-1 levels may be useful as predictors of responsiveness to apoptosis inducing cancer therapies. 1. Scotlandi et Al Eur J Cancer. 2006 Jan;42(1):91-6 2. The Effect of Crystalline Silica on Macrophages: Phagocytosis and Cell Death

G. N. Joshi, R. M. Gilberti, D. A. Knecht; Molecular and Cell Biology, University of Connecticut, Storrs, CT

Silicosis is a chronic lung disease induced by prolonged inhalation of crystalline silica dust. It is presumed that silica acts inside the cell, but there is no data showing that particles are actually phagocytosed. When macrophages are exposed to silica particles, (silica, latex, amino-latic, carboxy-latic), they extend protrusions to capture particles up to 7 μm away. Ovalbumin-opsonized silica phagocytosis is relatively slow (7% uptake at 15 minutes; 30% at 30 minutes; 71% uptake at 3 hours) compared to antibody-opsonized particles (70% uptake at 15 minutes through 3 hours).

2006 ASCB Annual Meeting Abstracts

393
demonstrated significant H₂O₂ production in cancer cells but had minimal effect in non-cancer cells. The basis of this key difference is unclear at present, but the observation may have apoptosis observed upon down-regulation of CK2 is preceded by intracellular generation of H₂O₂ in various normal and cancer cells (prostatic androgen-dependent ALVA-41 and androgen-by employing antisense CK2 apoptosis in cancer cells (Ahmed et al., Trends Cell Biol 12: 226-230, 2002). Downregulation of CK2 by employing its inhibitors such as apigenin or TBB (4,5,6,7-tetrabromobenzotriazole), or CK2 (formerly casein kinase 2 or II) is a ubiquitous protein ser/thr kinase that plays important roles in cell growth and proliferation, and has also been recognized as a potent suppressor of antioxidative activity of Fenretinide, 2147 2145 P13/Akt and MAPK Signaling Pathways in DNA-damaging Drug-induced Apoptosis E. Lee, Y. Kang, J. Kim, B. Kim, H. Choi, G. Kang, Y. Oh, S. Cho; Animal Biotechnology, Konkuk University, Republic of Korea The flavonoids are a group of natural products currently receiving a great deal of attention but flavonoids became known fully explained. In the present study, we have administered several flavonoids to human HacT keratinocytes, and determined that 3,4′-dihydroxy flavone (3,4′-DHF) exerts a slight stimulatory effect on cell growth, although other flavonoids, including kaemferol, quercetin, and isohamnetin exhibited growth inhibitory properties. 3,4′-DHF was found to exert an anti-apoptotic effect on etoposide-induced cell death of HacT keratinocytes. We were also able to determine that sustained ERK activation was intimately associated with the etoposide-induced apoptosis of HacT cells, and treatment with 3,4′-DHF induced a significant suppression of etoposide-induced ERK activation, concomitant with the repression of PARP or the cleavage of pro-caspase 3. ERK overexpression significantly override the anti-apoptotic function of 3,4′-DHF, but this was not true of ERK-DN. Moreover, treatment with 3,4′-DHF resulted in the protection of cells from H₂O₂-induced cell death, and also exerted an apparent suppressive effect on the stress-induced generation of ROS. Finally, we showed that 3,4′-DHF almost completely abolished kaempferol-induced apoptosis, coupled with a concomitant suppression of both intracellular ROS generation and the activation of ERK. Taken together, our data clearly indicate that a host of psychochemicals, including etoposide and a variety of flavonoids, differentially regulate the apoptosis of human HacT keratinocytes via the differential modulation of intracellular ROS production, coupled with the concomitant activation of the ERK signaling pathway. These results underline the distinct structure-activity relationship (SAR) inherent to several flavonoids.

P13/Akt and MAPK Signaling Pathways in DNA-damaging Drug-induced Apoptosis E. Lee, J. Kim, Y. Kang, J. Kim, B. Kim, H. Choi, G. Kang, Y. Oh, M. Jeong, S. Cho; Animal Biotechnology, Konkuk University, Seoul, Republic of Korea Previous studies have shown that doxorubicin induces apoptosis at low concentrations, but induces necrosis at higher concentrations in several cancer cell variants. In this study, we have conducted an investigation into the functions of the ERK1/2, p38 MAPK, JNK and P13/Akt pathways in the context of the mechanisms underlying the apoptogenic properties of important chemotherapeutic DNA-damaging drugs, most notably doxorubicin and etoposide. Doxorubicin was determined to elicit the apoptosis of NIH3T3 cells in a dose-dependent manner. Prior to cell death, both Akt and p38 MAPK were transiently activated, and subsequently inactivated almost wholly, whereas ERK and JNK evidenced sustained activations in response to the drug treatment. The inhibition of P13/Akt and p38 MAPK both accelerated and enhanced doxorubicin-induced apoptosis and ERK inhibition apparently exerted negative effect on apoptosis. The modulation of P13/Akt activation by treatment of LY294002 or expression of Akt mutants such as Akt-DN or Myr-Akt exerted a significant effect on the activation of ERK1/2. We also observed that P13/Akt and sustained ERK activation were associated intimately with the etoposide-induced apoptosis. Interestingly, the inhibition of Akt activation resulted in a dramatic increase in ERK1/2 phosphorylation. This suggests that the activation of the ERK signaling pathway may be regulated by the P13/Akt signalling pathway in doxorubicin-induced apoptosis.

Production of Intracellular H₂O₂ Is an Upstream Event in Mediation of Apoptosis Induced by Downregulation of CK2 G. Wang, K. A. Ahmad, H. Lindvall, A. Johnson, K. Ahmed; Research Service/Lab Med Path, V.A. Medical Ctr/Univ of Minnesota, Minneapolis, MN CK2 (formerly casein kinase 2 or II) is a ubiquitous protein ser/thr kinase that plays important roles in cell growth and proliferation, and has also been recognized as a potent suppressor of apoptosis in cancer cells (Ahmed et al., Trends Cell Biol 12: 226-230, 2002). Downregulation of CK2 by employing its inhibitors such as apigenin or TBB (4,5,6,7-tetrabromobenzotriazole), or by employing antisense CK2a or siRNA results in potent induction of apoptosis in cancer cells. In an effort to define the downstream mediators of this action, here we demonstrate that cell apoptosis observed upon down-regulation of CK2 is preceded by intracellular generation of H₂O₂ in various normal and cancer cells (prostatic androgen-dependent ALVA-41 and androgen-independent PC-3 cells). In this regard, both type of prostatic cancer cells behaved similarly in response to treatment with 80 μM apigenin or TBB or with antisense CK2a ODN or siRNA. Interestingly, while chemical inhibitors of CK2 (TBB, apigenin) elicited H₂O₂ production in both the cancer and non-cancer cells, the antisense CK2a-mediated down-regulation of CK2 demonstrated significant H₂O₂ production in cancer cells but had minimal effect in non-cancer cells. The basis of this key difference is unclear at present, but the observations may have implications regarding approaches to therapeutic targeting of the CK2 signal. The intracellular H₂O₂ production induced by antisense CK2a was associated with robust caspase 3 activity, NF-kB nuclear translocation, release of cytokine c in the cytosol, and subsequent DNA fragmentation in prostate cancer cells (ALVA-41 and PC-3). These findings describe, for the first time, a relationship between CK2 and ROS such that inhibition of CK2 leads to production of intracellular H₂O₂ which may serve as a downstream mediator of apoptosis under these conditions. [Supported by grant from N.C.I., and V.A. Medical Research Fund].

N-(4-Hydroxyphenyl)retinamide, Fenretinide: An Essential Structural Component of Biological Activity and the Mechanism of its Action T. Ohba, K. Kyob, Y. Watanabe, N. Takahashi; Institute of Medicinal Chemistry, Hokush University, Tokyo, Japan Fenretinide, N-(4-hydroxyphenyl)retinamide (4-HPR) is a synthetic amide of all-trans-retinoic acid (RA), which inhibits cell growth, induces apoptosis, and is an antioxidant, and cancer chemopreventive and antiangiogenic agent. This findings led us to investigate which structural component of 4-HPR contribute to these potent activities. Our approach was to examine 4-aminophenol (4-AP), p-methylnaphylinopin (p-MAP), and p-acetaminohip (p-AAP). It was found that vitamin E, 4-AP and p-MAP scavenge α,α-diethyl-β-picyridinhydrazyl (DPPH) radicals in a 1 : 2 ratio, in contrast to 4-HP and p-AAP, where a 1 : 1 ratio and 1 : 0.5 ratio was observed relative to DPPH radicals. However, RA was inactive. Lipid peroxidation in rat liver microsomes was reduced by compounds (RA, p-MAP, 4-HP, 4-AAP) in dose-dependent manner, while p-AAP was inactive. In addition, both p-MAP and 4-HP are potent inhibitors of cell growth and inducers of apoptosis in HL60 cells. p-MAP exhibits antiangiogenic activity to the same extent as 4-HP against HL60 cells, which are a resistant clone against RA, and it inhibits growth of various cancer cell lines (MCF-7, MCF-7Adr, HepG2, and DU-145) to an extent greater than 4-AP and p-AAP, but is less potent than 4-HP. Thus, although the antioxidant activity of p-MAP is more potent than 4-HP, 4-HP is more potent than 4-HP in its anticancer activity. These results suggest that both anticancer and antioxidant activities shown by 4-HP are due to the structure of p-MAP. The retinoyl residue or long alkyl chain substituent attached to an aminophenol, may be significant for anticancer properties.

SIRT1 Preserves DNA by Suppressing a Ubiquitin Ligase BTBD3
T. Kahyo,1 S. Sato,1 M. Setou2;3 Mitsubishi Kagaku Institution of Life Science, Machida-shi, Japan, 2National Institutes of Physiological Sciences, Okazaki-shi, Japan
SIRT proteins, including yeast Sir2, are involved in caloric restriction and lifespan extension in several species including S. cerevisiae, C. elegans and D. melanogaster. Mammalian Sir2 homologue SIRT1 is important for various cellular functions including apoptosis, differentiation and proliferation. In cells, SIRT1 functions as a NAD-dependent deacetylase and, some substrates have been reported, such as p53 and FOXO. To search for a novel SIRT1-interacting protein, we carried out yeast two-hybrid screening using SIRT1 as a bait. The C-terminal region of Broad Complex/Tramtrack/Bicaudal (BTB) domain containing protein 3 (BTBD3) was found as a SIRT1-interacting candidate. In addition to BTB domain, BTBD3 also contains PHR domain, similar to part of the PAM/Highwire/RPM-1 protein. BTBD3 formed the complex containing Cud3 and Roc1, which are known as a component of a ubiquitin ligase, and the ubiquitinated forms of BTBD3 were detected in HEK293T cells. These results indicate that BTBD3 is a component of a ubiquitin ligase. The deleted form lacking the BTB domain showed the decreased auto-ubiquitination, indicating that the BTB domain is necessary for sufficient ligase activity. Interestingly, the overexpression of SIRT1 suppressed the auto-ubiquitination of BTBD3 in HEK293T cells. The survival rate of the HEK293T cells overproducing BTBD3 was significantly decreased with the DNA-damaging agents, such as hydroxyurea and mitomycin C compared with the cells co-overproducing both BTBD3 and SIRT1 cells. The alkaline single cell gel electrophoresis (Comet) assay showed that the efficiency of DNA repair was significantly decreased in the BTBD3-overexpressing cells compared with that in the BTBD3-SIRT1-overproducing cells. These results show that SIRT1 preserves DNA by suppressing a ubiquitin ligase BTBD3.

Dynamic O-GlcNAc Modification in Response to Glucose Deprivation
J. Kang1,2 J. Cho1,2
1Department of Biology, Yonsei University, Seoul, Republic of Korea, 2Protein Network Research Center, Seoul, Republic of Korea
About 2–5% of extra-cellular glucose is converted into uridine diphosphate-N-acetyl glucosamine (UDP-GlcNAc) through hexosamine biosynthetic pathway (HBP). UDP-GlcNAc could be used for O-GlcNAc modification of nuclear-cytoplasmic proteins by aid of O-GlcNAc transferase (OGT). Accordingly the concentration of extra-cellular glucose is tightly related not only with HBP but also with O-GlcNAc modification of proteins. decreases. However, in A549, human lung cancer cell line, O-GlcNAc modification increases in response to glucose deprivation in a time dependent manner. On the other hand, the level of OGT is not changeable at this condition. This reflects that OGT activity increases in response to starvation in A549. Moreover the activity of GFAT, the first and rate-limiting enzyme in the hexosamine biosynthesis pathway, increases in steady glucose deprivation condition. We used SWGA precipitation method and MALDI-MS to identify the proteins in which O-GlcNAc modification increased at glucose deprivation condition. In view of the results so far achieved, we could identify several cytoskeletons, heat shock protein (HSP-70), ribosomal proteins etc. HSP-70 is known not only to be O-GlcNAc modified, but also to bind to other O-GlcNAc modified proteins. Thus, we will focus on revealing how the O-GlcNAc modification protect some proteins from degradation in response to glucose deprivation.

A Cytokine Receptor Common β Chain Box 2-associating Protein Mediates Apoptosis through Mitochondria-dependent Pathway in Hematopoietic Cells
C. Kao,1,3 K. Lin,1 P. Hwang,1 C. Li,1 J. J. Yen1; 1Institute of Biomedical Sciences, Taipei, Taiwan, 2Genome Research Center, Academia Sinica, Taipei, Taiwan, 3Stem Cell Program, Institute of Cellular & Organismic Biology, Taiwan, Taiwan
The cytokropic domain of human granulocyte-macrophage colony-stimulating factor (GM-CSF) receptor common β chain (βc) contains a region, proximal to the transmembrane domain, which is essential for induction of c-myc and pim-1 and is sufficient to mediate GS-CSF dependent mitogenic activity. This membrane proximal region has homology with other members of the cytokine receptor family and is designated as box 1 and box 2 motifs. Whereas box 1 motif is required for the recruitment and phosphorylation of JAK2 kinase, the function of box 2 motif remains largely unknown. Here we report the identification of a novel box 2-associating protein, the common beta chain associating protein (CBAP), which interacts with βc in the absence of cytokine and mediates apoptosis signal in hematopoietic cells. Yeast two-hybrid screening and GST-pull-down experiments showed that CBAP specifically associated with βc via the box 2 motif. Furthermore, co-immunoprecipitation experiments indicate that CBAP associates with βc in the absence, but not the presence, of GM-CSF in vivo via a region containing a WW-like domain on CBAP. Ectopic expression of CBAP in hematopoietic cells triggered apoptosis via mitochondria dysfunction, which could be completely abrogated by Bcl-2 overexpression. Moreover, reduced expression of endogenous CBAP by siRNA inhibited apoptosis significantly induced by GM-CSF deprivation. These findings suggest that CBAP is one of the important apoptosis regulators in hematopoietic cells. It also raises a possibility that βc may play a critical role in triggering apoptosis program in the absence of cytokine by specifically interacting with the apoptosis regulator CBAP.

Inhibition of Poleward Flux on Mitotic Spindles Delays Entry and Progression through Anaphase
I. Matos,1 A. J. Pereira,1 L. A. Cameron,2 S. Moutinho-Pereira,1 E. D. Salmon,2 H. Maiato1; 1Institute for Molecular and Cell Biology, Porto, Portugal, 2Department of Biology, University of North Carolina, Chapel Hill, NC
Flux remains one of the most mysterious properties of metazoan mitotic spindles. Two key flux players have already been identified. CLASP promotes the input of microtubule subunits at kinetochore/microtubule attachment, whereas KLP10A couples microtubule depolymerization at the poles. Interference with the function of these proteins results in the reduction of flux rates as well as spindle abnormalities - especially short-monopolar and long spindles. As an experimental hypothesis we proposed that simultaneous depletion of CLASP and KLP10A by RNAi in S2 cells would rescue normal spindle bipolarity and cease flux. As a complementary approach we have also treated metaphase cells with taxol, which suppresses spindle microtubule dynamics. In agreement with recent results from several labs, we were also able to significantly rescue spindle bipolarity after CLASP/KLP10A RNAi. By performing fluorescent speckle microscopy we found that both treatments resulted in a significant reduction of flux rates (1.24 ± 0.32 μm/min in CLASP/KLP10A RNAi; and 0.13 ± 0.11 μm/min taxol). To understand the underlying role of flux during mitosis we followed control, CLASP/KLP10A depleted, and taxol-treated S2 cells stably expressing GFP-α-tubulin and CID-mCherry by time-lapse fluorescence microscopy and DIC. Strikingly, we found that after CLASP/KLP10A RNAi and taxol treatment, anaphase entry was often delayed or even prevented. Quantitative fluorescent analyses revealed that accumulation of BubR1 at kinetochores was proportional to the degree of flux inhibition, suggesting that the observed delay in anaphase entry was due to the inability to satisfy the spindle checkpoint. Noteworthy, those cells that were able to enter anaphase showed a 30-40% reduction in chromosome poleward movement and lagging chromosomes could frequently be observed. Taken together, these data strongly suggest that, aside from the contribution of force for chromosome segregation, flux plays fundamental roles in kinetochore-microtubule attachment, which allows a timely metaphase-anaphase transition.

Lamin B Receptor Stimulates Nuclear Envelope Production and Targets Membrane Vesicles to Chromatin during Nuclear Envelope Assembly through Direct Interaction with Importin Beta
Y. Ma, S. Cai, Q. Jiang, Q. Zhang, S. Sodmergen, Z. Zhai, C. Zhang; The Key Laboratory of Cell Proliferation and Differentiation of Ministry of Education and The National Key Laboratory of Bio-membrane and Membrane Biotechnology, the College of Life Sciences, Peking University, Beijing, China
Lamin B receptor (LBR) is an evolutionarily conserved and developmentally essential inner nuclear membrane protein, ubiquitous in vertebrate, Drosophila, and yeast. LBR consists of a hydrophilic LaminB-binding and chromatin-binding N-terminal domain, a short hydrophobic C-terminal domain and eight predicted transmembrane segments which show a significant sequence similarity to vertebrate, yeast and plant steroid receptors. It has been shown that sea urchins LBR and an LBR like integral membrane protein are able to target membranes to the chromatin surface, which indicates an important role of LBR during nuclear assembly. The mechanism of how LBR is recruited to the chromatin surface is not clear. In the present study, based on transfection experiments, we show that overexpression of LBR in HeLa cells causes membrane overproduction, inducing NE invagination and membrane stacks formation, which is dependent on the first transmembrane domain of LBR. Biochemical analysis shows that the N-terminal domain of LBR directly interacts with importin beta in a Ran sensitive and importin α independent manner. In vitro binding assays with serials of truncated LBR shows that the region between the 45 amino acid to 90 amino acid of the N-terminal of LBR is responsible for the interaction of LBR and importin beta. Using an in vitro NE assembly assay, we also demonstrate that blocking the LBR binding sites on importin beta or competing for endogenous LBR, by addition of the LBR N-terminal domain, either reduces or seriously inhibits the recruitment of LBR containing vesicles to importin beta or Ran coated beads. Our results suggest that LBR is recruited to chromatin through direct interaction with importin beta to contribute to the fusion of membrane vesicles and formation of the NE.

A Network Model of *C. elegans* Early Embryogenesis Identifies a Novel AT-Hook Protein That Coordinates Nuclear Envelope Function and Chromatin Maintenance

A. G. Fernandez, F. Piano; Biology, New York University, New York, NY

Using combined network analysis of large-scale functional genomics, we mapped multi-protein modules required for distinct processes during early embryogenesis (Gunsalus et al. 2005). A basic question is how these molecular modules are coordinated to ensure the proper unfolding of early developmental events. To identify proteins that could coordinate different modules we searched for proteins that bridged different modules. One such protein, MEL-28, could be placed in either the nuclear pore complex module or in the chromosome maintenance module by a network clustering algorithm M-CODE (Bader et al. 2003). Consistent with its predicted roles at the nuclear pore and in chromosome segregation, GFP fusions and anti-MEL-28 immunolocalizations show that MEL-28 shuttles between the nuclear envelope and the kinetochore during the cell cycle. Functionally, MEL-28 is required for proper nuclear envelope and chromatin integrity (Mel-28(RNAi) embryos, the embryos without nuclear pore components, are incapable of completely separating cytoplasm from nucleoplasm, failing to exclude microtubules and affecting the nuclear localization of PIE-1, a protein normally enriched in the P1 nucleus (Mello, 1996). Additionally, pronuclei fail to meet, and centrosomes do not remain attached to the paternal pronucleus and segregate prematurely. In addition metaphase spindles are not established and chromatin neither condenses, congresse, nor segregates properly. These phenotypes resemble RNAi phenotypes of genes from the Ran GTPase cycle (Asgjaer 2002). Looking for MEL-28 phenotypic neighbors using PhenoBlazt (Gunsalus et al. 2004) or phenocloning from large-scale RNAi analyses (Simonich et al. et al. 2005) we identified ~25 other genes with similar defects when analyzed by time-lapse Nomarski microscopy. Of these, genes that are part of the RanGTPase pathway (ran-1, ran-2, npp-9) were required for proper MEL-28 localization. Thus MEL-28 is critical for both mitotic and interphase cell functions and is a likely target of the Ran GTPase pathway.

**The Persistence of Lamin B from Nuclear Envelope Breakdown through Spindle Assembly**

A. E. Goldman, L. Chang, T. Dechat, H. Lipschultz, R. D. Goldman; Cell and Molecular Biology, Northwestern University, Feinberg Medical School, Chicago, IL

Mature *S. pombe* oocytes are arrested in late prophase, pre-meiosis I. The nuclei of these oocytes contain condensed chromatin which are closely associated with the lamina, the major protein of which is the nuclear lamin, L67. Upon fertilization, L67 is phosphorylated by cdk1 as nuclear envelope breakdown (NEBD) proceeds in a highly synchronous fashion. Immuno-fluorescence observations demonstrate that some L67 remains associated with chromosomes throughout NEBD, and some becomes associated with aster microtubules, spindle poles and ultimately the mitotic spindle. The remaining L67 becomes dispersed throughout the cytoplasm. Biochemical studies in support of these observations have involved the isolation of nuclei from unfertilized eggs and并通过 NEBD following fertilization. The latter resulted in nuclear remnants containing chromosomes and subsequently mitotic spindles. Immunofluorescence and immunoblotting reveal the presence of L67 in all of these isolated structures. Within the isolated spindles L67 is associated with chromosomes, spindle poles, and microtubules. Spindle-associated factors (SAFs) such as Eg2 are also present in these spindles. We have developed a method for the enrichment of spindle matrices by isolating mitotic spindles in the presence of nocodazole. These matrices are devoid of polymerized microtubules and contain L67 and chromosomes. We are presently analyzing these matrices to determine whether SAFs are associated with L67 as previously shown (Tsai et al., 2006, Science). Similar results have been obtained with mitotic spindles isolated at first cleavage. These results demonstrate that lamins are retained throughout NEBD and become incorporated into the spindle matrix. Supported by NCI and the Ellison Medical Research Foundation.

**Modeling Interactions between Rev and Microtubules**

A. Sharma, K. R. Miller, S. Bedi, D. Sweaney, S. F. Nathan, M. W. Miller; Biological Sciences, Wright State University, Dayton, OH

Watts et al. (J. Cell Biol. 150:349-360, 2000) described a novel in vitro interaction between microtubules (MTs) and the human immunodeficiency virus-1 (HIV-1) protein Rev, a 13 kDa basic protein essential for HIV infection. Highly purified Rev rapidly depolymerizes equimolar MTs and produces bilayered rings of oligomeric Rev and tubulin. Addition of purified Rev to mitotic frog egg extracts inhibits the formation of asters formed in vitro indicating that Rev can affect the polymerization state of MT in a cellular environment. A molecular explanation of Rev:MT interactions is suggested from a limited amino acid similarity shared with members of the Kinesin-13 family, proteins known to stimulate MT catastrophes. To test this hypothesis, we have modeled Rev:MT interactions using the HEX computer program to dock Rev’s arginine-rich motif onto the tubulin heterodimer believing that basic residues might create an affinity for tubulin. Of the 512 best models generated, essentially only two different models were produced. Each had a calculated binding energy of ~1300 kcal/mol with electrostatic interactions and shape compatibilities contributing equally. These models are consistent both with our efforts to dock the comparable region of MCAK (506-542) to MT as well as with structural models of Kif2c:MT interactions. We have also assessed the ability of Rev to bind, depolymerize MT and affect MT function in vitro and in vivo. Sedimentation assays show that bacterially expressed Rev, purified by FPLC using Q-sepharose and heparin-sepharose columns, bind and depolymerize purified MT. Immunoprecipitation experiments suggest that Rev:MT complexes persist in living cells when Rev is transiently and stably expressed in HeLa cells. Flow cytometric analyses and measurement of mitotic indices show that Rev expression demonstrably affects HeLa cell cycle progression. These results suggest that Rev may destabilize MTs in HIV-infected cells.

**Mammalian CLASP1 and CLASP2 Cooperate to Ensure Mitotic Fidelity by Regulating Spindle and Kinetochore Function**

A. L. Pereira, 1 A. J. Pereira, 1 A. R. R. Main, 2 K. Drabeck, 1 C. L. Sayas, 1 P. Hergett, 1 M. Lince-Faria, 1 I. Matos, 1 C. Duque, 3 T. Stepanova, 2 C. Rieder, 2 W. C. Earnshaw, 1 N. Galjart, 1 H. Maatouk, 1, 3 Institute for Molecular and Cell Biology, Porto, Portugal, 1, 3Dept. of Cell Biology and Genetics, Erasmus Medical Center, Rotterdam, The Netherlands, 1, 3New York State Dept. of Health, Division of Molecular Medicine, Wadsworth Center, New York, NY, 1Laboratory of Cell and Molecular Biology, Faculdade de Medicina, University of Porto, Porto, Portugal, 2Welcome Trust Centre for Cell Biology, Institute of Molecular Biology, University of Edinburgh, Edinburgh, United Kingdom

CLASPs are widely conserved microtubule plus-end-tracking proteins with essential roles in the local regulation of microtubule dynamics. In yeast, *Drosophila* and *Xenopus* a single CLASP orthologue is present, which is required for mitotic spindle packaging by regulating microtubule dynamics at the kinetochore. In mammals, however, only CLASP1 has been directly implicated in cell division, despite the existence of a second paralogue, CLASP2, whose mitotic roles remain unknown. Here we show that CLASP2 localization at kinetochores, centrosomes and spindle is remarkably similar to CLASP1, both showing fast microtubule-dependent turnover rates. Strikingly, primary fibrobasts from Clasp2 knockout (KO) mice show numerous spindle and chromosome segregation defects that can be partially rescued by ectopic expression of Clasp1 or Clasp2. Moreover, chromosome segregation rates during anaphase are slower in Clasp2 KO cells, which is consistent with a primary role of CLASP2 at kinetochores and spindle microtubule flux. Noteworthy, although cell viability and proliferation were not impaired in Clasp2 KO cells, the fidelity of mitosis was strongly compromised leading to severe chromosomal instability in the adult. Together, our data support that the partially redundant roles played by CLASPs during mitosis act as a possible mechanism to prevent aneuploidy in mammals.

**Spindle Assembly Is Induced by Chromatin-dependent Activation of the Aurora B Pathway**

A. E. Kelly, 1 S. C. Sampath, 2 T. A. Manier, 2 E. M. Wou, 2 B. S. Tseng, 1 H. Funabiki 2; 1Laboratory of Chromosome and Cell Biology, Rockefeller University, New York, NY, 2Laboratory of Mass Spectrometry, Rockefeller University, New York, NY

Chromatin-induced spindle assembly depends on the chromosomal passenger complex (CPC), consisting of Incenp, Survivin, Dasra (Borealin) proteins, and the kinase Aurora B. How the CPC contributes to the spatial regulation of spindle assembly remains unclear. Here we show that the Aurora B pathway is suppressed in the cytosol of *Xenopus* egg extracts, but becomes activated by chromatin via a Ran-independent mechanism. Spindle assembly requires Dasra-dependent chromatin binding of the CPC, but this function of Dasra can be bypassed simply by clustering the CPC. Dasra-dependent chromatin binding of the CPC is required for chromosome segregation and cytokinesis in eukaryotic cells. In *silico* analysis of the *Giardia* genome identified a single AK ortholog (gAK), with 61% similarity to human AK. gAK contains conserved active site residues, activation loop, and destruction box motifs.
characteristic of AKs. Similar to many other giardial gene products, gAK has a unique insert within the kinase domain. Since giardial cell division is not well understood, we tested the hypothesis that gAK plays a role in mitosis and cytokinesis through interactions with either histones or cytoskeletal elements. gAK expressed under its own promoter with a C-terminal AU1 epitope tag localized exclusively to both nuclei in interphase cells. In addition, an antibody to phosphorylated AK (pAK) reacted only with the few mitotic cells in the non-synchronized trophozoite population. Using double labeling and DAPI staining, we followed the localization of total gAK and active phosphorylated gAK throughout the cell cycle. During mitosis, gAK localized to the basal bodies/centrosomes and a spindle-like structure. Localization to the centrosomal area was confirmed through double labeling of pAK and centrin, and the spindle-like structure with pAK and alpha-tubulin. During specific stages of mitosis, gAK also localized dynamically to cytoskeletal structures unique to *Giardia*: the parflagellum dense rods of the anterior-lateral flagellum, the median body, and the parent adhesive disc. Pharmacological inhibition of gAK decreased cell proliferation and increased the percentage of cells in cytokinesis, appearing to block the progression of late stages of cell division. Treated cells also had abnormal tubulin structures. Together, these results suggest that gAK is crucial for the regulation of mitosis and cytokinesis in *Giardia lamblia*.

**Cdk1 Acts Upstream of Aurora Kinases during G2/m Transition Revealed by Small Molecule Kinase Inhibitors and High Content Multiplex Assays**

R. D. Van Horn, Lilly Research Laboratory, Eli Lilly, Indianapolis, IN

Entry into and progression through mitosis are regulated by multiple evolutionarily conserved mitotic kinases. Mitotic kinases Cdk1, Plk1, NIMA and aurora all have essential and non-overlapping functions in mitosis. Cdk1 plays an essential role in entry into mitosis. In yeasts, activation of Cdk1 is necessary and sufficient to trigger mitosis, whereas in *Aspergillus nidulans*, activation of both Cdk1 and NIMA kinases is required. It was shown recently by RNAi that aurora-A kinase is required for mitotic commitment by recruiting Cdk1 to centrosomes where Cdk1 is initially activated to trigger mitosis. Here we developed highly selective and potent small molecule kinase inhibitors of Cdk1 and aurora kinases and high content/high throughput multiplex assays for cell cycle analysis by simultaneously measuring DNA content, cyclinB1 and phosphorylated histone H3 at the single cell level. We showed that inactivation of Cdk1 by small molecule inhibitors arrested cells in G2 with accumulated cytoplasmic cyclinB1. By contrast, inactivation of aurora A kinase arrested cells at mitosis with high levels of nuclear cyclinB1 and phosphorylated histone H3, indicating that unlike Cdk1, aurora-A kinase is not required for entry into mitosis. Indeed, using synchronized cells, we further showed that inactivation of Cdk1 prevented activation of aurora-A kinase, while inactivation of aurora kinases had no effect on the kinetics of either Cdk1 activation or entry into mitosis. Interestingly, inactivation of both aurora-A and aurora-B kinases with dual aurora kinase inhibitors promoted DNA endoreduplication in the absence of cell division. Live cell imaging revealed that the nuclear cycle of cells treated with dual aurora kinase inhibitors is uncoupled from cytokinesis and continues to oscillate in a Cdk1-dependent manner, resulting in multinucleated cells. Together, our studies with selective small molecule inhibitors and high content multiplex assays convincingly established that Cdk1 acts upstream, rather than downstream, of aurora kinases in mitosis.

**The N- and C-terminal Domains of MCAK Spatially Control Microtubule Depolymerization Activity and Spindle Assembly in Extracts**

S. C. Enns-McClung,1 K. M. Hertzer,2 X. Zhang,3 M. W. Miller,3 C. E. Walczak2; 1Medical Sciences Program, Indiana University, Bloomington, IN, 2Anatomy and Cell Biology, Indiana University, Bloomington, IN, 3Biological Sciences, Wright State University, Dayton, OH

The proper regulation of microtubule dynamics is critical for spindle assembly and accurate chromosome segregation. MCAK, a Kinesin-13, catalytically depolymerizes microtubules, regulates microtubule dynamics in vivo and is the major catastrophe factor in egg extracts. The N-terminal domain is required for kinesin function during cell division, while the C-terminal domain regulates microtubule depolymerization in vitro. However, the degree to which the different domains contribute to or correlate with their in vitro and physiological microtubule depolymerization activity is unknown. Five domain mutants were constructed, expressed and assayed for in vitro microtubule depolymerization and physiological spindle assembly in egg extracts. The N-terminal domain truncation mutant, GM(187-731), had wild-type in vitro microtubule depolymerization activity but did not fully rescue spindle assembly due to suppressed microtubule depolymerization activity in extracts. Thus, the N-terminal domain of MCAK is not dispensable for physiological microtubule dynamics but is expendable in vitro. In contrast, the C-terminal domain truncation mutant, GM(2-592), had reduced in vitro microtubule depolymerization activity but completely rescued spindle assembly due to enhanced physiological depolymerization activity. Neither construct was as efficiently kinesin-like as Cdk1, and these results also suggested control of spindle assembly by MCAK. Our results show that high MCAK depolymerization activity in vitro does not correlate with efficient spindle assembly in extracts. We propose that MCAK activity is spatially controlled by the N-terminal domain during spindle assembly. Specifically, the N-terminal domain is essential for targeting MCAK to kinetochores, while the C-terminal domain enhances the efficiency of kinesin targeting. Additionally, the N-terminal domain is necessary for cytoplasmic MCAK activity in extracts. Surprisingly the C-terminal domain also plays an inhibitory role by limiting the extent of spindle bipolarity.

**Mechanism of PavKLP-mediated Cortical-Spindle Interactions during Mitosis in *Drosophila* Embryos**

P. Sommi, R. Ananthakrishnan, D. K. Cheerambathur, I. Brust-Mascher, J. M. Scholey, A. Mogilner; University of California, Davis, CA

The spindle assembly checkpoint monitors microtubule-kinetochore attachments and tension across sister kinetochores to facilitate accurate division of chromosomes between daughter cells. Cortical-spindle interactions during mitosis in *Drosophila* embryos, also known as *PavKLP-mediated cortical-spindle interactions (PCSI)*, has been shown to recruit cortically localized PavKLP to kinetochores to facilitate proper spindle formation. Here we have investigated cortical-spindle interactions in *Drosophila* embryos, and observed that the kinesin-6 family member, PavKLP, influences both spindle morphogenesis and cortical dynamics. PavKLP, which behaves as a dimer in subcellular fractionation, localizes to mitotic spindles, where it is very dynamic, and to mitotic furrows, where it co-localizes with actin. The inhibition of PavKLP function causes defects in spindle dynamics, actin distribution and mitotic furrow ingression, suggesting that PavKLP is involved in stabilizing the spindle structure as well as promoting actin remodeling and membrane recruitment for furrow formation during mitosis and cellularization. Using in vivo experiments and modeling, we tested the hypothesis that PavKLP may contribute to furrow dynamics by driving membrane vesicle transport. In vivo, we observed that PavKLP interacts with Nuf1, a key component of recycling endosomes which is required for vesicle-mediated delivery and actin recruitment to the furrow, and that PavKLP inhibition interferes with Nuf1 distribution thus influencing vesicle delivery to the cortex. “Virtual Cell” modeling suggests that furrow ingression is biphasic and depends on a PavKLP-generated force during the initial slow stage, followed by PavKLP-driven vesicle transport during a subsequent fast stage. Thus PavKLP is required for proper spindle and furrow organization, and it mediates spindle-cortical interactions by transporting vesicles along astral microtubules to the cortex to promote actin remodeling and membrane recruitment.

**Light Intermediate Chain 1 of Cytoskeletal Dynein Is Required for Progression through the Spindle Assembly Checkpoint**

T. L. Wadzinski, S. J. Dossey, Program in Molecular Medicine, University of Massachusetts Medical School, Worcester, MA

The spindle assembly checkpoint monitors microtubule-kinetochore attachments and tension across sister kinetochores to facilitate accurate division of chromosomes between daughter cells. Cytoskeletal dynein function in this checkpoint, apparently by moving critical checkpoint components off kinetochores, including Mad2 and BubR1. The dynein subunit required for this function is unknown. Here we show that human cells depleted of dynein light intermediate chain 1 (LIC1) delay in metaphase. LIC1 remains intact, localized and functional in these cells implicating LIC1 directly in the metaphase delay. The kinetochore appears structurally intact as Mad2, BubR1, Mad1 and dynein are organized normally on unattached kinetochores. The prolonged metaphase requires an active spindle assembly checkpoint as depletion of Mad2 or Mad1 allows cells to progress through mitosis without delay. Moreover, Mad2 remains on some kinetochores in delayed cells suggesting that LIC1 facilitates removal of kinetochore-associated Mad2. This LIC1 function is selective as BubR1, the tension-associated protein, is normally removed from all kinetochores. The LIC1-associated metaphase delay is suppressed by re-expression of wild type LIC1 or a Cdk1 site phosphomimetic LIC1 mutant, but not by a phosphorylation-deficient mutant. We conclude that LIC1 phosphorylation at a Cdk1 site is required for removing Mad2 from kinetochores and resolution of the spindle assembly checkpoint. The presence of Mad2 on kinetochores that are under tension and lack BubR1 demonstrates that Mad2 is sufficient for checkpoint maintenance. We propose that LIC1 is an adaptor linking dynein to Mad2 either directly or indirectly, facilitating the removal of this checkpoint component off kinetochores.

**A Novel Role for Nup98 in the Regulation of the Spindle Function**

M. Cross, M. Powers; Cell Biology, Emory University, Atlanta, GA

The nuclear pore complex is comprised of approximately 30 different nucleoporins (Nups). During interphase of the cell cycle, this complex regulates the trafficking of proteins and RNA in and out of the nucleus. However, during mitosis, the nuclear pore complex is disassembled and increasingly, nucleoporins have been found to have alternate mitotic functions. Nup98, a 98kDa nucleoporin, interacts with several proteins implicated in regulation of mitotic spindle formation. We have utilized in vitro spindle assembly in Xenopus egg extracts to determine whether Nup98 itself plays a role during mitosis. When added to spindle assembly extracts, the C-terminal domain of Nup98 stimulates excess growth of microtubules. The C-terminal domain similarly stimulates microtubule polymerization in Ran-induced asters. Added however, we have shown that excess microtubule growth does not require the known interaction between the Nup98 C-terminus and...
and Nup96, a component of a nucleoporin complex associated with both the kinetochore and spindle. Instead, we have mapped the relevant region of Nup98 to a portion of the C-terminal domain without a previously characterized function. In contrast, either addition of domain-specific antibodies to extract or depletion of endogenous Nup98 from extract results in dramatic inhibition of microtubule growth and formation of minimal, but stable monopolar spindles. These findings strongly suggest that Nup98 itself, through a function of the C-terminal domain, is required for assembly of a proper mitotic spindle. Similar findings were obtained using preformed mitotic spindles; the Nup98 fragment induces a dramatic increase in size and microtubule density of the spindle whereas antibody addition leads to rapid decrease in pole to pole length. We conclude that Nup98, through a previously uncharacterized activity, is acting as a regulator of microtubule dynamics during mitosis. We are using fluorescent speckle microscopy to assess the influence of Nup98 on microtubule flux within the spindle.

γ-Tubulin Plays an Important Role in the Localization of Cyclin B
T. Naya, E. Sweeney, R. B. Oakley; Molecular Genetics, Ohio State University, Columbus, OH

Certain conditionally-lethal γ-tubulin alleles of Aspergillus nidulans allow normal mitotic spindle formation at restrictive temperatures, but cause dramatic failure of the regulation of late mitotic events. These data indicate that γ-tubulin has important, but incompletely defined, functions in mitotic regulation. To investigate these functions, we have GFP-tagged a number of mitotic regulators in the γ-tubulin mutant strain to determine if late mitotic events are regulated by temperature at restrictive temperatures. We find that in a temperature-sensitive delay, the spindle normally forms, but fails to progress beyond prometaphase. This reveals a requirement for γ-tubulin both in assembly and progression. Similar results were obtained for assembly and progression in a temperature-sensitive mutant of Cdc16, a different kinesin. In both cases, γ-tubulin is required for spindle pole body formation, but not for spindle pole body function. These data indicate that γ-tubulin is required for assembly and progression of the mitotic spindle, and that this requirement is not due to a temperature-sensitive defect in spindle pole body function.

A Small-molecule Inhibitor That Disrupts Importin-beta-mediated Nuclear Import and Spindle Assembly
J. F. Soderholm, K. Weis, R. Heald; Molecular and Cell Biology, University of California, Berkeley, Berkeley, CA

The Ran GTPase regulates nucleocytoplasmic transport and mitotic progression through its interaction with the transport receptor importin-beta. It has been hypothesized that a RanGTP gradient regulates mitotic events by releasing importin-beta-bound motif factors in a spatially-restricted manner across the chromosomes in living cells. To test this hypothesis directly we performed a high-throughput screen for small molecule inhibitors that disrupt the interaction between RanGTP and importin-beta. Our screen, which was based on fluorescence resonance energy transfer (FRET), identified about 100 compounds that interrupt the FRET signal generated by our probes. In subsequent experiments using Xenopus laevis egg extracts and cultured HeLa cells, we found that one of these compounds strongly inhibits spindle assembly and nuclear envelope assembly. The compound does not depolymerize microtubules directly in vitro. In digitonin-permeabilized tissue culture cells, this compound blocks nuclear import of GFP, and blocks nuclear localization of GFP. Importantly, the compound does not seem to affect the import of a transportin-dependent reporter in this assay, suggesting that the compound specifically targets importin-beta. We have found that this compound belongs to a larger class of easily-synthesized small molecules, many of which also abrogate spindle assembly in Xenopus extracts.

TOG Regulates Spindle Microtubule Dynamics and Kinetochore Motility
L. Cassimeris, B. Becker; Department of Biological Sciences, Lehigh University, Bethlehem, PA

TOG, a member of the XMAP215 MAP family, is required for bipolar mitotic spindle assembly, spindle pole integrity and chromosome bi-orientation (Gergely et al. 2003; Cassimeris and Morimoto, 2004). To understand how TOG contributes to spindle assembly, we examined microtubule dynamics in Hela cells depleted of TOGp by siRNA. FRAP of GFP-tubulin expressing cells demonstrated that spindle microtubule turnover is slowed by about 2 fold in the absence of TOGp. By following microtubule regrowth after washout of the depolymerizing drug nocodazole (Tulu et al. 2006 Curr. Biol. 16:536), we find that TOGp-depleted cells have fewer microtubules associated with centrosomes, while the microtubules assembling in association with mitotic chromatin are similar to those in untreated cells. Kinetochore fibers in both untreated and TOGp-depleted cells are stable to lysis in buffer containing calcium. Taken together, our results indicate that TOGp contributes specifically to assembly of centromal microtubules and is not required for kinetochore microtubule assembly or stability. Reduced centromal microtubules should reduce ejection force on chromosome arms and reduce tension across sister kinetochore. We estimated the ejection force by measuring the pole to pole distance in monotreated-processed cells. Kinetochore fibers were located closer to the poles in the TOGp-depleted cells (2.16 µm vs 3.04 µm in untreated cells), consistent with TOGp (and centromal microtubules) contributing to the ejection force. Loss of TOGp also reduced tension across sister chromatids (1.08 µm vs 1.24 µm in untreated cells). Images of living cells expressing CENPA-GFP showed that kinetochores in TOGp-depleted cells rapidly switch between poleward and away-from-pole motility, but show little net translocation in either direction. We hypothesize that TOGp-dependent assembly of centrosomal MTs and spindle pole recruiting contribute to chromosome congression by regulating kinetochore directional instability. Supported by NIH.
Evidence That Myosin Phosphatase Antagonizes Polo-like Kinase1 during Mitosis in Mammalian Cells

S. Yamashiro, Y. Yamaoka, F. Matsumura; Molecular Biology & Biochemistry, Rutgers, Piscataway, NJ

Protein phosphatase1 (PP1) plays essential roles in various aspects of mitosis including mitotic spindle assembly, chromosome segregation and cytokinesis. While PP1 has a limited number of isoforms for its catalytic subunit (PP1C), PP1C interacts with numerous PP1C regulatory subunits, and thus generates many forms of the phosphatase with distinct substrate specificities, Protein phosphatase1 (PP1) plays essential roles in various aspects of mitosis including mitotic spindle assembly, chromosome segregation and cytokinesis. While PP1 has a limited number of isoforms for its catalytic subunit (PP1C), PP1C interacts with numerous PP1C regulatory subunits, and thus generates many forms of the phosphatase with distinct substrate specificities, enabling PP1 to antagonize a wide array of Ser/Thr kinases. Little is known, however, about which PP1C regulatory molecules are involved in mitosis and what serine/threonine kinases they antagonize. Myosin phosphatase targeting subunit1 (MYPT1) is one of the regulatory subunits of PP1C, and is believed to target PP1C to myosin II, thus controlling the contractility of smooth muscle and nonmuscle cells. Surprisingly we found that mammalian MYPT1/PP1C regulates mitosis by antagonizing polo-like kinase1 (PLK1). During mitosis, MYPT1 binds to PLK1, apparently as a consequence of mitosis-specific phosphorylation of MYPT1 by cdc2. PLK1 depletion by small interfering RNAs is known to inhibit γ-tubulin recruitment to the centrosomes in mammalian cells, blocking centrosome maturation and resulting in mitotic arrest and apoptosis. We found that co-depletion of MYPT1 and PLK1 reactivates γ-tubulin at the centrosomes, restoring the assembly of bipolar mitotic spindles. Live-cell imaging revealed that double depletion rescues mitotic arrest caused by PLK1 depletion. MYPT1 depletion, on the other hand, induced assembly of multiple (more than 3) γ-tubulin-containing foci. This MYPT1 phenotype was also suppressed by co-depletion with PLK1, indicating the dependence of the MYPT1 phenotype on normal levels of PLK1. Mutual suppression is thus likely achieved by reducing the overall levels of PLK1 to better match reduced phosphatase activity after MYPT1 knockdown. PLK1 is an essential mitotic kinase that is upregulated in many cancers. Our finding of a novel MYPT1-mediated regulatory pathway for PLK1 sheds new light on how PLK1 controls cell division in both normal and cancer cells.

Int6 and Moe1 Interact with Cdc48 to Regulate Mitotic Progression in Schizosaccharomyces pombe

J. H. Otero, 1 J. Sun, 1 E. C. Chang, 1 Cell and Molecular Biology, Baylor College of Medicine, Houston, TX, 2Breast Cancer Center, Baylor College of Medicine, Houston, TX, 3Molecular and Cellular Biology Department, Breast Cancer Center, Baylor College of Medicine, Houston, TX

INT6 is a key gene involved in the formation of breast cancer, as its frequent site of integration by the mouse mammary tumor virus. To better understand the functions of INT6, we have characterized an Int6 homolog (Yin6) in the fission yeast Schizosaccharomyces pombe. Our data support a model in which Yin6 regulates many mitotic functions, including spindle formation, chromosome segregation, and mitotic exit by controlling the localization and assembly of subunits of the proteasome. In our study, I will further characterize Yin6 by focusing on an evolutionarily conserved protein, Moe1, to which Yin6 binds directly. In two-hybrid screens, we have isolated several Moe1-binding proteins that can bind ubiquitinated proteins. Of these, we are particularly interested in Cdc48, which like Yin6 and Moe1, regulates proteasome-mediated protein degradation and spindle dynamics. In support of the data, our biochemical evidence demonstrates that Cdc48 binds Yin6 and Moe1 in S. pombe. Additionally, genetic analyses show that mutations affecting cdc48, together with mutations inactivating either yin6 or moe1, act synergistically to create a mitotic defect by affecting spindle dynamics. My data also show that human Cdc48 rescues the phenotype of yeast cdc48 null mutant. In collaboration with other members of our lab, we found that Int6 and Moe1 also binds Cdc48 in human cells. These observations support the hypothesis that the Yin6-Moe1 complex can interact with Cdc48 to regulate mitotic progression in an evolutionarily conserved fashion.

Organization of Replication Sites in HeLa Cells

A. Ligasova, 1 J. Malinsky, 1 J. Raska, 1, 4 K. Kobetina 1 Department of Cell Biology, Institute of Experimental Medicine, Prague, Czech Republic, 2Department of Microscopy, Institute of Experimental Medicine, Prague, Czech Republic, 3Department of Cell Biology, Institute of Physiology, Prague, Czech Republic, 4Institute of Cellular Biology and Pathology, 1st. Faculty of Medicine, Prague, Czech Republic

We have performed high-resolution analysis of replication sites in HeLa cells during S phase. On the light microscopy level replication sites were visualised as fluorescent foci. The number of fluorescent foci increases rapidly in early S phase from several tens to around 1000 per cell nucleus. This number gradually decreases from mid to late S phase. In late S phase, only around 100 replication foci per cell nucleus were found. They were usually located around those observed in early S phase cells. By contrast, on the electron microscopy level 2100 replication domains (RDS) exhibited DNA synthetic activity in average cell nucleus in early and mid S phase and 1400 RDS in late S phase. Thereby, we suppose that the fluorescent foci are composed of one, several or even tens of RDS. The size of the single RDS is about one tenth of the size of the fluorescent foci. According to our results, replication domains persist in cell nucleus as structural entities also after the completion of their DNA synthesis and during next cell cycle. The size of such domains is substantially reduced with respect to replication domains with ongoing DNA synthesis. It can reflect post-replicationary re-folding of the chromatin. Electron microscopy analysis of the number of replication sites in mitotic HeLa cells showed the apparent increase in the number of replication sites in mitotic cells in comparison to S phase cells. We assume that this can be attributed to the complete separation of chromosomes pairs and their reorganization during mitotic changes of chromatine organization. Phosphorylation of a Motif Universally Conserved within the Cdc34 Ubiquitin Conjugating Enzymes Regulates SCF Substrate Abundance

R. R. Cocklin; Biochemistry and Molecular Biology, Indiana University School of Medicine, Indianapolis, IN

2179

Substrate specificity for ubiquitin-dependent protein degradation is in large part achieved by the presence of numerous ubiquitin ligases or E3 enzymes. This family of enzymes is necessary for the final step of ubiquitination whereby ubiquitin is attached to a lysine moiety of the substrate proteins. The SCF family of ubiquitin ligases are multisubunit complexes which ubiquitylate specific cyslins and cyclin dependent kinase inhibitors in a cell cycle dependent fashion. Ubiquitylation of protein substrates by the SCF ubiquitin ligase complexes is controlled primarily through phosphorylation of the substrate proteins which generates a binding site for the recognition component of the SCF complex, the F-Box protein. We demonstrate here that an additional mechanism for regulation of these complexes is via phosphorylation of Cdc34, the ubiquitin conjugating enzyme that functions in concert with the SCFcs. Cdc34 itself is phosphorylated upon several serine residues that constitute part of a motif is highly conserved within the entire family of Cdc34 ubiquitin conjugating enzymes. It is known that these amino acid residues are completely dispensable for Cdc34 catalytic activity in certain molecular contexts and thus likely to be serving a regulatory function. Furthermore, these phosphorylation events are regulated by treatment with phenformin in yeast. Loss of phosphorylation prevents proper signaling through the yeast mating pheromone pathway and leads to gross misregulation of the SCF substrates, Sic1, Far1 and Cln1.

Dual Roles of the Hepatitis B Virus X Protein in the ATM-dependent DNA Damage Response: Activation and Silencing

S. Kim, S. Park, W. Lim, H. Says, J. Lee, H. Cho; Biochemistry & Molecular Biology, Ajou University School of Medicine, Suwon, Republic of Korea, Department of Tumor Genetics and Biology, Graduate School of Medical Science Kumamoto University, Kumamoto, Japan

Eukaryotic cells have evolved a complex defense mechanism to maintain genomic integrity, which is often destroyed in cancer cells. During the chronic infection of the hepatitis B virus (HBV), HBx viral protein plays a multifunctional role in the development of hepatocellular carcinoma (HCC). Here, we attempted to investigate whether HBx viral protein alters genomic integrity during the pathogenesis of HCC. We found that one of the DNA double strand breakage markers, γ-H2AX foci were significantly increased in HBx expressing cells, which was accompanied with the activation of Chk2, a downstream kinase of DNA damage signaling. Consequently, the negative phosphorylation of Chk1 was increased and cell cycle progression was delayed at G1 phase. Inhibition of ataxia telangiectasia mutated (ATM) and ATM and Rad3 related (ATR) proteins, the upstream kinase of DNA damage checkpoint abrogated the HBx induced G1 delay. Intriguingly, low dose of irradiation (1 Gy) in Chang cells activated the DNA damage checkpoint pathway, evidenced by recruitment of 53BP1 to the DNA foci, increase of the phospho-Chk2 and consequent cell cycle delay at G1 phase. In contrast, the same dose of irradiation in HBx-expressing cells failed to transduce the DNA damage signaling and did not induce any delay in cell cycle progression. Taken together, we concluded that the activation of the DNA damage-induced signaling pathway by HBx viral protein weakens the ability of cells to respond extrinsic DNA damage response, which may provide a chance for increasing DNA damage accumulation.
Expression of Mesothelin Is Increased by Taxol at the G2/M Phase of Cell Cycle in Human Lung Carcinoma Cells

M. Ho, I. Bera, M. Willingham, M. Onda, R. Hassan, D. FitzGerald, I. Pastan; Laboratory of Molecular Biology, National Cancer Institute, NIH, Bethesda, MD, Department of Pathology, Wake Forest University School of Medicine, Winston-Salem, NC

Mesothelin is a glycosyl-phosphatidyl-inositol-anchored glycoprotein highly expressed in various human solid tumors including ovarian, pancreas and mesothelioma. To evaluate whether mesothelin can be a therapeutic target for the immunotherapy of lung cancer, we examined the expression of mesothelin in lung cancer tissue and cells. We also examined the effect of Taxol on the expression of mesothelin in Hela cells. The expression of mesothelin in lung cancer tissues was analyzed by immunohistochemistry and Western blotting. We observed that mesothelin expression is increased by Taxol at the G2/M phase of cell cycle in human lung adenocarcinoma cells. The expression of mesothelin is upregulated by Taxol in Hela cells and the increase is associated with the mitotic phase of cell cycle. The results suggest that Taxol interacts with the G2/M phase of cell cycle in which the canonical Wnt/beta-catenin signaling pathway is activated. This work indicates that mesothelin is a novel cell cycle-related gene. The association of mesothelin overexpression with Taxol resistance may provide a new therapeutic opportunity for treating chemotherapy-resistant lung cancer.

Regulation of the G2/M Transition by Sp1 and Plo1 Kinases
E. Lambrea, S. Lopez-Aviles, G. Mora, A. Fajardo, R. Aliguet; Cell Biology, University of Barcelona, Barcelona, Spain

The sp1 gene encodes a serine/threonine protein kinase involved in alteration of cell polarity in Schizosaccharomyces pombe. Previous studies have shown that Sp1 is required for alteration of growth polarity and actin localization after osmotic stress as well as during normal cell division cycle. The sp1 deletion causes stress sensitivity, reminiscent of defects in the stress-activated MAP kinase Sty1/Spc1. The sp1 deletion mutant exhibits monopolar actin distribution and a delay in G2/M transition (Matsusaka et al, 1995; Rupes et al, 1999). We have found that Sp1 function requires Srk1 kinase, a calmodulin-dependent protein kinase homologue in fission yeast. Srk1 kinase has a role in regulating the onset of mitosis. Deletion of srk1 gene is not essential but srk1 mutant cells divide at reduced size (9-10 μm) compared to wild type cells (14 μm). Srk1 is a nuclear kinase whose overexpression causes G2/M arrest. The G2/M arrest is dependent on Srk1 kinase and also on the Cdc25 mitotic phosphatase. Deletion of srk1 gene rescues the lethal overexpression of sp1 and it also rescues the G2/M delay of srk1 mutant cells. These results suggest that Sp1 and Srk1 are in the same pathway regulating the G2/M cell cycle transition. Moreover, recent studies have shown that Plo1 kinase is necessary for cells to undergo mitosis after DNA damage. Considering the role of Srk1 in cell cycle control, we tested a possible relation between these two kinases. Further studies describing how Srk1 phosphorylates Plo1 in vitro will be presented.

A Journey to the Centrosome for the Cdc25C Phosphatase
J. Wu, H. Jiang, W. Yang, H. Li; Children's Memorial Research Center, Feinberg School of Medicine, Northwestern University, Chicago, IL

Cdc25kinases play a central role in regulation of cell cycle progression through activating dephosphorylation of cyclin-dependent kinases. In humans three genetically distinct Cdc25 isoforms have been identified: A, B and C, with different structural and functional characteristics. Although the temporal windows of action of these phosphatases are intricate and overlapping, Cdc25B and C are most renowned for their implication in regulation of mitotic progression. It is thought that Cdc25B is responsible for triggering entry into mitosis, through initial activation of cdk1-cyclin B at centrosomes, whilst Cdc25C would act at a slightly later stage, promoting further progression through mitosis through amplification of this kinase activity in the nucleus. However the precise function of Cdc25C in mitosis, and its spatio-temporal pattern of activation still remain poorly characterized. We have found that Cdc25C localizes to centrosomes in cultured mammalian cells in G2, where it colocalizes with phosphorylated cyclin B in prophase. Moreover the first phosphorylated forms of Cdc25C are detected at the centrosome, and a fraction of Cdc25C persists at this organelle throughout mitosis and cytokinesis. We find that centrosomal localization of Cdc25C is independent of its catalytic activity and of its ability to interact with 14-3-3 and have characterized the molecular determinants involved. In addition, FRAP experiments demonstrate that like cyclin B, the centrosomal fraction of Cdc25C is mobile and rapidly exchanged with G1 cells. Intriguingly, the cyclin B levels in G2 phase of BubR1-depleted cells appear to be lower than those of control SIRNA transfected cells; however, early activation of the cyclinB/Cdk1 kinase in G2 phase was accompanied in BubR1-depleted cells. Moreover, immunofluorescence staining with antibodies against cyclin B and gamma-tubulin revealed early cyclin B localization at the centrosomes during G2 progression. This is the first indication that BubR1 regulates the G2-mitotic phase transition.

Expression of Mesothelin Is Increased by Taxol at the G2/M Phase of Cell Cycle in Human Lung Carcinoma Cells
M. Ho, T. Bera, M. Willingham, M. Onda, R. Hassan, D. FitzGerald, I. Pastan; Laboratory of Molecular Biology, National Cancer Institute, NIH, Bethesda, MD, Department of Pathology, Wake Forest University School of Medicine, Winston-Salem, NC

Mesothelin is a glycosyl-phosphatidyl-inositol-anchored glycoprotein highly expressed in various human solid tumors including ovarian, pancreas and mesothelioma. To evaluate whether mesothelin can be a therapeutic target for the immunotherapy of lung cancer, we examined the expression of mesothelin in lung cancer tissue and cells. We also examined the expression of mesothelin in normal lung tissue and cells. We observed that mesothelin is expressed on the cell surface of lung adenocarcinoma cells. In A549 cells, mesothelin expression is increased by Taxol at the G2/M phase of cell cycle in which the canonical Wnt/beta-catenin signaling pathway is activated. This work indicates that mesothelin is a novel cell cycle-related gene. The association of mesothelin overexpression with Taxol resistance may provide a new therapeutic opportunity for treating chemotherapy-resistant lung cancer and possibly other mesothelin-expressing solid tumors.

The p38 Mediated Checkpoint Delays Mitosis Under Stress in Normal Cells, but Is Progressively Lost with Tumorigenic Transformation
A. V. Mikhailov, D. Patel, D. McCance, C. L. Rieder; Molecular Medicine, Wadsworth Center of the NYS Dept of Health, Albany, NY, Biochemistry and Biophysics, University of Rochester, Rochester, NY
When growing cultures are exposed to various stresses, cells in the early stages of chromosome condensation (i.e., late G2) are rapidly delayed from entering mitosis via a cell cycle checkpoint mediated by the p38 kinase. This checkpoint protects the cells from dividing under stressful conditions which can lead to errors in chromosome segregation resulting in polyploidy or aneuploidy. We used Ansiomycin to rapidly activate this checkpoint in non-transformed, partially transformed and fully transformed cell lines. We found that when p38 is suddenly activated, entry into mitosis is rapidly and completely blocked for 4-5 hours in all primary, telomerase- or spontaneously immortalized (p53/pRb+) cells we examined. However, comparable or stronger p33 activation does not delay, or only briefly delays, entry into mitosis in tumorigenic cell lines. While there are many rapid, microplate compatible assay formats for looking generically at cell proliferation, not many are able to address mitosis specifically. A common mechanism-of-action for many anti-proliferative drugs involves disruption of cellular mitosis. While there are many ways to do this, we have developed an alternative approach optimized for small molecule or siRNA profiling and screening. This method utilizes human-derived biosensor cells that report mitotic events using positional complementation of an inactive β-galactosidase. The cells have been engineered to express two complementing fragments of β-galactosidase within different cellular compartments. When the nuclear envelope breaks down at the onset of mitosis, the two components interact in the cytoplasm, forming an active enzyme that is able to generate a detectable chemiluminescent or fluorescent signal. This unique approach provides a functional cell-based assay for screening chemical libraries for anti-mitotics, with the benefit of analysis on a simple luminometer as opposed to image analysis. Data will be shown highlighting the use of this biosensor system for both compound screening and siRNA profiling.

A Novel, Homogeneous Biosensor Assay for Identification of siRNAs and Small Molecules That Inhibit Mitosis

M. Mathrubutham, K. R. Olson; R&D, DiscoverRx Corporation, Fremont, CA

Disruption of cell cycle progression is a key intervention point in many drug development programs focused on cancer biology. While detailed cell biology analysis is critical to determine the mechanism of action for candidate compounds, this would be used as therapeutics, there is an equally important need for assays that allow for rapid analysis of a large number of small molecule candidates that show the potential for cell cycle perturbation. A common mechanism-of-action for many anti-proliferative drugs involves disruption of cellular mitosis. While there are many rapid, microplate compatible assay formats for looking generically at cell proliferation, not many are able to address mitosis specifically. One common approach that is specific to mitosis involves high-content image analysis with DNA-specific dyes and a phospho-histoneH3 antibody labeling. While effective, this approach presents challenges with respect to profiling a large number of molecules in a timely manner. We will present an alternative approach optimized for small molecule or siRNA profiling and screening. This method utilizes human-derived biosensor cells that report mitotic events using positional complementation of an inactive β-galactosidase. The cells have been engineered to express two complementing fragments of β-galactosidase within different cellular compartments. When the nuclear envelope breaks down at the onset of mitosis, the two components interact in the cytoplasm, forming an active enzyme that is able to generate a detectable chemiluminescent or fluorescent signal. This unique approach provides a functional cell-based assay for screening chemical libraries for anti-mitotics, with the benefit of analysis on a simple luminometer as opposed to image analysis. Data will be shown highlighting the use of this biosensor system for both compound screening and siRNA profiling.

A Subthreshold Concentration of Starfish Oocyte Maturation Hormone Causes Nuclear Entry of Cdc2/cyclin B, But Not GVBD

M. Terasaki; Cell Biology, University of California Health Center, Farmington, CT

Immature starfish oocytes are arrested in prophase of meiosis I. The maturation hormone 1-methyladenine (1-MA) at a concentration of 1 μM causes activation of Cdc2/cyclin B, resulting in GVBD after ~20 min. Using confocal imaging of cycling B-GFP in living oocytes, we previously found that Cdc2/cyclin B is present in aggregates that disperse ~7 min after 1-MA, followed a minute or two later by the beginning of Cdc2/cyclin B entry into the nucleus (MBC 14: 4685). If 1 μM 1-MA is removed when the aggregates are just beginning to disperse, the aggregates disperse completely and a significant amount of Cdc2/cyclin B enters the nucleus, but GVBD does not occur. Similarly, if oocytes are exposed to a subthreshold dose of 0.1 μM 1-MA, the aggregates disperse and Cdc2/cyclin B partially enters the nucleus without GVBD. These results indicate that the commitment to M phase occurs after the beginning of Cdc2/cyclin B entry into the nucleus. If oocytes that have been in subthreshold 1-MA for 1 hr are put into 1 μM 1-MA, GVBD occurs in ~12 min. The same speed-up also occurs if oocytes are kept in 0.1 μM 1-MA for 18 hrs, which indicates that oocytes can remain in a prolonged, intermediate state of activation.

T56-Bcl-2 Is a Specific In Vivo Substrate of Cyclin B1/Cdk1

J. W. Jacobberger, R. M. Sramkoski, P. S. Frisa, R. K. Wetzel; Division General Medical Sciences, Case Western Reserve University, Cleveland, OH, “Cell Signaling Technology, Inc., Danvers, MA

Background: A central part of cell regulation biochemistry are specific kinase - phosphatase systems. Generally, for a specific system activity is measured by immunoprecipitation and autokinolysis of phosphorylated substrates or lyase immunoblottting with phosphorylation state specific antibodies (phospho-antibodies). An alternative approach is to quantify immunoreactivity of phospho-antibodies by cytochemistry. These assays are easier and more accurate than western blotting, but this value increases significantly when the measurement is made within the mitotic context. The object here was to obtain a measure of cyclin B1/Cdk1 activity as a function of the cell cycle in asynchronous cells.

Methods & Materials: Human cell lines and stimulated lymphocyte samples, treated with kinase inhibitors, stimulators, and specific small interfering RNAs (siRNAs), were fixed, reacted with antibodies to cyclins B1 and A, mitotic epitopes (MPM-2 and phospho-S10-histone H3), phospho-T56-Bcl-2, and stained for DNA content; then measured by flow cytometry.

Results: The intensity of phospho-T56-Bcl-2 was highest in mitotic cells that were cyclin B1 (B1) positive and pBcl2 and B1 were correlated in mitotic cells. Cyclin A positivity was not correlated. Alsterpaullone reduced pBcl2 reactivity as a function of dose and time. Specific siRNA for cyclin B1 eliminated the positive signal, but siRNA for cyclin B2 or cyclin A did not. Several other non-Cdk1 kinase inhibitors did not inhibit reactivity. Small molecule stimulators (okadaic acid; taxol) both increased reactivity that was inhibitable with alsterpaullone.

Conclusion: Phospho-T56-Bcl-2 is a specific substrate of cyclin B1/Cdk1 in mitotic cells. The period of activity is phaseprophase by late mitosis, although activity decreases significantly after metaphase.

Xp95/Alix Is Phosphorylated within the Proline-rich Domain during Xenopus Oocyte Maturation and Mitotic Arrest of Mammalian Cells

R. Dejournet, R. Kobayashi, S. Pan, C. Wu, R. B. Clark, J. Kuang, O. Bogler; Dept. of Neurosurgery and Neuro-oncology, MD Anderson Cancer Center, Houston, TX, Dept. of Molecular Pathology, MD Anderson Cancer Center, Houston, TX, Dept. of Experimental Therapeutics, MD Anderson Cancer Center, Houston, TX, Dept. of Molecular Genetics, MD Anderson Cancer Center, Houston, TX, Dept. of Integrative Biology and Pharmacology, The University of Texas Medical School, Houston, TX

Xp95 is the Xenopus laevis ortholog of a conserved family of scaffold proteins that have in common a C-terminal proline-rich domain (PRD) and an N-terminal Brol domain. Although it is thought that the family of proteins interact with multiple partner proteins that participate in diverse cellular (endocytosis, apoptosis) and disease processes (tumor suppression and retroviral budding), their regulation is poorly understood. We previously demonstrated that Xp95 undergoes a phosphorylation-dependent gel mobility shift during progesterone-induced meiotic maturation of Xenopus oocytes, a model of M-phase induction. To further characterize phosphorylation of Xp95, we undertook two approaches. First, Xp95 was purified from immature and mature oocyte extracts and analyzed by mass spectrometry. We found a 5080 Da peptide (residues 706-756), which is phosphorylated at T745 and at least one additional site in mature oocytes. T745 is within the conserved binding site to SETA/CIN85/SHEKBP1, an adaptor protein involved in EGF receptor endocytosis. Xp95 phosphorylation at T745 was shown to inhibit SETA interaction: Xp95 from immature but mature oocytes can bind SETA in vitro, and a phospho-T745 peptide of Xp95 shows reduced binding to recombinant SETA. Xp95 phosphorylation was also characterized by identifying the minimal region (residues 705-786) which was sufficient for the gel-mobility shift during oocyte maturation. Extending these results to the mammalian ortholog, Alix, we determined that Alix also undergoes a gel-shift during mitotic arrest (MA), similar to Xp95 during Xenopus oocyte maturation. Further, deletion of residues 717-784 of Alix was sufficient to inhibit the gel-shift of Alix during MA. Lastly, transfected Xp95 in MA cells failed to bind SETA but instead could bind AMSH, a deubiquitinsase participating in vesicle sorting. Together, these findings indicate that Xp95/Alix is phosphorylated within the PRD during M phase induction and suggest that this phosphorylation regulates interaction with binding partners.

Ypi1: A Positive Regulator of Nuclear Protein Phosphatase Type 1 during Mitosis in Saccharomyces cerevisiae

J. P. Bharucha, L. Gao, K. Tatchell; Biochemistry and Molecular Biology, Louisiana State University Health Sciences Center, Shreveport, LA

PP1 is a highly conserved phospho-serine/threonine phosphatase with roles in diverse cellular processes such as chromosome segregation, muscle contraction, and synaptic transmission. The activity of the enzyme is regulated by the association of the catalytic subunit with different regulatory subunits. In many eukaryotes, including yeast, nuclear PP1 plays an important role in cell cycle regulation, although little is known about the subunit(s) that regulates this activity. In S. cerevisiae, YPI1, an essential gene, encodes a small protein that shares homology with mammalian PP1 inhibitor-3. Ypi1 interacts with Gcl7 (yeast PP1) and inhibits its activity in vitro (Garcia-Gimeno et al., J. Biol. Chem. 278, 47444-S2). To examine its role in vivo, YPI1 was placed under the control of a galactose-inducible promoter. Ypi1 deletion causes cells to arrest in G2 of the cell cycle, due to activation of the spindle assembly checkpoint. There is a
concomitant decrease in nuclear Gli7, which localizes aberrantly as foci throughout the cells. Nuclear levels of Sds22, an essential Gli7 regulatory subunit that also interacts with Ypi1, also decrease following depletion of Ypi1. A mutant of Ypi1 whose product fails to interact normally with Gli7 also results in reduced nuclear Gli7 and Sds22, and suppresses the temperature sensitivity of a mutant in the yeast A. oryzae B ortholog (ypl1-2). The nuclear localization of Ypi1-13Myc is lost in the temperature sensitive sds22-6 mutant. These in vivo results, together with studies on other YPI1 mutants and genetic interactions between YPI1, GLC7, and SED22 alleles, suggest that Ypi1 and Sds22 act together to positively regulate nuclear Gli7 activity during the mitotic cell cycle.

A Functional Link between Kinetochore and Spindle Assembly
A. D. McAinsh, 1 J. Winter, 1 A. Toso, 2 P. Meraldi 2; Chromosome Segregation Laboratory, Marie Curie Research Institute, Oxed, United Kingdom, 2Institute of Biochemistry, ETH Zurich, Zurich, Switzerland

Kinetochore are large multiprotein machines that perform at least two critical functions during cell division: (1) they promote the bipolar attachment of duplicated sister-chromatids by forming bridges between centromeric DNA and the plus-end of spindle microtubules; (2) they act as sensors of microtubule attachment, delaying anaphase onset via the spindle checkpoint in the presence of incorrect attachments. We have recently discovered a further function in which defective kinetochores, arising from the depletion of the kinetochore protein Mcm21R (CENP-0), can act in a dominant fashion to interfere with normal spindle assembly. Live cell imaging of double stable Histone2B-EGFP/ubrin-mRed HeLa cells reveals that Mcm21R-depleted cells fail to efficiently assemble a bipolar spindle. This phenotype is therefore distinct from that of Clasp, in which bipolar spindles form transiently, then collapse. How do kinetochores influence the assembly of the mitotic spindle? Kinetochore in Mcm21R-depleted cells remain correctly attached to microtubules, although cold treatment of cells causes the destabilization of α-fibers. This suggests that kinetochore-localized Mcm21R may act to stabilize microtubules, which in turn, is compatible with normal spindle assembly. Consistent with this idea, stabilization of microtubule plus-ends by depletion of the microtubule destabilizing kinesin MCAK or treatment with low doses of taxol can suppress the spindle assembly defect in Mcm21R-depleted cells. Future work aims to determine the precise molecular mechanism by which Mcm21R and related proteins control spindle assembly.

Pre-Mitotic Clustering of Centromeres May Help Efficient Microtubule Search-and-Capture in Mitosis in Drosophila S2 Cells
H. Shroff, C. Gradinaru, R. Wollman, R. Vale, G. Goshima; Physiology Course, Marine Biological Laboratory, Wood's Hole, MA

Centromeres are specialized chromosome regions that build kinetochore scaffolds that capture dynamic centrosomal microtubules during prometaphase (search-and-capture model). However, a recent theoretical study revealed that the mechanism of search-and-capture alone is insufficient to account for the rapid capture of all centromeres that is observed in vivo. Here, we present experimental and computational data suggesting that centromere clustering in the prophase nucleus may enhance search-and-capture efficiency. By observing Msi2-GFP and DAPI as centromere and nuclear markers, respectively, we found that centromeres are not uniformly distributed but are rather preferentially clustered near the center of the nucleus in interphase and prophase Drosophila S2 cells. Using our experimentally measured centromere distributions, computer simulations showed a significant reduction in the microtubule search-and-capture time compared to the case where centromeres are uniformly distributed in the nucleus. Preliminary observations suggest that centromeres are clustered around nuclear RNAs, particularly the nucleolus. Our results show that centromeres are preferentially clustered near the center of Drosophila nuclei, which we suggest facilitates the rate of achieving metaphase alignment. 1. The Conserved KMN Network Constitutes the Core Microtubule Binding Site of the Kinetochore
I. M. Cheeseman, A. Desai; UCSD, Ludwig Institute for Cancer Research, La Jolla, CA

The microtubule-binding interface of the kinetochore is of central importance in chromosome segregation. Although kinetochore components that stabilize, translocate on, and affect the polymerization state of microtubules have been identified, none have proven essential for kinetochore-microtubule interactions. Here, we examined the conserved KNL-1/Mis12 complex/Necl40 complex (KMN) network, which is essential for kinetochore-microtubule interactions in vivo. Previous work has suggested that these proteins function indirectly to generate kinetochore-microtubule attachments through a role in kinetochore assembly. We found that partially purified endogenous KMN network binds directly to microtubules in vitro suggesting that it is closely associated with a microtubule binding activity. Using bacterial co-expression to reconstitute these proteins, we identified two distinct microtubule binding domains within the KMN network. Future work aims to determine the precise molecular mechanism by which Mcm21R and related proteins control spindle assembly.

Crystal Structure of a TOG Domain: Conserved Features of XMAP215/Dis1 Family Proteins and Implications for Tubulin Binding
J. Al-Bassam, 1 A. Hyman, 2 S. C. Harrison 1,2; Department of Molecular Pharmacology and Biological Chemistry, Harvard Medical School, Boston, MA, 2Max Planck Institute for Molecular Cell Biology and Genetics, Dresden, Germany, 3Howard Hughes Medical Institute, Boston, MA

Stu2p from budding yeast and XMAP215 from Xenopus belong to the conserved Dis1/XMAP215 family of microtubule-associated proteins (MAPs) that are essential for mitotic division. A common feature of MAPs in this family is the presence near the NH2 terminus of two to five, 250-residue conserved repeats termed TOG domains. Our recent work has shown that TOG domains in Stu2p associate directly with tubulin dimer and microtubule ends. When it captures a tubulin heterodimer, Stu2p homodimer undergoes a large conformational transition from an open structure to a closed one around tubulin. We have determined the structure of a single TOG domain from the C. elegans ortholog Zyg9 to 1.9 Angstrom resolution using x-ray crystallography. A TOG domain is a flat paddle-like structure composed of six HEAT repeat domains that are stacked side by side. There is a strong pattern of sequence conservation in multiple TOG domains within each family and among different members of the Dis1/XMAP215 family. The most conserved solvent-exposed residues of the TOG domain are in the turns between the first and second helices of each HEAT repeat. These conserved turns appear on a single face of the paddle-like TOG structure. We propose that this conserved face of the TOG domain contacts a tubulin heterodimer.

The Human Spindle Checkpoint Protein Bub3 Regulates Kinetochore-Microtubule Attachments
E. Logarinho, T. Resende, C. Torres, H. Bousbaa; Molecular and Cellular Biology, ICS-N, CESPU cru, Gandra PRD, Portugal

Accurate segregation of chromosomes during mitosis is ensured by spindle checkpoint mechanisms that monitor kinetochore-microtubule (K-MT) attachments and induce a mitotic delay until full metaphase alignment is achieved. Recent data have implicated the checkpoint proteins Bub3 and BubR1 in the regulation of chromosome-to-spindle attachments. Unlike these proteins whose roles during mitosis have been well defined, Bub3 role has remained poorly studied. Here we show, using RNA interference and small molecule inhibitors, that besides its role in spindle checkpoint activity, Bub3 is also required for proper K-MT attachment. Chromosomes in Bub3-depleted cells are able to congress and organize a metaphase plate that, however, typically exhibits misaligned chromosomes. Although both aligned and misaligned kinetochores attach to microtubules in Bub3-depleted cells, these attachments are defective in terms of stability, microtubule occupancy and pulling force generation. Comparative analyses between Bub3, Bub1 and BubR1 depletion phenotypes indicate that whereas chromosome attachment and alignment are severely compromised following BubR1 repression, in the absence of Bub3 or Bub1, attachments are still established which, though defective, account for significant chromosome congression. Importantly, analysis of Bub3/Bub1, Bub3/BubR1 or Bub1/BubR1 double-depletion phenotypes strongly suggests that Bub3 acts differently from BubR1 and cooperatively with Bub1 in the regulation of K-MT attachments.

Investigating the Spindle Checkpoint in Early C. elegans Embryos
A. W. Essex, 1 I. Cheeseman, A. Dammermann, K. Oegema, A. Desai 1; Biomedical Sciences, University of California, San Diego/Ludwig Institute for Cancer Research, San Diego, CA, 2Laboratory of Chromosome Biology, Ludwig Institute for Cancer Research, San Diego, CA

403
The spindle checkpoint delays anaphase onset until all chromosomes are properly attached to the spindle. Previous studies have shown that BUB-1 and the Rod/Zwilch/Zw10 (RZZ) complex are essential for checkpoint activation and also have checkpoint-independent functions in chromosome segregation. We are utilizing the early C. elegans embroyo to investigate BUB-1 and RZZ complex functions and to analyze the relationship between checkpoint structure and checkpoint activation. To develop a robust functional assay for checkpoint activation in C. elegans, we have explored the consequences of deleting ZYG-1, a kinase required for centrosome duplication. Following ZYG-1 depletion, the first mitotic division is normal, but monopolar spindles form in both daughter cells in the second division. The presence of monopolar spindles results in a striking delay in the metaphase-anaphase transition, assessed using chromosome decondensation and onset of cortical contractility in live imaging data. Double depletion of ZYG-1, and MAD-1/MDF-2 does not affect first division timing but abolishes the delay observed in the second division. Using an integrated strain expressing GFP-MAD-2, we have found that GFP-MAD-2 localization is enriched on unattached kinetochores in monopolar spindles. By performing double depletions of ZYG-1 with other checkpoint pathway and structural kinetochore proteins, we have defined the requirements for GFP-MAD-2 localization and checkpoint activation.

We have also independently utilized quantitative assays to characterize the chromosome segregation defects observed following BUB-1 and RZZ complex inhibition. Our results indicate that both of these components contribute to the timely establishment of mechanically stable kinetochore-microtubule connections after nuclear envelope breakdown.

A Complex of Sli15-Bir1 (INCENP-Survivin) Connects Centromeres to Microtubules and Is the Likely Tension Sensor Controlling Aurora B Activation

Spindly, a Novel Regulator of Mitotic Dynein Activity

Aurora B Phosphorylation of Hec1/Ndc80 Is Required for Mitotic Spindle Assembly

Regulation of Kinetochore-Microtubules by Hec1 and Aurora B Kinase
The Multiple Roles of Mps1 Kinase Activity in Human Mitosis

N. Jelluma, R. H. Medema, G. J. P. Kops; Medical Oncology, UMC Utrecht, Utrecht, The Netherlands

The mitotic checkpoint is the primary guardian against chromosome missegregation that result in aneuploidy, a hallmark of human cancers. At the heart of the mitotic checkpoint are three kinases, Mps1, Bub1 and BubR1 that are responsible for the transduction of the checkpoint signal from unattached kinetochores. Bub1 and BubR1 have additional roles in mitosis, as both are required for chromosomes to properly attach to the spindle and Bub1 is needed for maintenance of centromeric cohesion. It is unclear whether the phospho-transfer activities of the three kinases are required for the mitotic checkpoint or for any of the additional roles in mitosis in human cells. We show here that Mps1, like BubR1 and Bub1, has multiple functions in mitosis, all of which require its kinase activity. siRNA-driven depletion of Mps1 abrogates the mitotic checkpoint and causes massive chromosome missegregations and cell death. Replacement of endogenous Mps1 with exogenous kinase-deficient protein proved that Mps1 kinase activity is indispensable for checkpoint function and viability. Like BubR1 and Mps1, Mps1 participates in the timing of mitosis, as furrow ingression follows nuclear envelope breakdown twice as fast in Mps1-depleted cells vs. control. This increased rate of mitotic progression is reverted to normal by exogenous wild-type Mps1 but not kinase-deficient Mps1. Analysis of chromosome movements in Mps1-depleted cells in real-time furthermore showed that ~80% of cells had severe chromosome alignment problems. Of these, ~75% could not reach full alignment within 2-3 hours when forced to stay in a checkpoint-independent manner. Mps1 kinase activity was also requisite for this novel mitotic function of Mps1. In short, Mps1 kinase activity is critical for mitotic checkpoint signaling, proper timing of mitosis, chromosome alignment, and viability. This places the Mps1 kinase as a central activity in controlling proper execution of mitosis.

Vor-tebrate Slugoshin 1 Is a Substrate for Aurora B Kinase and Necessary for Kinetochore Assembly

J. Pouwels, A. M. Kukkonen, W. Lan, P. T. Stuenenberg, M. J. Kalliio; VTT Medical Biotechnology, Turku, Finland, 3Department of Biochemistry and Molecular Genetics, University of Virginia Medical School, Charlottesville, VA, 4Center for Biotechnology, University of Turku, Turku, Finland

We have previously shown that Aurora B is required to generate spindle checkpoint signals and assemble kinetochores, yet the exact mechanisms of these reactions are not known. Slugoshin 1 (Sgo1) has a role in protecting the centromeric cohesion between sister chromatids, implying that Sgo1 is implicated in the tension sensing system and in regulation of kinetochore microtubule stability. We investigated the fine localization of Sgo1 in HeLa cells at the light microscope level by (Sgo1) has a role in protecting the centromeric cohesion between sister chromatids, both in somatic cells and in meiocytes. The mechanism of Sgo1 mediated protection of cohesion is unknown, but recent studies point to an essential role for dephosphorylation of cohesion by protein phosphatase 2A (PP2A). Sgo1 is functionally related to Aurora B kinase as both have been implicated in the tension sensing system and in regulation of kinetochore microtubule stability. We investigated the fine localization of Sgo1 in HeLa cells at the light microscope level by comparing localization of YFP-Sgo1 to the localization of several kinetochore marker proteins. During prophase and prometaphase YFP-Sgo1 accumulates at the inner-kinetochore between the Aurora B and Hecl1 domains. Sgo1 diminishes at each kinetochore after the chromosome arrives at the metaphase plate. Depletion experiments using siRNA in HeLa cells showed that Sgo1 binding to kinetochores depends on INCENP, Bub1, but not PIK1, Cenp-F and the spindle checkpoint protein BubR1. In a reverse experiment, we discovered that the kinetochore localization of PIK1, Bub1 and CENP-F, but not INCENP, Bub1 and Hecl1 depended on Sgo1. Xenopus Sgo1 is phosphorylated by Aurora B kinase in vitro. Moreover, depletion of the Aurora B activator INCENP by siRNA or chemical inhibition of Aurora B activity disrupts the kinetochore localization of Sgo1 and instead causes Sgo1 to accumulate on chromosome arms. These data demonstrate that Sgo1 plays a central role in proper kinetochore assembly and suggest that Aurora B kinase works through Sgo1 to regulate the spindle checkpoint and kinetochore function.

Polo-like Kinase 1 Phosphorylation and Promotes Translocation of MAD1 during G2-M Transition

Y. Chi, H. Kerstin, K. Jeang; NIAID, NIH, Bethesda, MD

The mitotic spindle assembly checkpoint (SAC) monitors attachment of duplicated chromosomes to spindle poles and ensures proper chromosome segregation in mitosis. Mitotic arrest deficient protein 1 (MAD1) is a component of the mitotic spindle assembly checkpoint. MAD1 associates with nuclear pore complex (NPC) in interphase and translocates to kinetochores as the nuclear envelope breaks down. Kinetochore-attachment by MAD1 is proposed to trigger MAD1 to depart from MAD1 and to associate with CDC20-APC/C complex leading to inhibition of premature chromosome segregation. Currently, how MAD1 is regulated during the G2-M transition is unknown. Polo-like kinase 1 (PLK1) is a Ser/Thr kinase that plays a critical role in regulating APCC/ and mitotic progression. Here we show that MAD1 is hyper-phosphorylated in M phase, and that MAD1 and PLK1 co-localize at the nuclear periphery during nuclear envelope breakdown. When the cell progresses into prometaphase, both MAD1 and PLK1 translocate to kinetochores. Knocking down PLK1 using RNAi abolished the kinetochore localization of MAD1 and erased the hyperphosphorylation of MAD1. We present evidence that PLK1 phosphates MAD1 in the latter’s N-terminus to regulate MAD1 function.

Identification of Phosphoprotein Complexes Associated with the Mitotic Apparatus

The chromosomal passenger complex (CPC) controls chromosome, cytokinesis and membrane dynamics during mitosis. By performing mass spectrometry, imaging and biochemical analyses on mitotic complexes immunoprecipitated by a phosphorylation specific antibody that cross reacts with the CPC, we identified known and potential CPC interacting proteins and a mitotic phosphorylation motif on a subset of these proteins. Proteins identified in the phosphoprotein complexes have linkages to the CPC (Aurora-B, INCENP, TD-40, cdc11, and protein phosphatase 2A), the anaphase promoting complex/cyclosome (cdh1, SMAD2), microtubule regulation (ch-TOG, stathmin-1, NudMA, cytoplasmic dynein, MAPs, tubulin), cytokinesis (Ric-8, actin, myosin, rac1, clathrin, actin-binding lim protein 1) and cell signaling pathways (SMAD2, catenins, casein kinase, cyclin B, 14-3-3 proteins, small G proteins). Phosphopeptide analysis confirmed ch-TOG and Ric-8, two proteins important for mitosis, in kinetochore assembly and cytokinesis respectively, are phosphorylated on a motif recognized by the antibody. We infer, based on co-immunoprecipitation experiments, that INCENP and cdc11 are phosphorylated during mitosis and, in the case of INCENP, this phosphorylation is associated with CPC complexes containing Aurora-B. Phospho-specific antibodies demonstrate that the TGF-beta signaling molecule, SMAD2 and Polo-like kinase 3 (Pik3) are phosphorylated on this motif during mitosis. Moreover, Pik3 phosphorylation correlates with its localization on mitotic sites that overlap with Pik1 and the CPC. These results characterize a novel receptor for the analysis of mitotic phosphoprotein complexes and identify its phosphorylation motif that may regulate the recruitment (or activation) of proteins to the mitotic apparatus and the CPC.

The Arp2/3 Complex Requires Phosphorylation of the Arp2 Subunit to Nucleate Actin Filaments

The actin-related protein (Arp) 2/3 complex is the primary nucleator of new actin filaments in most crawling cells. Nucleation promoting factors (NPFs) of the WASP/Scar family are the currently recognized activators of the Arp2/3 complex. We now report that phosphorylation of the Arp2 subunit is critical for activation of the Arp2/3 complex by NPFs. Arp2 phosphorylation increased in cells in response to growth factors and was confirmed in purified Arp2/3 complexes from Acanthamoeba, bovine, and yeast, and from baculovirus-expressed recombinant Arp2/3. We identified phosphorylation of conserved T237, T238, and Y202 and used computational modeling of bovine Arp2/3 to predict that T237 and Y238 interact with conserved R105 and R106 in the p20 subunit and pY202 interacts with a conserved R490 in the Arp3 subunit to induce a conformational change and align Arp2 and Arp3 subunits to resemble an actin dimer. Testing this prediction, mutation revealed that Arp2 must be phosphorylated on either T237/238 or Y202 to nucleate actin filaments. When dephosphorylated by either PP2Cα or YOP or a dual specificity phosphatase the Arp2/3 complex does not nucleate actin filaments. Threonine and tyrosine-dephosphorylation of Arp2/3 is able to bind the sides of actin filament and NPFs but cannot bind the pointed-ends of gelsolin-capped actin seeds. The functional significance of Arp2 phosphorylation sites was confirmed in Drosophila S2 cells, which form lamellae. S2 cells transformed with Arp2
Functional Mapping of Residues Involved in Arp2/3 Complex Activation by Nucleation-promoting Factors

A. D. Siripsa, E. D. Goleuy, E. A. Znarsers, M. D. Welch; Molecular and Cell Biology, University of California, Berkeley, Berkeley, CA

Actin nucleation and filament branching by the Arp2/3 complex requires binding to activating factors that include nucleotide, actin, and nucleation-promoting factors (NPFs). However, the precise molecular interactions involved in complex activation remain unclear. To identify sites of interaction with binding partners and gain insight into the molecular machinery of Arp2/3 complex activation, we have performed site-directed mutagenesis on conserved Arp2/3 complex surface residues. We have identified several mutations in putative NPF binding regions of Arp2 and Arp3 that reduce the nucleating activity of the complex. Preliminary experiments suggest that mutation of these surface patches in Arp2 and Arp3 reduces the affinity of the complex for the WCA domain of the NPF WASP. Of the putative WASP-binding surfaces that we identified in Arp2 and Arp3, mutations in Arp3, but not in Arp2, also inhibit binding of the complex to the NPF cortactin, suggesting that the two NPFs share distinct binding sites, yet also differ in their interactions with the Arp2/3 complex. To identify complimentary NPF residues that are critical for Arp2/3 binding and activation, we have also generated a series of mutations in the Arp2/3-binding domain of WASP. Preliminary results suggest that WASP C-region residues that are required to promote Arp2/3 complex activation are also required to induce a conformational change in the complex, as measured by fluorescence resonance energy transfer (FRET). We will compare the effect of these mutations on NPF affinity with their effects on Arp2/3 conformation, to determine whether NPF binding, conformational change, and activation are mediated by the same residues, or whether they are separable activities. By developing a more detailed picture of the molecular interactions and conformational changes required for Arp2/3 activation, we hope to better understand the complex process by which multiple factors come together to promote regulated actin polymerization in the cell.

Distinct Roles of Myo1p and Wsp1p in Fission Yeast Actin Patch Assembly

V. A. Sirotkin, K. Macmillan, T. D. Pollard; Molecular, Cellular and Developmental Biology, Yale University, New Haven, CT

Depletion of two different subunits of the Arp2/3 complex in B35 neuroblastoma cells resulted in altered cell morphology, severe depletion of F-actin at the leading edges, inhibition of growth cone formation, and death of the cells. In addition, filopodia were absent. Filopodia are long, narrow extensions of the cell surface that are thought to protrude from the cell in a directed manner and to mediate contact guidance. The protrusion of the cell's leading edge is driven by two types of actin-based organelles, lamellipodia and filopodia, which are thought to form in a coordinated manner. Structural, kinetic and immunochemical analyses of growth cones in two neuroblastoma cell lines and two types of primary neurons revealed that filopodia are formed from lamellipodia-like veins, which have denticrystall organization and contain Arp2/3 complex and cortactin. Correlative electron microscopy demonstrated that, similar to other cells, filopodia in neuronal cells are formed by the conversion of lamellipodia to filopodia. Functional characterization of the Arp2/3 complex in the protrusive behavior of neuronal cells was tested by RNAi approach. Depletion of two different subunits of the Arp2/3 complex in B35 neuroblastoma cells resulted in altered cell morphology, severe depletion of F-actin at the leading edges, inhibition of growth cone formation, and death of the cells. In this work, we analyzed the mechanisms of protrusion in neuronal growth cones, which are thought to resemble filopodia in two neuroblastoma cell lines and two types of primary neurons revealed that filopodia are formed from lamellipodia-like veins, which have denticrystall organization and contain Arp2/3 complex and cortactin. Correlative electron microscopy demonstrated that, similar to other cells, filopodia in neuronal cells are formed by the conversion of lamellipodia to filopodia.
Traction forces impinged on the extracellular matrix (ECM) by migrating cells are dynamically regulated to create a gradient of force from the cell front to the rear. Mechanical forces are generated in the actin cytoskeleton by myosin-II motors and transmitted to the ECM via dynamic macromolecular assemblies called focal adhesions (FA). However, little is known about how dynamics of the contractile actomyosin cytoskeleton is translated into a spatiotemporally regulated pattern of traction forces exerted on the ECM. To address this question, we have developed compliant cell culture substrates compatible with both the glass trasecco microcopy and fluorescent speckle microscopy (FSM). Far red 40-nm latex spheres are co-polymerized into a polyacrylamide (PAA) gel that is covalently bound to both the glass coverslip; the gel thickness, controlled by the volume of PAA per coverslip, is varied between 5-15 microns and fibroinect is coupled to the PAA surface using established techniques. PtK1 epithelial cells are cultured overnight and we express GFP constructs of the FA protein, paxillin and micro-inject x-rhodamine labeled G-actin. Using a multi-spectral spinning disk confocal microscope, we image actin, paxillin and spheres every 10 sec. The spheres are embedded at sufficiently high density to obtain a near diffraction-limited deformation map of the substrate. Using established techniques, we reconstruct the force field generated by the cell from these substrate deformations to visualize dynamic maps of cellular traction with submicron resolution. To assess the assembly, disassembly and motion of the actin cytoskeleton with high spatiotemporal resolution, we use quantitative FSM. By correlating the speed and direction of actin, FA size and the magnitude and direction of the traction force, we hope to elucidate the biophysical mechanisms by which an actomyosin network generates traction force through substrate adhesions. This is of essential importance to further our understanding of the underlying biophysical regulation of cell migration.

Spire and Cappuccino - Coordinated Actin Nucleators

M. E. Quinnan,1 E. Ekerhoff,2 R. D. Mullins3; 1Cell and Molecular Pharmacology, UCSF, San Francisco, CA, 2Institut für Medizinische Strahlenkunde und Zellforschung, Universität Würzburg, Würzburg, Germany

Spire (Sp) and Cappuccino (Capu) are actin nucleation factors required to establish polarity of Drosophila oocytes. Their mutant phenotypes are nearly identical, and they interact genetically. We found that Sp and Capu proteins physically interact in vitro and in vivo, and that this interaction regulates the actin nucleation and microtubule binding activities of Capu. Direct coordination between distinct actin nucleators has not been described before and begs the question of why cells require a complex that can nucleate by two mechanisms and bind microtubules.

To address this question we have studied the individual components and their interactions. Spire forms directly nucleate and elongate actin filaments through their carboxy-terminal FH (formin homology) domain and FH2 domains. Although molecular function of formin has been uncovered using actin assembly assay with pyrene-labeled actin as the standard method, the cellular roles of each formin in mammalian cells are not fully understood. To study actin polymerization in the intracellular environment, we established a simple in vitro actin polymerization assay using cytosol. Briefly, glutathione beads coated with recombinant GST-FH1-FH2 of formin were incubated with human platelet cytosol in the presence of ATP to allow actin to polymerize on beads. After incubation, beads were washed, fixed and stained with rhodamine-labeled phalloidin.

The fluorescence was observed with a fluorescence microscope and quantified with a fluorometer. The actin polymerization in the cytosol was dependent on ATP and temperature. GST or GST-FH2 alone could not polymerize actin, suggesting that some G-actin sequestering factor like profilin exists in human platelet cytosol, which is consistent with the fact that excess actin polymerization does not occur in the resting platelets. Daam1 is a member of formin family abundantly expressed in platelets and its FH2 domain consists of five regions (lasso, linker, knob, coiled-coil and post) like yeast Bni1p. Using newly established assay here, we demonstrated that Daam1 had actin polymerizing activity and the length, not specific amino acid sequence, of its linker region was significant for polymerization. This assay is simple and reproducible and could become a powerful tool to investigate the behavior of actin molecule in the intracellular environment.
PfACTI and PfACTII, which are similar to TgACT1 and also diverge from conventional actin. Molecular modeling was used to identify residues unique to apicomplexan actin that may affect polymerizes into very short filaments. Remarkably, TgACT1 has a low critical concentration, but apparently fails to fully anneal and is thus unstable.

Actin filament turnover is crucial to motility as shown by the paralyzing effects of jasplakinolide, an agent that stabilizes actin filaments. Apicomplexans contain few predicted for a Brownian ratchet. In addition, motion was saltatory with a broad distribution of step sizes that is correlated in time. These data point to a model in which thermal fluctuations of propelled microspheres using three-dimensional laser tracking. In these experiments, velocity was inversely proportional to viscosity and proportional to the amplitude of bead fluctuations as determined from videos of vectorial force transients. This result is consistent with cofilin's ability to enhance actin filament turnover and our finding that cofilin is required for EGF-induced actin filament assembly in the cell edge by supplying actin monomers for polymerization, not by directly creating new barbed ends through its severing activity. By measuring the fluorescence decay of locally photoactivated Drosha-actin in the cytoplasm, we analyzed the actin monomer population in the cytoplasm of living cells and showed that cofilin inactivation by LIM-kinase expression reduced the cytoplasmic actin monomer population and coexpression of a cofilin mutant, which has severing activity but only weak depolymerizing activity, significantly rescued it. These results suggest that the severing activity of cofilin is required for supramolecular activity in the cytoplasm. They also showed that the cytoplasmic actin monomer population correlates well with the rate of actin monomer incorporation into the tip of the lamellipodium. Cofilin inactivation suppressed the EGF-induced decrease in the rates of new Arp2/3-mediated cortical filaments not only appear to provide mechanical support but adjust the surface interactions of the vesicles as well. Our artificial cell-like system has initiated an avenue to bridge the interior of our vesicles; these structural modes are directly related to the response of the artificial cells. By analyzing images and force curves in atomic force microscopy studies, the actin filaments not only appear to provide mechanical support but adjust the surface interactions of the vesicles as well. Our artificial cell-like system has initiated an avenue to bridge the understanding of living cells with in vitro biopolymers. These results will be useful in a wide range of fields including polymer physics, cell biology, and biotechnology.

Coronin Synergizes with Cofilin In Vitro and In Vivo to Drive Rapid Turnover of Actin Filaments

M. Gandhi, B. Balcer, M. Jangi, B. Goode; Rosenthal Basic Medical Sciences Research Center, Brandeis University, Waltham, MA Dynamic remodeling of cell shape and infrastructure requires the on-going and rapid turnover of actin networks, yet the mechanisms driving actin filament disassembly have only just begun to emerge. Here, we describe a new role in promoting actin turnover for a conserved component of the actin cytoskeleton, coronin. To date, two functional activities of coronin have been described, filament bundling and direct inhibition of Arp2/3 complex, both of which require the coronin coiled coil domain. We show that budding yeast coronin (Cmr1) genetically interacts with cofilin, and that loss of Cmr1 in vivo reduces rates of actin patch and cable turnover and exacerbates the actin turnover defects of a cof1-22 mutation. A construct lacking the coronin coiled coil domain, Cmr1 (1-460), is sufficient to complement the genetic interaction between Cmr1 and cof1, indicating that the mechanism by which coronin promotes actin turnover is distinct from its previously described activities. Consistent with these genetic results, purified Cmr1 (1-460) enhances cofilin-dependent acceleration of actin filament disassembly and amplification of barbed ends in vitro. Using site-directed mutagenesis, we mapped the actin-binding surface to conserved surface residues on Cmr1 and demonstrate that actin binding is required for coronin’s function in promoting actin turnover. Further, we show that Cmr1 increases the apparent affinity of cofilin for actin filaments, suggesting a possible mechanism for the turnover function. We are now investigating how this new cellular function is integrated with coronin regulation of Arp2/3 activity and whether it is a conserved function. Coordination of the effects of coronin on Arp2/3-dependent actin assembly and cofilin-dependent disassembly may be important in a variety of species, where coronin promotes endocytosis and cell motility.

Coronin Synergizes with Cofilin In Vitro and In Vivo to Drive Rapid Turnover of Actin Filaments

Villin Severing Activity Enhances Actin Based Motility

C. Revenu, M. Coustoix, C. Sykes, D. Louvard, S. Rohme; 1UMR144, Institut CURIE, Paris, France, 2UMR168, Institut CURIE, Paris, France Villin, a protein associated with actin in microvilli, bundles, caps, macropodia and severs actin in a calcium-dependent manner in vitro. We hypothesised that villin severing activity is responsible for its reported role in enhancing cell plasticity and motility. To test our hypothesis, mutations were introduced in villin to impair this activity. By pyrene-actin assays, we demonstrate that this mutant has a strongly reduced severing activity whereas nucleation and capping remain unaffected. The bundling activity and the morphogenic effects of villin in cells are also preserved in this mutant. We thus succeeded in dissociating the severing from the other three activities of villin. To analyse the contribution of villin severing to actin dynamics, we reconstituted in an vitro actin-based motility assay in which the usual capping protein is replaced by either the WT or the severing mutant of villin. Villin severing activity enhances the velocity of beads by more than two folds and reduces the density of actin in the comets. We propose a model in which by severing actin filaments and capping their barbed-ends, villin increases the concentration of actin monomers available for polymerisation, a mechanism that might be parallelled in vivo when an enterocyte undergoes an epithelio-mesenchymal transition. We are now analysing the impact of the loss of villin severing activity on the motility of epithelial cells and on the infectious process of Shigella flexneri. The role of villin severing activity will also be tested in vivo by trying to rescue with this mutant the lack of plasticity of the villin knock-out mice.

Understanding Biological Structures through Exploring the Mechanical Response of Artificial Cell-like Systems

Y. Zhang, C. Cheng, B. Cusick, T. Kowalewski, P. LeDuc; 1Mechanical Engineering, Carnegie Mellon University, Pittsburgh, PA, 2Chemistry, Carnegie Mellon University, Pittsburgh, PA The mechanical response of a living cell is highly tuned to the structural environment that is provided by the cytoskeleton. This architectural arrangement, which has many components, provides both structural and organizational regulation that is essential for complex cellular response such as chemotaxis and mitosis. While many investigations have provided insight into determining the mechanical response of the cell from either an in vivo or in vitro perspective, a significant gap exists in determining how this response is bridged between the components such as the individual cytoskeletal elements and the higher order organism such as the living cell. To address this gap and to understand this highly efficient and hierarchical organization, we construct an intermediate model by mimicking the cell cytoskeleton in an artificial environment composed of membrane-like spherically distributed lipid bilayers. We establish an experimental model by first encapsulating G-actin into giant unilamellar vesicles using an electroformation method and then we polymerize actin filaments (F-actin) within individual liposomes. Through visualizing our system by epi-fluorescent and laser confocal microscopy, we observe that actin filaments remain inside the artificial cell membrane near the bilayer or as free filaments within the interior of our vesicles; these structural modes are directly related to the response of the artificial cells. By analyzing images and force curves in atomic force microscopy studies, the actin filaments not only appear to provide mechanical support but adjust the surface interactions of the vesicles as well. Our artificial cell-like system has initiated an avenue to bridge the understanding of living cells with in vitro biopolymers. These results will be useful in a wide range of fields including polymer physics, cell biology, and biotechnology.

Experimental Confirmation of the Brownian Ratchet Mechanism of Actin-based Motility

J. W. Shaevitz, D. A. Fletcher; 1Integrative Biology, UC Berkeley, Berkeley, CA, 2Bioengineering, UC Berkeley, Berkeley, CA A Brownian ratchet mechanism has been proposed to couple actin polymerization to cellular translocation through the rectification of thermal motions. We tested this model by following actin-propelled microspheres using three-dimensional laser tracking. In these experiments, velocity was inversely proportional to viscosity and proportional to the amplitude of bead fluctuations as predicted for a Brownian ratchet. In addition, motion was saltatory with a broad distribution of step sizes that is correlated in time. These data point to a model in which thermal fluctuations of the microsphere, and not the actin filaments, govern motility. This conclusion is supported by Monte carlo simulations of an adhesion-based Brownian ratchet.

Divergent Actin in Apicomplexan Parasites

K. M. Skillman, K. Tang, N. Sahoo, D. Sept, L. D. Sibley; 1Department of Molecular Microbiology, Washington University School of Medicine, St. Louis, MO, 2Department of Biomedical Engineering, Center for Computational Biology, Washington University in St. Louis, St. Louis, MO Plasmodium falciparum and Toxoplasma gondii are important parasitic pathogens of the phylum Apicomplexa. Parasite invasion of host cells involves a gliding motility mechanism that is dependent on polymerization of parasite actin. During gliding, myosin motors anchored in the inner membrane complex translocate actin filaments rearward. The actin is linked to secreted cell surface adhesins that move along the surface, resulting in forward motion of the parasite. In non-motile parasites, the majority of actin is monomeric and filaments only assemble upon initiation of gliding motility. Actin filament turnover is crucial to motility as shown by the paralyzing effects of jasplakinolide, an agent that stabilizes actin filaments. Apicomplexans contain few conventional actin binding proteins, but a conserved profilin and actin-depolymerizing factor are likely important for regulating turnover. During gliding, actin and profilin recycle from diffuse and punctate distributions in the cytoplasm, respectively, to the parasite periphery. T. gondii actin (TgACT1) is functionally highly divergent from conventional actin and only polymerizes into very short filaments. Remarkably, TgACT1 has a low critical concentration, but apparently fails to fully anneal and is thus unstable. P. falciparum has two actin alleles, PfACTI and PfACTII, which are similar to TgACT1 and also diverge from conventional actin. Molecular modeling was used to identify residues unique to apicomplexan actin that may affect filament stability. These studies reveal critical subdistinctions in the hydrophobic plug and in an intramolecular salt bridge in parasite actins. Consistent with these changes being responsible for
2233 Actin Filament Fragmentation and Annealing Are Responsible for Unexpectedly Large Length Diffusivities Measured In Vitro
J. Fass, J. Bamburg, A. Mogilner 1; Mathematics, University of California Davis, Davis, CA; 2; Biochemistry and Molecular Biology, Colorado State University, Fort Collins, CO
Recent studies of actin dynamics in vitro have found unexpectedly large length diffusivities that are ~30-fold greater than expected. Stochastic modeling attempting to address this discrepancy predicted that high diffusivity resulting from random exposure of the ADP-actin core should occur below but not at the critical concentration, or that the controversial assumption of vectorial hydrolysis is necessary to match observed diffusivities. However, these models disregarded fragmentation and annealing. We incorporated these two processes into multi-filament, variable volume stochastic simulations in order to evaluate their contributions to empirically observed length diffusivities. We found that annealing and fragmentation - even at the higher levels expected from the use of labeled actin - do not change the distribution of nucleotide states at the barbed end. Nevertheless, the inclusion of fragmentation and annealing yield length diffusivities comparable to those observed experimentally (~30 mon/sec). Thus we conclude that fragmentation and annealing directly increase actin filament length diffusivity, explaining recent experimental results.

2234 The Hsp90 Co-Chaperone Unc45b Targets the Myosin Motor Domain
R. Sriakulam, L. Liu, D. A. Winkelmann; Pathology and Laboratory Medicine, Robert Wood Johnson Medical School, Piscataway, NJ
Myosin folding and assembly in striated muscle is mediated by the general chaperones Hsc70 and Hsp90. This pathway may involve a myosin specific co-chaperone, UNC45. C. elegans UNC45 is a founding member of the Ucs family of proteins that all share sequence homology in a putative myosin binding domain. These genes are known to affect myosin dependent cellular processes such as muscle contraction, establishment of cell polarity, cytoskeleton, and vesicle transport. In addition to the C-terminal UCS domain, UNC45 has N-terminal TPR motifs that are common to many Hsp90/Hsc70 co-chaperones and a central domain with β-catenin homology repeats. Two UNC45 genes are found in vertebrates, including a striated muscle specific form, Unc45b/SM-UNC45, that is believed to mediate the folding and/or assembly of striated muscle myosin. We have investigated the role of Unc45b in myosin folding. Epitope tagged marine Unc45b was expressed in and isolated from muscle and non-muscle cells. Under physiological conditions, Unc45b isolates as a stable complex with the endogenous Hsp90. This interaction can be disrupted at high ionic strength, and purified Unc45b re-binding human Hsp90 in solution and rabbit Hsp90 when diluted into a reticulocyte lysate. Unc45b binds the partially folded myosin motor domain when incubated with myosin subfragments synthesized in a reticulocyte lysate. This binding is independent of the myosin rod or light chains, and Unc45b does not bind native myosin subfragments. Furthermore, Unc45b enhances the folding of the myosin motor domain when included in the lysate during synthesis. Thus, mammalian Unc45b forms a stable complex with Hsp90, binds an unfolded configuration of the myosin motor domain, and promotes motor domain folding during de novo synthesis. (Supported by NIH grant R01 AR38454)

2235 Myosin-IIA Heavy Chain Phosphorylation Regulates the Motility of Carcinoma Cells
N. G. Dullanovna, R. P. House, A. R. Bresnick; Biochemistry, Albert Einstein College of Medicine, Bronx, NY
In non-muscle cells, multiple mechanisms control the localized formation of myosin-II filaments. We demonstrated previously that the assembly of myosin-IIA is regulated by phosphorylation on the heavy chain and the binding of S100A4, a member of the calcium-regulated S100 family of proteins. Phosphorylation on the heavy chain by either protein kinase C or casein kinase 2 (CK2) significantly inhibited the assembly of myosin-IIA into filaments. In addition, CK2 phosphorylation inhibited the binding of S100A4 to myosin-IIA, thus providing an additional level of regulation for the S100A4/myosin-IIA interaction. To investigate the mechanisms controlling filament assembly and disassembly during motility and chemotaxis, we examined the EGF-dependent phosphorylation of the myosin-IIA heavy chain in human breast cancer cells. EGF stimulation of MDA-MB-231 cells resulted in transient increases in both the insolubility and phosphorylation of the myosin-IIA heavy chains. Phosphoamino acid analysis and two-dimensional tryptic phosphopeptide maps revealed that in EGF-stimulated cells, the myosin-IIA heavy chain is phosphorylated on the CK2 site (S1944). The interaction of CK2 with myosin-IIA was confirmed in a pull-down assay, utilizing His-tagged myosin-IIA rods. In vitro assays demonstrate that the assembly properties of myosin-IIA rods containing aspartic or glutamic acid substitutions at S1944 are similar to those of CK2-phosphorylated rods; however, these substitutions had no effect on S100A4 binding. Expression of full-length GFP-myosin-IIA heavy chains containing alanine, aspartic or glutamic acid substitutions at S1944 showed that S1944E and S1944D mutants were primarily cytosolic, whereas the S1944A mutant associates over assembled into stress fibers and cortical regions. Cells expressing the S1944E and S1944D mutants displayed increased migration into a wound and enhanced EGF-stimulated lamellipod extension as compared to cells expressing wild-type myosin-IIA. In contrast, cells expressing the S1944A mutant exhibited reduced migration and lamellipod extension. These observations suggest a direct role for myosin-IIA heavy chain phosphorylation in mediating motility and chemotaxis.

2236 Studies of Dictyostelium Myosin II Heavy Chain Kinase C Subdomains
M. Russ, O. Al, C. Alyssa, P. Padilla, P. A. Steinle; Biology, University of North Carolina at Greensboro, Greensboro, NC
Myosin II in Dictyostelium and nonmuscle cells exists in a dynamic equilibrium between a cytoplasmic pool of monomers and a cytoskeleton-associated assembly of bipolar filaments. Myosin II filament disassembly in Dictyostelium is driven by phosphorylation of the myosin II heavy chain (MHC) "tail" region via the activities of three structurally-related MHC kinases: MHCK-A, -B, or -C. All three of the MHCKs share homologous catalytic and WD-repeat domains. MHCK-A is the most extensively-studied of the MHC kinases. Recent studies from our lab have revealed a unique relationship between MHCK-A and F-actin, whereby F-actin is a potent activator of MHCK-A activity (50-fold); and MHCK-A, in turn, possesses the ability to organize actin filaments into bundles. In contrast to MHCK-A, there is essentially no information about the structure-function relationships defining the activities of the MHCK-B and -C enzymes. We have examined the in vivo function of the WD-repeat domain of MHCK-A by over-expressing either full-length MHCK-C (MHCK-C++) or a truncated version of MHCK-C lacking the WD-repeat domain (MHCK-CΔWD++) in Dictyostelium cells, and then assaying for myosin II-dependent activities such as cytokinesis and multicellular development. As has been reported previously (Betapudi et al., 2005, Mol Biol Cell, 16:2248), MHCK-C++ cells exhibited cytokinesis defects with reduced growth in suspension culture and increased multicellularity. Interestingly, we found that MHCK-CΔWD++ cells also do not proliferate in suspension culture; however, this growth defect is not accompanied by an increase in multicellularity. In addition, the MHCK-CΔWD++ cells, unlike their MHCK-C++ counterparts, retain the ability to undergo multicellular development. Together, these results suggest that the WD-repeat domain of MHCK-C may not serve the same myosin targeting function as the WD-repeat of MHCK-A. Moreover, our results also indicate that under certain conditions, MHCK-C may exhibit activities outside of its known MHC kinase function in the cell.

2238 The Role of C. elegans UNC-82 Serine/Threonine Kinase in Myosin Organization in Striated Muscle
A. R. Reedy, C. M. Carter, P. E. Hoppe; Biological Sciences, Western Michigan University, Kalamazoo, MI
Mutations in the unc-82 gene cause defects in thick filament organization in striated muscle (Waterston et al., 1980). UNC-82 is a serine/threonine kinase orthologous to human ARAK5 and SNARK. A rescuing UNC-82-GFP fusion localizes at or near the M-line (Chass, Flanagan, Schriefer, and Hoppe, unpublished). In current studies we are using antibody staining and FRAP analysis to define the role of UNC-82 in cytoskeletal organization. Defects in the localization of myosin and the M-line protein UNC-89/obscurin are apparent in all unc-82(e1323) null mutant embryos by the 3rd stage of embryogenesis. Abnormal aggregates of myosin are observed in addition to the organized lines of myosin signal. Integrin and vinculin localization appear normal at this stage, suggesting that UNC-82 acts in a process independent of the hypothetical-muscle-cell signaling required for early patterning of the contractile apparatus. Embryos and adults homoygous for the putative kinase-dead allele unc-82(e1220) exhibit less severe defects; however, the unc-82 catalytic domain promotes M-line or thick filament organization. To test this, we have generated constructs containing canonical kinase-dead mutations for production of transgenic worms. Our current model is that UNC-82 regulates turnover of thick filaments or M-lines during muscle cell growth and body elongation, perhaps through phosphorylation of the myosin tailpiece. The myosin defects in unc-82 mutants are similar to those observed in transgenic animals expressing truncated myosin that lacks the C-terminal phosphorylation motifs. To assess myosin filament turnover, we have introduced GFP-mycosin into mutant and wild-type worms, and monitoring FRAP experiments. Results to date suggest a faster recovery of myosin signal within organized stripes in wild-type worms in comparison to those present in unc-82 mutant animals. The abnormal myosin aggregates in unc-82 mutants show no discernible recovery within the timeframes examined to date.
Phosphorylation of Recombinant Smooth Muscle Myosin Light Chain Kinase by Various Ser/Thr Kinases

A. Nakamura, R. Ishikawa, K. Kohenm; Department of Molecular and Cellular Pharmacology, Gunma University Graduate School of Medicine, Maebashi, Japan

Smooth muscle myosin light chain (MLC) can be phosphorylated by myosin light chain kinase (MLCK) in vitro and in vivo, and it plays an important activating actomyosin-linked contractility in smooth muscle cells. However, it is not clear how MLCK is regulated by upstream signaling. We have already reported the purification of recombinant smooth muscle MLCK (rMLCK) by using an E. coli cold-shock expression system. Using this rMLCK as a substrate, we examined what kind of kinases phosphorylated rMLCK. Usually, the purified MLCK from mammalian cells may be often phosphorylated by endogenous kinase, but this rMLCK is not phosphorylated in E. coli. rMLCK was phosphorylated by MAPK, PAK1, PKA, PKC and ROCK1 in the absence of Ca/calmodulin. Among them PAK1 and PKC could not incorporate phosphate into rMLCK when calmodulin was bound to rMLCK. MLCK may be regulated by these kinases.

Additive Roles of Phosphorylation and the Extended N-terminus of the Regulatory Light Chain in Drosophila Flight Muscle Function

M. S. Miller, G. P. Farman, F. N. Soto-Adames, M. C. Reedey, J. M. Braddock, T. C. Irving, J. O. Vigoreaux, D. W. Maughan; Molecular Physiology and Biophysics, University of Vermont, Burlington, VT, 1BPCS, Illinois Institute of Technology, Chicago, IL, 2Biology, University of Vermont, Burlington, VT. 3Department of Cellular Biology, Duke University Medical Center, Durham, NC

We investigated the effects of myosin regulatory light chain (MLC2) mutations on Drosophila indirect flight muscle (IFM) function. Four MLC2 lines were examined: a rescued null control (Mlc2^-), one with a truncated N-terminal extension (Mlc2^T'), one with disrupted myosin light chain kinase phosphorylation sites (Mlc2^556/557), and one double mutant (Mlc2^556/557, 62/63). Wing beat frequency was significantly reduced in the single mutation lines compared to controls (165 ± 3 Hz, Mlc2^-; 158 ± 3 Hz, Mlc2^556/557, vs. 202 ± 4 Hz, Mlc2^-). The double mutant was unable to beat its wings. Chemically skinned fibers were compressed osmotically to in vivo resting lattice spacing, and mechanically examined in maximally Ca2+-activated (pCa 4.5) fibers using small amplitude (0.125% muscle length) sinusoidal length perturbation analysis. The frequency at which maximum power output occurs, a sensitive indicator of myosin kinetics, was significantly different between Mlc2^- (116 ± 4 Hz), Mlc2^556/557 (101 ± 3 Hz), and Mlc2^556/557, 62/63 (87 ± 3 Hz), and significantly less than control (128 ± 3 Hz). Corresponding power output was significantly reduced in both phosphorylation site mutants, with the double mutant barely able to produce power. Structural data from small angle x-ray diffraction and electron microscopy is consistent with the mechanical results, which together suggest that phosphorylation of conserved serines and the upstream (N-terminal) extension play a complementary, and in some respects additive, role in moving the myosin heads closer to actin and that the phosphorylation sites orient or pre-position the myosin heads for optimum interaction with the actin target sites. We conclude that both structural adaptations help position myosin heads for rapid binding to actin during the extremely brief wing beat cycle, thereby boosting power generation in IFM fibers and the whole fly.

Structure of Two Heads of Rabbit White Skeletal Muscle Myosin

A. Inoue; Biology, Osaka University, Toyonaka, Japan

Myosin has two heads, which react with ATP and bind with actin, however the function of two heads of myosin in muscle contraction has not yet been well clarified. We showed that two heads of myosin have different functions; Head A forms myosin-ATP complex, and head B forms myosin-P-ADP complex, respectively, as an ATPase intermediate, and only head B catalyzes actomyosin-type ATPase reaction and works as a motor, while head A helps the movement of head B, though the structure of heads A and B has not been elucidated. Here, we have cloned the cDNAs of rabbit white skeletal muscle myosin heavy chains A and B, which form heads A and B, respectively, and determined the amino acid sequences of these two heavy chains. It has shown by Elzinga that there exist two amino acids as a microheterogeneity in the amino-acid sequence of myosin heavy chain. We found that these two amino acids derive from the difference in the amino acid between heavy chains A and B. The amino-acid sequences of these two heavy chains differ by about 3 per cent. However, the nucleotides of these two cDNAs differed by almost 10 per cent. Therefore, these two chains are derived from different DNAs. The difference in the amino acid was observed not in the ATPase active site but in the actin binding site. We found that tryptic digestion pattern of 25K-50K junction are different between heads A and B. Actually, the amino-acid sequences of 25K-50K junction were different. Furthermore, there exists heterodimer-forming amino acids pairs in the neck region of myosin. We made 3 sets of heads A and B specific antibodies. These antibodies bound specifically with heads A and B. Therefore, skeletal muscle myosin is the products of these two mRNAs.

Mechanism of Myosin-IIA Regulation by S100A4 during Carcinoma Cell Motility

R. P. House, E. L. Snapp, A. R. Bresnick; 1Biochemistry, Albert Einstein College of Medicine, Bronx, NY, 2Anatomy and Structural Biology, Albert Einstein College of Medicine, Bronx, NY

S100A4, a member of the Ca2+ regulated S100 family of proteins, has been shown to be a metastasis factor and is implicated in the regulation of both the motility and invasiveness of cancer cells. In vitro studies from our lab demonstrate that S100A4 regulates non-muscle myosin-IIA assembly and promotes the monomeric, unassembled state of myosin-IIA. These observations are consistent with previous reports that S100A4 may sequester myosin-IIA monomers and function as a myosin-IIA inhibitor. However, recent in vivo studies from our lab demonstrate that S100A4 enhances cell polarization and motility, which is inconsistent with S100A4 having an inhibitory function in vivo. An alternative hypothesis is that S100A4 mediates cell motility by enhancing the turnover of myosin-IIA filaments. To investigate these two models of S100A4-mediated regulation of myosin-IIA function, we are using photobleaching methods to examine the dynamics of GFP-tagged full-length non-muscle myosin-IIA heavy chain in EGF-stimulated human breast cancer cells. Our studies in MDA-MB-231 cells suggest two populations of myosin-IIA filaments with distinct patterns of movement during EGF-stimulated lamellipod extension. Studies examining myosin-IIA turnover as a function of S100A4 expression are in progress.

Development of a S100A4 Biosensor to Track Activation In Vivo

S. C. Garrett, A. Toutchkine, K. M. Hahn, A. R. Bresnick; 1Biochemistry, Albert Einstein College of Medicine, Bronx, NY, 2Pharmacology, University of North Carolina at Chapel Hill, Chapel Hill, NC

S100A4, a member of the S100 family of proteins, binds specifically to nonmuscle myosin-IIA in a calcium-dependent manner and regulates the monomer-polymer equilibrium of myosin-IIA filaments. To obtain novel information regarding the spatial and temporal activation of S100A4 during directed cell motility, we developed an S100A4 biosensor to report transient or localized calcium binding in vivo. This unique reagent will allow the activation of S100A4 to be examined directly during motility, and will permit a direct correlation between localized, transient activation of S100A4 and the regulation of myosin-IIA assembly during directed motility. The biosensor was constructed using the novel merocyanine dye ISO-IIIA, which displays sensitivity to both solvent polarity and hydrogen bonding, thus small changes in protein conformation can strongly influence the fluorescence properties of the dye. Similar to other S100 proteins, S100A4 undergoes a significant conformational change upon calcium binding; exposing a hydrophobic cleft that forms the target-binding surface. The biosensor was generated by the derivatization of a single cysteine residue (C81) proximal to the hydrophobic pocket. The resulting biosensor (Mero-S100A4) displays a 3.0-fold increase in fluorescence intensity upon calcium binding, which does not significantly change with myosin-IIA binding. A dillBAPTA calcium competition assay demonstrates that Mero-S100A4 has the same binding affinity for calcium as wild-type S100A4 (Mero: Kd=412 μM, Kd=0.85 μM; wt: Kd=2.37 mM, Kd=0.75mM). In addition, myosin-IIA cosedimentation experiments demonstrate that Mero-S100A4 has the same affinity for myosin-IIA as wild-type S100A4 (Mero: Kd=2.11 μM; wt: Kd=4.32 μM). Fluorescence calcium titration experiments demonstrate that in the presence of myosin-IIA, S100A4 exhibits a substantial increase in its binding affinity for calcium. In 3T3 fibroblasts the biosensor shows diffuse fluorescence without any sign of aggregation. In vivo studies examining S100A4 activation and its relationship to myosin-IIA are in progress.

How Might Microtubules Control Cortical Contractility during Cytokinesis?

V. E. Doe, G. von Dassow, G. M. Odell; Center for Cell Dynamics, University of Washington, Friday Harbor, WA

Using one antibody to myosin heavy chain and another to the activating phospho-ser19 of myosin regulatory light chain we show, using fixed echinoderm blastomeres, that activated myosin II (a small fraction of total myosin II) recruits to the cortex in a RhoA and cell cycle-regulated manner. During anaphase microtubule outgrowth, myosin II falls off the cortex everywhere, then recruits in active form intensely, but only to the presumptive cleavage furrow. Low nM nocodazole doses that reduce microtubule densities, block both this global anaphase dephosphorylation/deactivation and furrow-specific activation of myosin. High (20 nM) nocodazole doses that depolymerize all dynamic microtubules, reveal a population of stable microtubules.
microtubules which, starting at anaphase onset, elongates to form not only the central spindle but also an oriented fan of stable astral microtubules aimed chiefly toward the future furrow, and which disappears during abscission. Their formation schedule, the finding by Shannon et al. (2005) that taxol-stabilized microtubules can induce furrowing, and the proximity of their plus ends to areas of cortical myosin recruitment, lead us to believe these stable microtubule convey signals that activate equatorially Rhodamin-A/myosin II during furrow formation. We propose a mechanism wherein: 1) active Ect2 (RhoA GEF) binds microtubules (by complexing with MgcRacGAP/MKLP1) to the cortex than dynamic microtubules, which depolymerize out from beneath kinetosomes moving along them; 2) MgcRacGAP/MKLP1 (which transports Ect2) does not run off microtubule plus ends (Nishimura & Yonemura, 2006) but collects preferentially at tips of stabilized MTs boosting Rho/A/myosin II activation in an equatorial zone. Our computer simulations demonstrate this mechanism can produce, simultaneously, a diffusion-resistant band of Rho/A/myosin activation wherever the highest density of stable microtubule tips lie, and a general diminution of cortical Rho/A/myosin II activation elsewhere.

2245 Nonmuscle Myosin II-dependent Force Inhibits Cell Spreading and Drives F-actin Flow Y. Cai, 1 N. Bains, 1 G. Gianmone, 1 M. Tanase, 1 G. Jiang, 1 J. Hofman, 1 C. Wiggins, 2 C. Buguin, 2 A. Buguin, 3 B. Ladoux, 4 M. Sheetz, 1; 1Biological Sciences, Columbia University, New York, NY, 2Applied Physics and Mathematics, Columbia University, New York, NY, 3Physico-Chimie Curie, Institut Curie, Paris, France, 4Matière et Systèmes Complexes, Université Paris, Paris, France

Nonmuscle myosin IIA (NMIIA)-IA is involved in the formation of focal adhesions and neurite retraction. However, the role of NMIIA in these functions remains largely unknown. Using RNA interference (RNAi) as a tool to decrease NMIIA expression, we have found that NMIIA is the major myosin involved in traction force generation and retrograde F-actin flow in mouse embryonic fibroblasts (MEFs). Quantitative analyses revealed that ~60% of traction force on fibronectin-covered surfaces is contributed by NMIIA and ~36% by NMIIIB. The retrograde F-actin flow decreased dramatically in NMIIA-depleted cells, but seemed unaffected by NMIIIB deletion. In addition, we found that depletion of NMIIA caused cells to spread at a higher rate and to a greater area on fibronectin substrates during the early spreading period, whereas deletion of NMIIB appeared to have no effect on spreading. The distribution of NMIIA was concentrated on the dorsal surface and approached the ventral surface in the periphery whereas NMIIIB was primarily concentrated around the nucleus and to a lesser extent at the ventral surface in cell periphery. Our results suggest that NMIIA is involved in generating a coherent cytoplasmic contractile force from one side of the cell to the other through the croslinking and the contraction of dorsal actin filaments.

2246 Cortical Actomyosin Dynamics and the Maintenance of PAR Polarities in the C. elegans Embryo H. R. G. Clarke, C. M. Schoe, E. M. Munro; Center for Cell Dynamics, University of Washington, Friday Harbor, WA

The C. elegans egg polarizes in response to a transient cue associated with the sperm centrosomes/microtubule organizing center (MTOC). AP polarity is established during interphase when the sperm MTOC triggers an asymmetrical actomyosin contraction and cortical flows that carry the conserved polarity determinants PAR-3/PAR-6/aPKC to the anterior and allow others (PAR-1 and PAR-2) to associate with a complementary posterior domain. However, the mechanisms that maintain PAR asymmetries between the end of interphase and the onset of cytokinesis remain unclear. Here we explore how actomyosin assembly and activity are involved in the maintenance of PAR polarities. During the maintenance phase, both F-actin assembly and myosin recruitment are biased to an anterior domain defined by high levels of PAR-3/PAR-6/aPKC, and these are closely associated with persistent anterior-directed cortical flows. Myosin recruitment and cortical flow during maintenance absolutely require the small GTPase CDC-42 and its downstream effector, ROKC (Mystic dystrophy kinase-related Cdc42-binding kinase), a known activator of myosin contractility. Anterior-biased F-actin assembly during maintenance requires components of the conserved ARP-2/3 complex, which promotes the assembly of branched F-actin meshworks. ARP-2/3 is not required for the establishment of PAR polarities, but depletion of ARP-2/3 components leads to hyper-contractation and mechanical destabilization of the anterior PAR-3/PAR-6/aPKC cap during the maintenance phase, and a corresponding anterior extension of the posterior PAR-2 domain. Interestingly, mutations in the posterior PAR protein PAR-1 also lead to hyper-contraction of the anterior cap and simultaneous removal of PAR-1 and ARP-2 produce a strongly synergistic effect. We hypothesize that robust maintenance of PAR asymmetries requires two redundantly acting mechanisms: One involves conserved cross-inhibition among anterior and posterior PAR proteins; the other involves the asymmetrical contraction of actomyosin against an anterior domain that is stiffened by the assembly of a dense network of branched actin filaments.

2247 Myosin-II Activity Regulates the Development of Neuronal Polarity K. M. Collins, H. Francisco, J. Ha, G. Gallo; Drexel University College of Medicine, Philadelphia, PA

The earliest stage in the development of neuronal polarity is characterized by the extension of undifferentiated “minor processes” (MPs). Subsequently, MP growth and differentiation gives rise to structurally and functionally distinct neurites, terminated axons and dendrites. The cellular and molecular mechanisms underlying the initial outgrowth of MPs remain unclear. Through interactions with actin filaments, myosin II regulates cellular contractility and axonal extension; therefore, we investigated the role of myosin II in MP extension using cultured forebrain neurons. Both myosin IIA and IIB isoforms were expressed in developing MPs, with the IIA isoform predominating. To examine the role of myosin II in MP extension we treated neurons with the myosin II inhibitor, blebbistatin, which resulted in a 76% increase in MP length. Thus, myosin II activity restricts MP extension. Myosin II activity is determined by phosphorylation of its regulatory light chains (rMLC), which can be mediated by myosin light chain kinase (MLCK) or RhoA-kinase (ROCK). Pharmacological inhibition of MLCK or ROCK increased MP length by 22% and 43%, respectively. Combined inhibition of MLCK and ROCK resulted in an 85% increase in MP length, similar to the effect of direct inhibition of myosin II. RhoA/ROCK complex formation results in ROCK activation. Selective inhibition of RhoA signaling with cell-permeable C3 transfase produced increases in both the length (28%) and number (41%) of MPs, suggesting additional pathways for regulation of MP outgrowth. To determine whether myosin II affected the development of neuronal polarity, morphogenesis was examined in cultures chronically treated with direct or indirect myosin II inhibitors. Inhibition of myosin II, MLCK, or ROCK promoted rapid morphogenesis without altering characteristic neuronal polarity. Together, these data indicate that myosin II activity negatively regulates MP extension, and the time course for development of neuronal polarity.

2248 The B2 Alternatively Spliced Isoform of Nonmuscle Myosin II-B Lacks Enzymatic Activity and In Vitro Motility K. Y. Kim, 1 J. Baso, 1 J. R. Sellers, 2 R. S. Adelstein, 1; 1Laboratory of Molecular Cardiology, NHLBI, National Institutes of Health, Bethesda, MD, 2Laboratory of Molecular Physiology, NHLBI, National Institutes of Health, Bethesda, MD

Previous work has demonstrated that the presence of an alternatively-spliced exon in loop 1 near the ATP-binding region of the myosin II heavy chain results in an increase in both the actin-activated MgATPase activity and in vitro motility of vertebrate smooth muscle and nonmuscle heavy meromyosins (HMMs) II-B and II-C. We now report that the presence of a 21 amino acid insert in loop 2, which is near the actin-binding site of nonmuscle myosin heavy chain II-B, results in the loss of those activities. This alternative exon is normally expressed in certain neuronal cells such as the Purkinje cells in the cerebellum and has been shown to affect motor coordination in mice. Surprisingly, the F2249 max of baculovirus-expressed HMM II-B2 (inserted isoform) was less than 7% of that of the noninserted HMM II-B0 and HMM II-B2 compared to 0.15 ± 0.003 s−1 for HMM II-B0. Combined inhibition of MLCK and ROCK resulted in an 85% increase in MP length, similar to the effect of direct inhibition of myosin II. RhoA/ROCK complex formation results in ROCK activation. Selective inhibition of RhoA signaling with cell-permeable C3 transfase produced increases in both the length (28%) and number (41%) of MPs, suggesting additional pathways for regulation of MP outgrowth. To determine whether myosin II affected the development of neuronal polarity, morphogenesis was examined in cultures chronically treated with direct or indirect myosin II inhibitors. Inhibition of myosin II, MLCK, or ROCK promoted rapid morphogenesis without altering characteristic neuronal polarity. Together, these data indicate that myosin II activity negatively regulates MP extension, and the time course for development of neuronal polarity.

2249 Mechanism of Alternative Splicing of Nonmuscle Myosin Heavy Chain II-B and II-C Pre-mRNAs: Role of Fox-1 Family Proteins S. Nakahata, S. Kawamoto, NHLBI, National Institutes of Health, Bethesda, MD

The genes encoding nonmuscle myosin heavy chain (NMHC) II-B and NMHC II-C generate alternatively spliced isoforms which include or exclude a cassette of amino acids near the ATP-binding domain. Inclusion of alternative exon B2 in NMHC II-B pre-mRNAs is restricted to some neural cells. Alternative exon C1 is excluded entirely from NMHC II-C pre-mRNAs in striated muscles, but is included in nonmuscle cell mRNAs. Here, we report that the intronic RNA element UGCAUG and the RNA-binding proteins, Fox-1 family proteins, play a critical role in regulation of both B1 and C1 alternative splicing, but in a different manner. Minigene transfection analysis using a number of cell lines revealed that the UGCAUG elements located in the downstream exon of B1 was essential for B1 inclusion in cells. This RNA element was also present in both the upstream and downstream introns of C1. However, only the upstream
elements were found to be important for C1 exclusion in muscle cells. We further examined the effects of exogenous expression of Fox-1 family proteins, which can bind to the UGCAUG element, during B1 and C1 splicing. Fox-1, Fox-2 and Fox-3, which contain highly homologous RNA recognition motifs (RRMs), belong to the Fox-1 family in mammals. RT-PCR and other analyses revealed that multiple alternative promoters and alternative splicing of pre-mRNA gave rise to a number of tissue-dependent isoforms of Fox-2. We made expression constructs encoding 24 Fox-2 isoforms, which differ in their N-terminus, internal and C-terminal sequences, but share an identical RRM. Inclusion of B1 was activated by the isoforms containing a particular internal and C-terminal sequence. In contrast, exclusion of C1 could be enhanced by all isoforms. These results suggest that a different distribution of the same splicing regulatory element as well as isoform diversity of Fox-2 confer tissue-specificity on alternative splicing of B1 and C1.

Using Double Knockout Nonmuscle Myosin II-B and II-C Mice to Study Cardiac Myocyte Development

X. Ma, S. Kawamoto, G. Homayounfar, R. S. Adelstein; Laboratory of Molecular Cardiology, NHLBI, National Institutes of Health, Bethesda, MD

Nonmuscle myosin IIs (NM IIs) play an important role in many basic cellular processes including cell division, cell migration and cell-cell adhesion. In addition, it has been proposed that NM II is required for sarcomere formation in cardiac myocytes. In order to study the role of nonmuscle myosins in cardiac myocyte development, we generated double knockout NM II-B and II-C (B/C/ B/C) mice. Immunofluorescence confocal microscopy of heart sections from wild-type mice shows that cardiac myocytes express NM II-A during cardiac loop development (embryonic day, E7.5-8.5) and in the arterial pole between E9.5-11.5, but not thereafter. On the other hand, both NM II-B and II-C are expressed in the developing cardiac myocytes. Ablation of II-B in mice results in partial impairment of cytokinesis in cardiac myocytes leading to binucleation, but loss of NM II-B has no effect on sarcomere formation. We attributed this to the expression of NM II-C in the B/C- ablated myocytes. Ablation of II-C alone has no obvious effect on the myocytes during embryonic heart development. Ablation of both isoforms, however, leads to abnormalities in the mitotic spindle resulting in a defect in cytokinesis, in addition to the defect in cytokinesis. More than 90% of the B/C- BC- cardiac myocytes contain abnormal nuclei. More than 90% of the B/C- BC- cardiac myocytes in mice do not affect the formation of sarcomeres in embryonic cardiac myocytes. Since there is no detectable myocyte expression of NM II-A after E9.5 (except for the outflow tract) nor is NM II-A expression increased in B/C- BC- cardiac myocytes, we suggest that NM II-A, II-B and II-C are not necessary for mouse cardiac sarcomere formation. Our results show the importance of nonmuscle myosins in cardiac myocyte cytokinesis and karyokinesis.

Activated Myosin II Is Required for Cell Alignment in the Drosophila Epidermis

R. Simone, S. Dinardo; Cell and Molecular Biology, The University of Pennsylvania, Philadelphia, PA

Epithelial sheets undergo coordinated cell shape changes that are vital to organogenesis and development in general. The ventral epidermis of the Drosophila embryo is an epithelial sheet that undergoes differential cell shape changes during the parasegmentation. This epithelium is an especially promising tissue in which to study this phenomenon because much is known about the signaling pathways that underlie the establishment and maintenance of differential cell fates across the parasegment. Initially, the epithelial cells of the ventral epidermis maintain a roughly hexagonal shape and are randomly packed. Over the course of several hours, cells within this epithelium change shape: their anterior and posterior edges lengthen and their dorsal and ventral edges shorten. Our quantitative measurements showed that each row of cells in one population align their anterior and posterior edges to form parallel lines while cells in another population align their edges to a lesser degree. We observed an enrichment of Actin, Myosin II (MyoII) and MyoII related proteins along the aligning edges of these cells and suspected that MyoII-mediated actomyosin contraction might be responsible for cell alignment. To test this, we exposed embryos at the onset of cell alignment to a Rho Kinase inhibitor (Y27632), which is known to prevent MyoII activation by blocking the activation of the myosin regulatory light chain. We observed the disruption of cell alignment and order, thus implicating MyoII in the alignment of cells within the ventral epidermal sheet. Discerning the role of actomyosin contractility in cell alignment will contribute to the further description of Drosophila epibolyogenesis specifically and the understanding of epithelial morphogenesis generally.

Comparison of Transcription Profiles of myo1Δ and chs2Δ Mutants in Budding Yeast Saccharomyces cerevisiae

J. F. Rodriguez-Quijones, J. R. Rodriguez-Medina; Department of Biochemistry, University of Puerto Rico Medical Sciences Campus, San Juan, Puerto Rico

Saccharomyces cerevisiae myo1Δ gene encodes the myosin type II heavy chain (Myo1p), a protein required for normal cytokinesis in budding yeast. In a myo1Δ mutant the Pck1p/Skp2p pathway is activated by cell wall stress. Delocalized chitin deposition and increased chitin synthesis by Chs3p are associated with this response. The CHS2 gene encodes chitin synthase II (Chs2p), an enzyme that catalyzes the transfer of N-acetylglucosamine (GlcNAc) to chitin and is essential for chitin synthesis in the primary septum during cytokinesis. chs2Δ strains are characterized by absence of the primary septum and share several phenotypes with myo1Δ mutants such as: abnormal cytokinesis, formation of attached cells, abnormal budding patterns, delocalized chitin deposition in the cell wall and a requirement of Chs3p expression for normal growth. The purpose of this study is to compare the transcriptional profiles of these two similar mutants in order to identify genes that could be differentially expressed in response to abnormal cytokinesis. A transcriptional profile was generated for both mutants using yeast oligonucleotide microarrays. The hybridized arrays were analyzed using statistical methods and classified by biological processes. A total of 172 genes of different categories were differentially expressed in both strains. Excluding genes of unknown function, the categories most represented in common for both profiles were: protein biosynthesis, metabolism and stress response. Notable similarities were found among down regulated genes coding for protein biosynthesis functions and RAS1. Genes involved in cell wall organization and biogenesis that were up-regulated are responsible for secretion and morphogenesis in the two strains. Our preliminary transcriptional analysis shows that ZTL transcription may not be activated in this chs2Δ mutant. Therefore these mutant strains may activate the transcriptional response by different pathways. This work was supported by a PHS grant M08224 (S06-GM08224) with partial support from NSF.

Myosin II Activity Regulates the Shape of Three-Dimensional Epithelial Cysts

A. I. Ivanov, A. M. Hopkins, G. T. Brown, K. Gerner-Smidt, B. Babbin, C. A. Parkos, A. Nusrat; Pathology and Laboratory Medicine, Emory University, Atlanta, GA

Development of luminal organs such as gut, lungs and kidneys begins with the formation of hollow spherical cysts composed of single layers of polarized epithelial cells. This initial cystogenesis depends on reorganization of the actin cytoskeleton, however mechanisms that mediate such actin reorganization are poorly understood. This study was designed to investigate the role of the major actin motor, myosin II, in the epithelial polarization of cysts using a three-dimensional in vitro cell culture model. Caco-2 intestinal epithelial cells were embedded into Matrigel and allowed to grow for three days in the presence of either vehicle, or a myosin II inhibitor, blebbistatin. While control cells formed typical spherical cysts with a smooth surface, blebbistatin-treated cysts developed multiple radiating actin-rich surface protrusions. These protrusions contained components of the Arp2/3 complex and the neuronal Wiskott-Aldrich protein (N-WASP) and their development was inhibited by an actin-depolymerizing drug, latrunculin B or the N-WASP-inhibitor, wiscostatin. The appearance of blebbistatin-induced protrusions did not depend on the activity of Rac-1 and Cdc-42 GTPases, but was attenuated by depolymerization of microtubules with either nocodazole or vinblastin. In Caco-2 cells, blebbistatin caused disappearance of peripheral actomyosin bundles which was accompanied by reorientation of cortical microtubules and their accumulation in the vicinity of the plasma membrane. The formation of blebbistatin-induced protrusions was also blocked by pharmacological inhibition of phospholipase C (PLC). We hypothesized that inhibition of myosin II eliminates a cortical actomyosin barrier allowing cell-cell contacts to reach the plasma membrane and to activate phospholipase C. We speculated that such activation of PLC acts activating actin-severing proteins to create free actin-barbed ends and results in stimulation of N-WASP-Arp2/3 dependent act polymerization and the formation of peripheral protrusions. We conclude that myosin II controls spherical shape of epithelial cells by preventing MT-dependent actin polymerization at the cyst surface. Supported by CCF and NIH.

Defective Platelet Function and Reduced Thrombosis Induced by Megakaryocyte-specific Disruption of Non Muscle Myosin IIA Gene

C. Leon,1 A. Eckly,1 B. Hecher,1 B. Aki,1 M. Freund,1 J. Cazenave,1 R. Tiedt,2 R. Skoda,2 C. Gachet1; 1Etablissement Français du Sang, INSERM U311, Strasbourg, France, 2Experimental Hematology, Basel University Hospital, Department of Research, Basel, Switzerland

Mutations in MYH9 encoding non muscle myosin heavy chain IIA (NMHC-IIA) lead to several disorders such as the May-Hegglin anomaly and the Fechtner, Sebastian or Epstein syndromes. The intracellular localization of NMHC-IIA is mainly characterized by a decrease in cortical actomyosin (enhanced thrombomodulin) associated with morphological changes with large platelets, leading to minor hemorrhagic manifestations. To understand the role of NMHC-IIA in normal platelet function and in pathology, we generated mice with disruption of MYH9 (exon1) in megakaryocytes, the precursors of platelets. MYH9A mice exhibited a selective severe deficiency in platelet NMHC-IIA, residual myosin amounting 15-20% of the normal. This decrease in myosin resulted, like in the human disease, in thrombomodulin (117±10 x 16x105 vs. 47±10 x 105 platelets/µL for wild-type and MYH9A, respectively, mean±sem). Moreover, platelets from MYH9A mice appeared...
ovoid instead of discoid, twice the normal size, with abnormally abundant rough endoplasmic reticulum and altered organelles distribution, some platelets appearing devoid of organelles. Bleeding time measurements were performed and all MYH9A mice bled for more than 600s, compared to 153±15s for wild-type mice. Clot retraction, which is important in thrombus stabilization, was totally abolished. Upon activation by soluble agonists, platelet contraction was absent in MYH9A platelets while subsequent aggregation and secretion were near normal. MYH9A platelets were still capable to adhere and extend lamellipodia on a fibrinogen-coated surface but without stress fiber formation. Thrombus growth under flow was investigated by perfusing whole blood over collagen. The MYH9A platelets adhered on collagen but thrombus were reduced in size (56% vs 22% surface coverage for wild-type and MYH9A platelet, respectively) and did not grow in height, showing the importance of platelet contraction to resist the flow. Overall, these results demonstrate the role of myosin IIA in platelet contractile phenomena which in addition to thrombocytopenia, may encounter for the haemostasis defects observed in MYH9A-disorders.
defects in arginyl-adenylylation of several human congenital heart defects is suggested that some of the underlying mechanisms of heart disease may be related to the defects of protein arginylation. Our results outline a new function of arginylation in the regulation of actin cytoskeleton in cardiac myocytes.

Rho Kinase Inhibitor Y27632 Affects Initial Heart Myofibrillogenesis in Cultured Chick Blastoderm
H. Sakata, M. Skabe, H. Matsui, N. Kawada, K. Nakatani, K. Ikeda, T. Yamagishi, Y. Nakajima; 1Anatomy and Cell Biology, Osaka City University Graduate School of Medicine, Osaka, Japan, 2Department of Pathology, Osaka City University Graduate School of Medicine, Osaka, Japan, 3Anatomy, Saitama Medical School, Saitama, Japan
During early vertebrate development, Rho-associated kinases (ROCK) are involved in various developmental processes, such as gastrulation and endocardial epithelial-mesenchymal transition. Here we investigated spatiotemporal expression patterns of ROCK1 protein in early chick embryos and examined the role of ROCK during initial heart myofibrillogenesis in cultured chick blastoderm. Immunohistochemistry showed that ROCK1 protein was distributed in migrating mesendoderm cells, visceral mesoderm of the pericardial coelom (from which cardiomyocytes will later develop) and cardiomyocytes of the primitive heart tube. Pharmacological inhibition of ROCK by Y27632 in cultured posterior blastoderm did not affect the transcripts of Nkx2.5, GATA4 and sarcomeric α-actinin suggesting that ROCK inhibition did not alter the myocardial specification process. However, Y27632 disturbed the formation of striated heart myofibrils in cultured posterior blastoderm. Furthermore, Y27632 affected the formation of costamere, a vinculin/integrin-based rib-like cell adhesion site between Z-bands and the sarcolemma/extracellular matrix. In such cardiomyocytes, epithelialization was disrupted and N-cadherin was distributed in the peri-nuclear region, thereby cardiomyocytes showed a fibroblast-like phenotype. Western blot analysis showed that the expression of smooth muscle α-actin, sarcomeric integrin α6β1 and N-cadherin was downregulated in explants treated with Y27632. Pharmacological inactivation of myosin light chain kinase, a downstream of ROCK, by ML-9 perturbed the formation of striated myofibrils as well as costameres, but not myocardial epithelialization. These results suggest that ROCK may play a role in the initial heart myofibrillogenesis via actin-myosin assembly, focal adhesion/costamere and cell-cell adhesion.

Krp1, a Muscle-Specific Kelch-related Protein, Is Required for Mature Myofibrill Accumulation in Primary Mouse Embryonic Cardiomyocytes
C. C. Greenberg, R. Horowits; NIAMS, National Institutes of Health, Bethesda, MD
Krp1 is a skeletal- and cardiac-muscle-specific member of the kelch repeat family of proteins. Kelch repeats form actin-binding domains, and many kelch proteins are involved in cytoskeletal organization. In transformed rat fibroblasts, Krp1 colocalizes with actin in pseudopodia and is required for pseudopod elongation. However, the physiological functions of Krp1 in muscle are unknown. Krp1 binds N-RAP, which acts as an assembly catalyst in the early stages of muscle myofibril formation; in cultured chick cardiomyocytes, Krp1 localizes to sites with laterally fusing myofibrils, indicating that Krp1 may be involved in later stages of myofibrillogenesis (Lu et al., 2003). To elucidate the role of Krp1 in myofibril assembly, endogenous Krp1 expression was reduced using RNA interference. Chemically synthesized siRNA against a Krp1 target sequence was transfected into primary mouse embryonic cardiomyocytes, and Krp1 expression was determined by quantitative PCR and immunoblotting. Krp1 transcript levels were reduced over 70% within 48 hours post-transfection compared to mock- and scrambled siRNA-transfected control cells, and Krp1 protein levels were decreased 50% by 72 hours. In contrast, levels of sarcomeric alpha-actin and muscle myosin were unaffected. Alpha-actinin organization into mature structures was used as a measure of myofibril content and assessed by confocal microscopy and morphometric analysis. Cardiomyocytes transfected with scrambled siRNA and Krp1 siRNA contained mean myofibril areas corresponding to 52% and 29% of total cell area, respectively, indicating that Krp1 is required for myofibril assembly and/or maintenance of mature myofibrils. In control cells transfected with scrambled siRNA, many broad Z-lines were observed with 1.8 to 2.2 micron periodicity. After Krp1 knockdown, broad Z-lines were often absent and alpha-actinin was organized into continuous fibers, aperiodic dots, or narrow bands or dots with 1.8 to 2.2 micron periodicity. These data are consistent with a role for Krp1 in myofibril assembly.

Tropomodulin and Tropomyosin Are Required for Cardiac Myofibril Assembly and Looping Morphogenesis in the Mouse
C. R. McKewen, R. B. Nowak, V. M. Fowler; Department of Cell Biology, The Scripps Research Institute, La Jolla, CA
During heart development, the linear heart tube undergoes dramatic morphogenetic changes in order to specify chambers and become a mature, functioning organ. This process, known as cardiac looping morphogenesis, is highly dynamic and not well understood. Mechanisms that may play a role in looping morphogenesis include cell shape changes, cell proliferation, differentiation, myofibril assembly, and contractile function. We are interested in testing the contributions of cardiomyocyte myofibrillogenesis and contraction in looping morphogenesis. Mice lacking the sarcomeric proteins tropomodulin (Tmod1) or alpha-tropomyosin (αTM1) are embryonic lethal due to cardiac development defects. In both mutants, embryonic development ceases during the cardiac looping stage around day E8.5-9, suggesting that these myofibril components are also required for looping morphogenesis. In order to test the hypothesis that myofibril assembly and function are coupled to cardiac development, we have begun a comparative analysis of the αTM1 and the Tmod1 null mice. By whole-mount immunofluorescence, both αTM1 and Tmod1 null hearts display aberrant α-actinin and F-actin rod-like structures reminiscent of skeletal muscle nemaline rods. The Tmod1 null hearts do not form visible myofibrils and fail to loop. However, ex vivo imaging of cultured Tmod1 null embryos demonstrates that the hearts do have some contractile function. Together, these data indicate that myofibril assembly is required for looping but not for contractile function. Preliminary data show that the αTM1 null hearts develop slightly further than the Tmod1 nulls, initiating looping and raking nascent myofibrils.

Myofibrillogenesis in Zebrafish Skeletal Muscle Cells
J. M. Sanger, A. Dube, B. Holloway, J. Wang, J. W. Sanger; 1Cell and Developmental Biology, SUNY Upstate Medical University, Syracuse, NY, 2Cell and Developmental Biology, University of Pennsylvania, Philadelphia, PA
The premyofibril model that we have proposed to explain myofibrillogenesis suggests that the formation of mature myofibrils is preceded by two intermediary structures: premyofibrils and nascent myofibrils. To examine myofibrillogenesis in a living animal we have begun to use the zebrafish model system where there is a temporal progression of myofibril formation that can be followed as myotomes increase in length from the youngest to the oldest. To determine if there is evidence for the premyofibril model in zebrafish, antibodies to sarcomeric alpha-actinin and muscle myosin II were used to stain embryos that were fixed at 20 - 25 hours post-fertilization. The earliest myotomes exhibited small periodic bodies of alpha-actinin (z-bodies) that were arrayed along actin fibers in a pattern that appeared identical to premyofibrils detected in avian muscle. In young myotomes, muscle myosin was present in overlapping bundles that resembled the patterns in myotomes in avian nascent myofibrils. A-bands and Z-bands were present in mature myofibrils in the elongated cells in older myotomes. However, at the ends of these cells the patterns of alpha-actinin and muscle myosin resembled the arrangement seen in younger myotomes, suggesting that as the cells elongated, premyofibrils were involved in the extension of sarcomeres that comprised cell growth. For live cell observations, zebrafish skeletal muscle alpha-actinin promoter encoding GFP-sarcomeric alpha-actinin or FATZ or skeletal actin were injected into one of the first two blastomeres. Mosaic transgenic zebrafish displayed the expected localization of alpha-actinin, FATZ and actin in the young and old myotomes even after several days. Fluorescence Recovery After Photobleaching measurements showed that the dynamics of GFP-alpha-actinin measured in the Z-bands had a recovery profile similar to that found for avian Z-bands. These observations indicate that myofibrillogenesis in zebrafish is consistent with the premyofibril model of myofibrillogenesis.

Interaction between p94/calpain 3 and Sarcomeric α-actinin in Skeletal Muscles
K. Ojima,1,2 Y. Ono,1 N. Ooi,1 K. Yoshioka,2 Y. Kawasaki,1 H. Sorimachi1; 1Department of Enzymatic Regulation for Cell Functions, Tokyo Metropolitan Institute of Medical Science (Rinshoken), Tokyo, Japan, 2CREST, Japan Science and Technology Agency (JST), Kawaguchi, Japan, 3Graduate School of Agricultural and Life Sciences, The University of Tokyo, Tokyo, Japan
p94/calpain 3 is a Ca2+-regulated intracellular cytosine protease, and is predominantly expressed in skeletal muscles. A defect of its proteolytic activity leads to limb-girdle muscular dystrophy type 2A. In myofibrils, p94 is localized at Z-band, N2A, and M-line regions. At the latter two regions, p94 directly binds to connectin/titin. However, p94 binding molecule(s) of myofibrill components other than connectin/titin have not been reported. In this study, to identify a binding partner of p94 in particular in Z-band components, yeast two-hybrid screening was performed using p94 NS domain, the N-terminal region of p94, as bait. Out of the 4000 clones plated on the selection medium plates, 22 clones were identified as potential p94 binding molecule. Interaction between p94 and s-α-actinin was further investigated in mammalian cells. Both s-α-actinin and p94 were co-expressed in COS7 cells, and immunoprecipitated with specific antibodies. As a result, s-α-actinin was co-immunoprecipitated with full-length p94 as well as the p94 NS domain, indicating that the p94 NS domain directly bound to s-α-actinin. Furthermore, a specific antibody against the p94 NS domain captured p94 positive Western blot analysis showed that the expression of smooth muscle α-actin, sarcomeric α-actinin, integrin α6β1 and N-cadherin was downregulated in explants treated with Y27632. Pharmacological inactivation of myosin light chain kinase, a downstream of ROCK, by ML-9 perturbed the formation of striated myofibrils as well as costameres, but not myocardial epithelialization. These results suggest that ROCK may play a role in the initial heart myofibrillogenesis via actin-myosin assembly, focal adhesion/costamere and cell-cell adhesion.
signals in the Z-bands of cultured muscle cells, although other p94 antibodies whose epitopes were located to the C-terminal regions of p94 detected p94 in N2A and/or M-line regions, not in the Z-bands. These data suggest that the N-terminal fragments of p94 are involved in the Z-band structure by linking with s-α-actinin.

Point Mutations in Myosin Differentially Affect ATPase and Actin Motility and Perturb Skeletal and Cardiac Muscle Structure and Physiology
A. R. Cammaroto,1,2 C. M. Dambacher,1 K. Occor,3 M. C. Reedy,3 A. F. Knowles,4 W. A. Kronert,1 R. Bodmer,5 S. I. Bernstein1; 1Biological Department, San Diego State University, San Diego, CA, 2The Burnham Institute for Medical Research, La Jolla, CA, 3Cell Biology, Duke University Medical Center, Durham, NC, 4Chemistry and Biochemistry, San Diego State University, San Diego, CA

Myosin is the molecular motor that drives muscle contraction. *Drosophila melanogaster* is a powerful model system to study the in vitro and in vivo properties of mutated myosins and their effects on different striated muscles possessing distinct contractile properties. We investigated the influence of specific mutations, from the molecular through the organ level, of the myosin heavy chain (MHC) mutants D45 (A261T), which changes a residue near β7, and Mhc1 (G200D), which alters a residue located at the base of loop I. Both regions likely regulate the rate of nucleotide exchange. D45 myosin has decreased Ca2+-ATPase activity and reduced basal and actin-stimulated Mg2+-ATPase activity as compared to the wild-type indirect flight muscle (IFM) isoform (Hill coefficient 1.6). D45 myosin shows a greater than two-fold increase in basal Mg2+-ATPase activity but a similar actin-stimulated Mg2+-ATPase rate as the IFM. The average actin sliding velocity was reduced by two-fold for D45 myosin compared to the IFM, while Mhc1 myosin increased actin filament velocity by 15%. Ultrastructural analysis of IFM expressing D45 myosin revealed white-type myofibril structure, while flies expressing Mhc1 myosin displayed severe hypercontraction. Both mutations had similar effects, however, exhibited decreased flight ability. We also investigated the effects of these mutations on cardiac structure and performance. Beating hearts of semi-intact flies were imaged using direct immersion DIC optics in conjunction with a high-speed digital camera. Movies processed to produce edge tracings allowed us to monitor heart tube movements. Compared to wild-type, D45 hearts appeared wider or dilated while Mhc1 hearts exhibited restricted, non-contractile regions. Computational analysis revealed altered systolic and diastolic function in both mutants. Ultrastructural perturbations were also found in the mutant cardiomyocytes.

Overall, our data show that distinct molecular defects in the myosin molecule differentially affect the structure of skeletal muscle and the structure and function of cardiac muscle.
charged ankryin-like repeats that are bilaterally symmetric. Supported by T32 HL 072751 (M.A.B.), by a Development Award from the Muscular Dystrophy Association (MDA; to A.K.-K.), and by the NIH (RO1 HL64304) and the MDA (to R.J.B.).

Obscurin Interacts with Filamin C and Is Present at Costameres
A. L. Bowman, A. Kontogianni-Kstantonopoulou, A. O'Neill, R. J. Bloch; Physiology, University of Maryland, Baltimore, Baltimore, MD

Obscurin is a giant sarcomeric protein that is critical in the development of the A band and M line in skeletal muscle. Obscurin has previously been localized to structures that surround individual myofilaments at the level of Z-disks and M-bands. Using a yeast two-hybrid assay, we identified filamin C as a binding partner of the Rho-GEF/PH domains of obscurin. Amino acids 2188-2288 of filamin C contain the minimal binding region necessary for binding the Rho-GEF/PH domains in yeast. Inclusion of the dimerization domain of filamin C enhances binding in overlay assays, however, suggesting that obscurin preferentially binds dimerized filamins or that longer sequences of filamin are necessary for proper folding of the binding site. In addition to colocalizing at the periphery of Z-disks and M-bands of myofibrils, filamin C and obscurin co-localize at costameres at the sarcolemma of skeletal muscle. Both proteins are lost from the costameres that remain in muscle from mdx (dystrophin-deficient) mice, consistent with their association with the dystrophin-glycoprotein complex in healthy muscle. The identification of PC-lok (the other obscurin isoform) and the presence of costamers and its links to the underlying contractile apparatus of striated muscle. Supported by a training stipend (T32 GM08181, to ALB), grants from the NIH (RO1 HL64304 and the Muscular Dystrophy Association (to RJB) and a Development Award to AKK from the Muscular Dystrophy Association.

Characterization of the Binding Site on Obscurin for Small Ankryin 1
B. Busby, M. A. Borzok, A. Kontogianni-Kstantonopoulou, R. J. Bloch; University of Maryland, Baltimore, MD

Obscurin is a recently discovered ~800 kDa high-mannose glycoprotein that is synthesized in striated muscle cells, where it surrounds myofilaments at the levels of Z disks and M bands. The localization of actin and tropomysin may play a role in the contractile apparatus apparatus of the sarcoplasmic reticulum (SR) of skeletal and cardiac muscles. The C-terminus of the molecule is localized near the SR and binds a small protein spanning the SR membrane known as small ankryin 1 (sAnk1). We used the yeast two-hybrid screen to identify a short sequence of amino acids in obscurin that mediate binding to sAnk1 (6324-KWVEEETEVVKK-6338) and site-directed mutagenesis to identify the amino acids involved in binding. Mutation of either K6324 or K6338 to A reduces binding strongly, whereas mutation to E inhibits binding significantly. Mutation of each of the four E's to A individually has little effect; mutation of several inhibits binding significantly; and mutation of all four completely abolishes binding. The two central residues, E6329 and E6330, contribute most to these results. R6335A has little effect on binding, whereas R6335E enhances binding. Our results suggest that this sequence and nearby amino acids, constitute a minimum binding domain for sAnk1, and that electrostatic interactions, mediated by positive charges flanking a highly negatively charged core, contribute significantly to binding. Supported by a grant to RJB from the NIH (RO1 HL64304). BB receives support from T32 GM08181.

Tropomyosin 4 Defines Novel Filament Systems in Normal and Diseased Muscle
N. E. Vlahovich, E. Kettle, G. Schevzov, V. Nair-Shalliker, B. Iwokshi, D. Hernandez-Diveiez, R. Parton, A. Keel, K. N. North, P. W. Gunning, E. C. Harderman; 'Muscle Development Unit, Children's Medical Research Institute, Westmead, Australia, 2School of Natural Sciences, University of Western Sydney, Penrith, Australia, 3Oncology Research Unit, The Children's Hospital, Westmead, Australia, 4Neurogenetics Unit, The Children's Hospital, Westmead, Australia, 5Institute for Molecular Bioscience, University of Queensland, Brisbane, Australia

Tropomyosins (Tms), a family of filamentous proteins consisting of over forty isoforms, play an important role in defining the function of actin filaments in both muscle and non-muscle cells. Tm isoforms are derived from four genes (alpha, beta, gamma and delta) and are generated through the use of alternative promoters and alternative RNA splicing. In non-muscle cells, Tm isoforms have been shown to be functionally distinct, playing roles in diverse processes such as cell growth, differentiation, cell division and vesicle transport. We have previously shown that Tm5NM1 localizes to the Z-line associated cytoskeleton (ZLAC) in skeletal muscle fibers and disruption of this structure causes a dystrophic phenotype in transgenic mice. The current study shows that cytoskeletal Tm4 localizes to regions in muscle fibers that are distinct from those containing Tm5NM1. Using Tm5NM1 and Tm4 isoform-specific antibodies in immunofluorescence and immuno-electron microscopy, we found that Tm4 co-localizes with caldesmon at the terminal cisternae of the sarcoplasmic reticulum and Tm5NM1 co-localizes with the dihydroyphindine receptors in the T-tubules in normal muscle. In muscles undergoing remodelling and repair in response to injury, stretch and disease, Tm4 is upregulated and is present in longitudinal filaments along the length of muscle, perpendicularly to the Z-line. An elevated level of Tm4 is diagnostic of repair in dystrophies and nemaline myopathy. The discovery of these ‘nonmuscle’ filament systems in skeletal muscle demonstrates that, in parallel with all other cell systems examined, skeletal muscle contains compartmentalized cytoskeletal systems characterized by the segregation of different cytoskeletal tropomyosins. The association of distinct Tm isoforms with the internal membranes in muscle fibers suggests a role for the local actin cytoskeleton in the functions of these membranes.

Comparison of the Localization and Dynamic Properties of Tropomyosin Isoforms: TPM1alpha and TPM1kappa in Skeletal Muscle Cells
J. Wang, J. M. Sanger, H. Thurstorn, L. Z. Abbott, D. K. Dube, J. W. Sanger; Cell and Developmental Biology, SUNY Upstate Medical University, Syracuse, NY

Tropomyosin (TM) and the troponins associate with actin filaments and regulate the interaction of the thin and thick filaments of mature myofibrils. There are four known tropomyosin genes (designated as TPM1, TPM2, TPM3, and TPM4) in vertebrates. The predominant TPM1 isoform, TPM1alpha, is specifically expressed in both skeletal and cardiac muscles. Recently a newly discovered alternatively spliced isoform, TPM1kappa, containing exon 2a instead of exon 2b contained in TPM1alpha, was found to be cardiac specific and developmentally regulated. However the role of TPM1kappa in myofibrillogenesis and contractile activity is yet to be understood. In this work, we transfected avian cardiac and skeletal muscle cells with green fluorescent proteins (GFP) coupled to Chicken TPM1alpha and Chicken TPM1kappa and compared their localizations in premyofibrils and mature myofibrils. In addition, we used the technique of fluorescence recovery after photobleaching (FRAP) to compare the dynamics of TPM1alpha and TPM1kappa in premyofibrils versus mature myofibrils. Expression of TPM1alpha and TPM1kappa did not affect muscle cell growth and myofibrillogenesis. Both TPM1alpha and TPM1kappa have similar localization and dynamic properties in skeletal and cardiac muscle cells with both isoforms exchanging more rapidly in premyofibrils than in mature myofibrils. The faster exchange properties of the TPM1 isoforms in premyofibrils associated with mature myofibrils has also been seen when the dynamics of Z-band proteins are compared in premyofibrils and mature myofibrils. These results suggest that as myofibrils assemble, proteins of the thin filament become less dynamic. This could be attributed to CapZ (binds the barbed ends of actin filaments) and nebulin (tropomyosin binding molecule) that associate with actin later in forming myofibrils than the muscle tropomyosins. These experiments are supportive of a maturing thin filament and stepwise model of myofibrillogenesis (Sanger et al., 2006). Work supported by grants from AHA, MDA and NIH.

Expression of the Mouse e-SG Gene Having an Exon Trap Retrovirus Vector Integrated into Intron 11
M. Imamura, S. Takezaki; Department of Molecular Therapy, National Institute of Neuroscience, NCNP, Tokyo, Japan

Conventional sarcoglycans (alpha, beta, gamma and delta) comprise a subcomplex within the dystrophin-associated protein complex, which is critical for the function of the striated muscle cell membrane. A fifth broadly expressed sarcoglycan (SG), e-SG, was identified as a glycoprotein similar to a-SG that is encoded by the causative gene for autosomal recessive limb-girdle muscular dystrophy type 2D. However, unlike a-SG, loss-of-function mutations in e-SG gene cause myoclonus-dystonia syndrome (M-D) but not muscular dystrophy, indicating the importance of e-SG for the function in the central nervous system rather than in muscle cells. We found a brain-specific isoform of e-SG (e-SG2) in neuronal cells and suggested the functional importance of its C-terminal unique sequence in the brain. Therefore, to investigate the role of e-SG2, we generated a mouse lacking the C-terminal sequence by poly-A trap strategy with a removable exon trap (RET) retrovirus vector. Insertion of RET-vector into the intron 11 of the mouse e-SG gene (Sgce) resulted in making the hybrid mRNA with human bcl-2 exon 3 instead of the last two exons (exon 11b and 12) of Sgce. In the translation of the hybrid transcript, the C-terminal unique sequence of e-SG2 was replaced by the artificial 14-amino acid sequence. Reverse transcription-PCR clearly detected the expression of the hybrid transcript in a variety of mouse tissues. Analysis of heterozygous RET-vector-inserted Sgce indicated paternal expression of e-SG mRNA. Furthermore, we generated an antibody specific for the hybrid e-SG molecule and succeeded in detection of the protein product from the vector-inserted Sgce allele. M-D is a neurological disorder showing an autosomal dominant inheritance with incomplete penetrance. Our Sgce partial knockout mice would be useful for the study of inheritance mode of M-D as well as the analysis of e-SG2 function in the central nervous system.
2275 Interaction between the Muscular Dystrophy Proteins Myotilin and Telethonin
H. Suila,1 M. Moza,2 G. Faulkner,2 O. Carpen1; 1Biomedicum Helsinki, Program of Neuroscience, Department of Pathology, University of Helsinki, Helsinki, Finland, 2Muscle Molecular Biology Unit, International Centre of Genetic Engineering and Biotechnology, Trieste, Italy, 3Department of Pathology, University of Turku and Turku University Central Hospital, Turku, Finland

Myotilin and telethonin are components of the muscle sarcomere Z-disc. Missense mutations in both proteins cause muscle disorders and cardiomyopathies. Myotilin plays an important role in maintaining the structural integrity of the sarcomere and it has been shown to bind several Z-disc proteins including a-actinin and calcalcicins. It also interacts with the transcriptional regulators MrXR1 and 2 involved in sensing of mechanical load. Telethonin is a part of the muscle stretch sensor machinery and it anchors the giant muscle protein titin to the Z-disc. When analyzing myotilin knock-out mice, we noticed a consistent upregulation of telethonin mRNA and protein, suggesting a functional interplay between the proteins. The aim of this study was to analyze further the link between myotilin and telethonin. By yeast-two-hybrid and in vitro protein assays we have detected a direct interaction between the two proteins. The interaction sites are currently being mapped. We are also testing how the interaction is regulated and comparing the telethonin binding specifics of myotilin and titin.

2276 Interaction between the Myofibrillar Myopathy Proteins Myotilin and ZASP
P. von Nandanestad1, O. Carpen2; 1Department of Pathology and Neuroscience Program, University of Helsinki, Helsinki, Finland, 2Department of Pathology, University of Turku and Turku University Central Hospital, Turku, Finland

Myotilin is a component of the striated muscle sarcomeric Z-discs, which cross-link actin-containing thin filaments. Point mutations in the myotilin gene, typically replacing either a serine or threonine, causes two forms of muscle disorders, limb-girdle muscular dystrophy type 1A and myofibrillar myopathy (MFM). Functional studies on myotilin have demonstrated an association with important components of the sarcomere: α-actinin, a core structural component of the Z-disc, filamin C, and actin. Experiments using myotilin fragments with dominant negative effect have shown its critical involvement in sarcomere organization. Myotilin bundles and stabilizes actin effectively, which suggests a role for myotilin in the organization and maintenance of the Z-disc integrity. To gain further insight into myotilin’s molecular interactions, we carried out a yeast two-hybrid screen using myotilin as bait. In this screen we identified the Z-band alternatively spliced PDZ motif-containing protein (ZASP) as a novel binding partner for myotilin. Additional in vitro and in vivo studies have further verified the interaction. As both ZASP and myotilin are expressed predominantly in cardiac and skeletal muscle and their mutations can result in a similar disease phenotype characterized by disintegration of the Z-disc and by abnormal accumulation of multiple proteins, we hypothesize that the two proteins act in concert in the maintenance of the sarcomere.

2277 Nicotine Affects the Secondary Meiosis and Embryonic Development of Bovine Oocytes
G. Li, B. R. Sessions, Y. Liu, T. D. Bunch, K. L. White, L. Rickords, B. J. Pate, K. I. Astorn; Department of Animal, Dairy and Veterinary Sciences, Utah State University, Logan, UT

Effects of nicotine on the secondary meiotic spindle formation, embryo development and embryo quality were studied. The majority of the oocytes activated by ionomycin were with irregular anaphase and telophase spindles when cultured the oocytes in the presence of nicotine at 0.2 mmol concentration, the shape of spindles became worse disfiguration with the increase of nicotine concentrations. Cleavage and blastocyst rates of the embryos derived from parthenogenetical activation (PA) were not affected when the embryos were cultured in 0.2 and 0.5 nM nicotine media. With the increase of nicotine concentration to 1.0 mM the blastocyst development (9.9%) was numerically lower than the control (15.5%). Culture of the in vitro fertilized (IVF) embryos in 0.2, 0.5, and 1.0 mM nicotine media resulted in similar cleavage and blastocyst rates to the control. None of the embryos developed to beyond 16-cell stage when cultured the IVF or PA embryos in 2.0 and 4.0 mM nicotine media. Chromosomal analyses of both IVF and PA blastocysts showed that the majority (60-90%) of them were polyplody and mixoploidy. Cell number of the blastocysts derived from nicotine treatment was significantly lower than the control. Analyses of the un-cleaved 1-cell embryos after treatments with 2.0 mM and 4.0 mM nicotine showed that nicotine inhibited cytokinesis and resulted in the formation of poly-nuclei.

2278 Macromolecular Interaction of Halichondrin B Analogos E7389 and ER-076349 with Tubulin by Analytical Ultracentrifugation
J. J. Correa, P. H. Alday; Biochemistry, University of Mississippi Medical Center, Jackson, MS

Halichondrin B is an anti-mitotic drug that inhibits microtubule assembly. To understand the molecular details of its interaction with tubulin we investigated the binding of two analogs, E7389 and ER-076349, to tubulin by quantitative analytical ultracentrifugation. E7389 is currently undergoing Phase II clinical trials for cancer; ER-076349 is a closely-related analog with C.35 hydroxyl instead of C.35 primary amine (Towel MJ et al., Cancer Res. 61:1013, 2001). Below the Cc for microtubule assembly and in the presence of GDP, tubulin undergoes weak self-association into short curved oligomers. E7389 completely inhibits oligomer formation, while ER-076349 slightly stimulates oligomer formation by two fold. This is in contrast to vinblastine, which strongly stimulates large spiral polymers by 1000-fold. Colchicine binding to the intra-dimer interface has no effect on small oligomer formation, while the presence of bound colchicine also has no effect on the inhibitory activity of E7389. E7389 also inhibits vinblastine-induced spiral formation. These results suggest halichondrin B derivatives bind to the inter-dimer interface, disrupt polymer stability, and compete for vinblastine binding. Statomin is known to form a 1:2 complex with tubulin. E7389 inhibits formation of 1:2 statamin-tubulin complex, while ER-074369 dramatically weakens formation of the 1:2 complex. These results suggest E7389 is a global inhibitor of all tubulin polymer formation, disrupting tubulin-tubulin contacts at the inter-dimer interface. ER-076349 also perturbs tubulin-tubulin contacts in a polymer specific manner. This implies halichondrin B derivatives may exhibit unique cellular activities that reflect inhibition of tubulin interaction with specific regulatory, cell cycle specific factors. (Supported by Eisai Research Institute, Andover, MA.)

2279 FtsZ From Divergent Foreign Bacteria Can Function for Cell Division in E. coli
M. Osawa, H. P. Erickson; Cell Biology, Duke University Medical Center, Durham, NC

E. coli FtsZ, Mycoplasma pulmonis (MpuFtsZ) and Bacillus subtilis (BfBtsZ) are the only 46% and 52% identical in amino acid sequence to FtsZ from Escherichia coli (EcFtsZ). In the present study we show that MpuFtsZ and BfBtsZ can function for cell division in E. coli provided we make two modifications. First, we replaced their C-terminal tails with that from E. coli, giving the foreign FtsZ the binding site for E. coli FtsA and ZipA. Second, we selected for mutations in the E. coli genome that facilitated division by the foreign FtsZ’s. These suppressor strains arose at a relatively high frequency of 10^-3 - 10^-5, suggesting that they involve loss of function mutations in multi-gene pathways. These pathways may be negative regulators of FtsZ, or structural pathways that facilitate division by slightly defective FtsZ. Related suppressor strains were obtained for EcFtsZ containing certain point mutations or insertions of YFP. The ability of highly defective FtsZ to form functional Z-discs in E. coli replicates the binding specifics for EcFtsZ containing certain point mutations or insertions of YFP. The ability of highly defective FtsZ to function for division in E. coli is consistent with a two-part mechanism. FtsZ assembles the Z-ring, and perhaps generates the constrictor force, through self interactions; the downstream division proteins remodel the peptidoglycan wall by interacting with each other and the wall. The C-terminal peptide of FtsZ, which binds FtsA, provides the link between FtsZ assembly and peptidoglycan remodeling.
and TBCA. Overexpression of TBCB induces microtubule depolymerization. We found that this function is based on the ability of TBCB to form a binary complex with TBCE that greatly enhances the efficiency of this cofactor to dissociate tubulin in vivo and in vitro.

2281 Tubulin Cofactor B Expression in Developing Nervous System Suggest a Role in Neurogenesis
J. C. Villegas,1 G. Carranza,2 J. Bellido,3 D. Kortazar,3 J. C. Zabala,2 M. L. Fanaraga1; 1Anatomy & Cell Biology, University of Cantabria, Santander, Spain, 2Molecular Biology, University of Cantabria, Santander, Spain, 3Unidad de Metabolómica, CICbioGUNE, Derio, Spain Tubulin folding cofactor B (TBCB) is not apparently required for tubulin biogenesis and unnecessary for life. Here we show by Northern and Western blot that TBCB is abundantly expressed during neurogenesis. Immunostaining in neonate brain cyrossections and primary cultures demonstrate abundant TBCB levels in proliferating and migrating nestin-positive neuroblasts. In adult central nervous system TBCB immunostaining is less conspicuous being mostly localized at the ependymal cells. TBCB studies of overexpression by transitory cell transfection and expression knock down by interference RNA performed in a neuronal cell line (NG-108) suggest that TBCB participates at microtubule dynamics in neuroblasts as well as in ependymal cilia microtubule turnover.

2282 Characterization of the Colchicine Binding Site on Tubulin Isootype JVI
S. Sharma,1 B. Poliks,2 R. Ravindra,1 S. Bune1; 1Chemistry, SUNY Binghamton, Binghamton, NY, 2Physics, SUNY Binghamton, Binghamton, NY The protein tubulin exhibits seven β isotypes. All except the isotype JVI are highly homologous to each other. The sequence divergence of JVI with other β isotypes is implicated in its dissimilar in vitro assembly mechanisms. The overall aim of this project is to explore the consequences of the isotype JVI sequence divergence for ligands binding to the colchicine site. Chicken erythrocyte tubulin (CETb), which is composed solely of the αCETb, which is composed solely of the αCETb isotypes, was purified from chicken blood. Superimposition of chicken isotype JVI with the electron diffraction structure of mammalian brain tubulin-colchicine complex revealed four divergent residues within 5Å of colchicine binding site, indicating that the colchicine binding site on JVI possesses topography different from that of the other β isotypes. No evidence for colchicine binding to purified CETb was found. Taxol-induced assembly of 5 µM CETb was unaffected by up to 140 µM colchicine. No enhancement of colchicine fluorescence or quenching of intrinsic CETb fluorescence was observed at molar ratios of colchicine/tubulin up to 50:1. Podophyllotoxin inhibited taxol-induced assembly of CETb with an IC50 15-fold greater than the value for podophyllotoxin inhibition for taxol-induced assembly of bovine brain tubulin. This indicates that the colchicine A ring binding pocket on isotype JVI is structurally compatible for the trime-thoxyphenyl portion of colchicine. Surprisingly, allcolchicine, which possesses an aromatic C ring rather than the tropone ring of colchicine, binds to CETb. The kinetics of binding and fluorescence titration at 25°C revealed an apparent on rate constant and affinity constant about 23 and 28 times less than that for allcolchicine binding to bovine brain tubulin. The slow and suppressed binding of allcolchicine with iso type JVI indicates that the C ring binding pocket on JVI may either be shrunken or incompletely accessible to the colchicine C ring.

2283 The Molecular Mechanism of Taxol Function
A. Mitra,1 D. Sept2; 1Chemical Engineering, Washington University, St. Louis, MO, 2Biomedical Engineering, Washington University, St. Louis, MO Drugs such as Taxol are important antitumor agents since they stabilize microtubules and inhibit mitosis. Although we can understand this function at the cellular level, the molecular details of how these compounds work are not well understood. We have performed large-scale molecular dynamics simulations on a piece of a microtubule both with and without taxol. By comparing these two simulations, we can determine which parts of tubulin undergo conformational and/or dynamical changes upon Taxol binding. As we expected, we see differences in M-loop, H1/S2 loop interactions, however we also see long-range allosteric effects that produce significant changes in the T3, T4 and T5 loops surrounding the nucleotide in the beta monomer. These results suggest that taxol may partially counteract the effects of GTP hydrolysis and alter the interaction with the next longitudinal tubulin dimer, thereby preventing the protofilament from becoming curved as observed with GDP-tubulin.

2284 Investigation of the Paclitaxel-Binding Site in Tubulin Using Mutants of Saccharomyces cerevisiae
R. D. Winefield, T. B. Feland, R. H. Himes; Department of Molecular Biosciences, The University of Kansas, Lawrence, KS Tubulin from the budding yeast Saccharomyces cerevisiae does not bind paclitaxel. However, previously we were able to create paclitaxel binding to S. cerevisiae tubulin by mutating five residues in yeast β-tubulin (purported to play important roles in the putative taxoid-binding site in mammalian β-tubulin) to those that occur in brain β-tubulin. We also created a S. cerevisiae strain that is sensitive to paclitaxel by introducing the mutated β-tubulin gene into a yeast strain that has diminished multi-drug transporter activity. To determine the relative importance of the five residues we have now created new strains that contain different combinations of the five mutations; A19K, T23V, G26D, N227H and Y270F, and tested their sensitivities to paclitaxel. Strains containing only the N227H, Y270F, or the three N-terminal (NT) mutations showed greatly reduced sensitivity to paclitaxel. Similarly, the strains containing the N227H-Y270F or NT+N227H mutations were resistant to paclitaxel. The results indicate that one or more of the mutations in the NT region and the Y270F mutation are required to produce maximum sensitivity to the taxanes. On the other hand, the NT+Y270F strain (without the N227H mutation) was as sensitive to paclitaxel as was the strain with all five mutations. This is a surprising result since His227 has been proposed to play a significant role in paclitaxel binding. In contrast, however, the N227H mutation was necessary to produce maximum sensitivity to docetaxel. Tubulin assembly studies confirmed this result. Docetaxel was twice as effective as paclitaxel in stimulating assembly of tubulin from the strain with all five mutations, but about 60% as effective as paclitaxel when tubulin from the strain lacking the N227H mutation was used. The results indicate that His227 plays a greater role in tubulin’s affinity for docetaxel than for paclitaxel. Supported by NIH grant CA105305

2285 Vinca Alkaloids Demonstrate Differential Effects on Apoptosis
A. Aggarwal,1 A. Kruczynski,1 A. Frankfurter,1 J. Correa,1 S. Lobert1; 1Biochemistry, University of Mississippi Medical Center, Jackson, MS, 2Institute de Recherche Pierre Fabre, Castres, France, 3Biology, University of Virginia, Charlottesville, VA We compared the effects of vinblastine, vinorebine and vinflunine on mouse leukemic P388 sensitive and vinorebine-resistant cells. Interestingly, vinorebine-resistant cell lines were cross-resistant to vinblastine but retained sensitivity to vinflunine as confirmed by IC50 measurements. For example, IC50 values for vinblastine and vinorebine for resistant cell lines increased 2-16-fold relative to sensitive cell lines; while responses of the same cells to vinflunine increased less than 2-fold. Furthermore, flow cytometry demonstrated that at 10X IC50 drug concentrations, vinorebine caused earlier and more pronounced G2/M arrest compared to vinorebine and vinflunine. Apoptotic events were examined by flow cytometry using annexin-V-FITC which also showed earlier apoptosis with vinorebine. Quantitative Western blotting demonstrated that there were no changes in beta tubulin isotype levels, total tubulin or microtubule fractions in the resistant cells compared to the drug sensitive cells; however, by qRT-PCR, we found significantly increased levels of stathmin1, stathmin3 and MAP4 mRNA in the drug-resistant cell lines compared to drug-sensitive cells. Comparisons of the effects of vinblastine, vinorebine and vinflunine on mitochondrial potential change by flow cytometry and cytochrome C release by Western blotting in the drug sensitive and resistant cell lines are in progress. We conclude that differential effects of vinflunine on cell lines compared to other vinca alkaloids may due to its differential effects on apoptotic pathways.

2286 M and N Loop Mutations in Alpha-tubulin Stabilize Microtubules to Confer Dinitroaniline Resistance
L. Ganesan, C. Li, C. Ma, N. Morrisette; Molecular Biology and Biochemistry, UC Irvine, Irvine, CA Plant and protozoan microtubules are sensitive to disruption by dinitroanilines, a group of compounds used in commercial herbicide formulations. Dinitroanilines kill intracellularly Toxoplasma gondii parasites without affecting microtubule function in vertebrate host cells. We previously isolated a number of Toxoplasma lines that are resistant to dinitroanilines and harbor mutations to the single α-tubulin gene. Some of the mutations (Val41Leu, Tyr24His, Thr239Ile, Arg243Cys and Arg243Ser) map to a computationally determined binding site located beneath the N loop. Other resistance mutations (His228Glu, Phe52Ile, Phe49Cys, Phe252Leu, Phe253Thr, Met208Thr, Ala273Val, Ile275Thr, Ala295Val and Met301Thr) are localized in or near the M and N loops, domains that coordinate lateral interactions between protofilaments within the microtubule lattice. Allelic replacement of wild type tubulin with the M and N loop mutations is sufficient to
2287
Expression of Dinitroaniline-sensitive Tubulin for Biochemical Characterization
S. Lyons-Abbott, J. De Leon, N. Morrisette; Molecular Biology and Biochemistry, University of California—Irvine, Irvine, Irvine, CA
Microtubules in the protozoan parasite Toxoplasma gondii are sensitive to disruption by dinitroaniline compounds such as oryzalin. Computational analysis indicates that oryzalin binds as well as the α-tubulin N loop and dinitroanilines are predicted to disrupt protofilament interactions. Oryzalin resistant Toxoplasma lines contain mutations to residues in the N and M loops as well as to the predicted binding site. The M and N loops of α- and β-tubulin coordinate lateral interactions between protofilaments in the microtubule lattice and we hypothesize that point mutations in the M and N loops increase dimer-dimer affinity, compensating for dinitroaniline disruption of protofilament contacts. Similarly, we predict that binding site mutations decrease the affinity of dinitroanilines for Toxoplasma tubulin. To test these hypothesized mechanisms of resistance, we need to purify large amounts of sensitive tubulin dimers as well as heterodimers containing the individual point mutations that confer resistance. Since Toxoplasma is an obligate intracellular parasite, it would be difficult and expensive to recover sufficient amounts of parasite tubulin for biochemical characterization. We are investigating expression of sensitive α-β-tubulin dimers using E. coli, but did not co-express α- and β-tubulin or assess whether the tubulin was polymerization competent. We have developed plasmids for inducible co-expression of MBP-fusions in Toxoplasma α-tubulin and β-tubulin in E. coli. The budding yeast S. cerevisiae contains tubulin folding chaperones and we have developed an inducible co-expression construct for Toxoplasma α-tubulin and β-tubulin. Lastly the non-pathogenic ciliate Tetrahymena is an attractive expression system since it expresses abundant amounts of dinitroaniline-sensitive tubulin and has a genetically tractable system for replacement of wild type α-tubulin with tubulin mutants.

Proteomics of the Tubulin Cytoskeletal Scaffold in Hepatic Neoplasia
L. M. Miller, 1 A. Menthen, 1 P. Verderi-Pinar, 1 P. M. Novikoff, 1 S. B. Horwitz, 1 R. H. Angeletti, 1 Developmental and Molecular Biology, Albert Einstein College of Medicine, Bronx, NY, 2Molecular Pharmacology, Albert Einstein College of Medicine, Bronx, NY, 3Pathology, Albert Einstein College of Medicine, Bronx, NY
Understanding the changes that occur at the molecular level during the development of hepato cellular carcinoma is important in both the prevention and treatment of the disease. One characteristic of preneoplastic cells is a structural reorganization, which could be due to changes in the microtubule cytoskeleton. Using a rat liver cancer model that exhibits similar tumor progression stages as in humans, we are examining the tubulin cytoskeletal scaffold and associated proteins. Microtubules are dynamic protein polymers that play an essential role in cell division, maintenance of cell shape, transport of vesicles, and motility. They are comprised of different isotypes of α- and β-tubulin. Expression of various tubulin isotypes may not only affect the assembly of the microtubules, but may also influence the endogenous proteins that bind to microtubules. In this study, the tubulin isotypes and associated proteins present in multiple stages of liver cancer will be determined. The tubulin cytoskeletal scaffold has been purified from rat liver using a Tasel and glutamate based polymerization method. To identify the tubulin isotypes present, we measured the intact mass of the isotypes and then verified the assignment by measuring the mass of CNBr released C-terminal peptides, which contain the isoform defining region. The proteins associated with the microtubules can be released from tubulin with a high salt wash. Associated proteins were digested with trypsin, analyzed by LC-MS/MS and identifications assigned using the Mascot search engine. Initial studies indicate the presence of 3 α- and 3 β-tubulin isotypes in normal liver, along with post-translationally modified isoforms. LC-MS/MS analysis has so far identified 58 proteins that are associated with the cytoskeletal scaffold in normal liver. The methods established herein will be extended to the study of early and late stages of liver cancer.

Versatile Yet High Specific Fluorescent Labeling of Tubulin
A. Banerjee, 1 T. D. Panosian, 1 B. Cowen, 1 O. Dilek, 1 R. Ravindra, 1 D. L. Sackett, 2 S. Bane 1; 1Chemistry, SUNY-Binghamton, Binghamton, NY, 2Laboratory of Integrative and Medical Biophysics, NICHD/NHL, Bethesda, MD
Three dimensional structures of tubulin solved to date lack the full 15-20 amino acids of the C-terminus of each subunit. These peptides are of interest because they are the primary locus of tubulin sequence heterogeneity and posttranslational modification of the protein. In polymerized tubulin, the C-terminal peptides are on the exterior of the microtubule and are implicated in the association of microtubules with other proteins in the cell. The overall goal of this project is to explore the conformational properties and protein-protein interactions of the C-termini of tubulin using fluorescence spectroscopy. The goal of this aspect of the investigation was to develop a method by which the C-terminal amino acid on one of the subunits can be covalently labeled with a fluorophore. A chemically reactive derivative of tyrosine was synthesized that was a substrate for tubulin tyrosine ligase (TTL), an enzyme that is highly specific for the C-terminus of α-tubulin. Incorporation of the modified tyrosine into α-tubulin was confirmed by immunoblotting and by mass spectrometry. Fluorophores containing a functional group that is covalently reactive with the modified tyrosine were synthesized. Covalent bond formation between the tyrosine derivative and the fluorophores was characterized. The coupling reaction can be performed under conditions that preserve the native structure of the protein (neutral pH, temperature below 37 °C, reaction time less than two hours). The fluorescein-labeled tubulin retained its ability to assemble into normal microtubules. That the fluorescent labeling was successful and specific was confirmed by SDS-PAGE of the fluorescently-labeled protein, which showed a single fluorescent band that corresponds to α-tubulin. The tyrosine derivative and the synthetic fluorophores were not cytotoxic to PC-3 cells at low micromolar concentrations, indicating that this methodology may be applicable to fluorescent labeling of tubulin in living cells.

Behavioral and Neuropathological Abnormalities in γ-Tubulin 2 Knockout Mice
A. Kubo, 1 A. Kubo, 1 T. Miyakawa, 1 S. Tsukita, 1 S. Tsukita, 1-5 Cell Biology, Kyoto University Faculty of Medicine, Kyoto, Japan, 2Solution Oriented Research for Science and Technology, Japan Science and Technology Corporation, Kyoto, Japan, 3Dermatology, Keio University School of Medicine, Tokyo, Japan, 4Horizontal Medical Research Organization, Kyoto University Graduate School of Medicine, Kyoto, Japan, 5School of Health Sciences, Kyoto University Faculty of Medicine, Kyoto, Japan
γ-Tubulin is a universal component of microtubule organizing centers where it is believed to play an important role in microtubule nucleation. Mammalian have two γ-tubulin genes named TUBG1 and TUBG2. TUBg1 is a ubiquitously expressed γ-tubulin, and TUBg1 knockout mice showed early embryonic lethality. On the other hand, TUBg2 is a neuron specific γ-tubulin. TUBg2 knockout mice were normally developed and fertile, but they showed behavioral abnormalities. In this study, we analyzed TUBG2 -/- mice with many kinds of behavioral tests. TUBG2 -/- mice are normal on measurement of general health, neurological reflexes, sensory abilities, muscular strength, and spatial working memory, as compared to wild type littermate controls. On Morris water task, Tuba2 -/- mice do not show selective search on the probe trial. Tuba2 -/- mice can swim straight forward, but they can’t turn or search around. As a result, Tuba2 -/- mice hit the pool wall frequently. In the Barnes circular maze, another test for spatial navigation learning, Tuba2 -/- mice show normal performance on time spent around the target hole. On balance beam walking test, Tuba2 -/- mice significantly slower show walking speed and frequent slips as compared with wild type littermate mice. Tuba2 -/- mice sometimes show a sudden movement to backward. These observations could mean that Tuba2 -/- mice are normal on spatial learning, but deficient in behavioral paradigm sensitive to dysfunction of the nigrostriatal pathway. Hematoxylin and eosin staining of paraffin embedded section show many cytoplasmic eosinophilic hyaline inclusions in thalamic neural cells of TUBG2-/- brain. Shapes of the inclusions vary from small ovoid structures to longer, narrow bodies (5-10 μm in width, 10-20 μm in length). Together these findings provide the first evidence for a novel role of γ-tubulin in neural cells.

α-Tubulin Polyglutamylation Modulates KIF1 Traffic-dependent Synaptic Vesicle Targeting
K. Ikagami, 1 M. Itarashi, 1 R. Heier, 1 H. Takagi, 1 M. Mukai, 1 S. Shimma, 1-2, S. Taira, 1 K. Hatanaka, 1-2, S. Morone, 1 M. Matsumoto, 1 Y. Yao, 1 P. Campbell, 1 S. Yuasa, 1 C. Janke, 2 G. MacGregor, 1 M. Setou, 2-4, MITLS, Machida, Japan, 2PRESTO, JST, Saitama, Japan, 3University of California, Irvine, Irvine, CA, 4NIPS, Okazaki, Japan, 5University of Tokyo, Tokyo, Japan, 6NIN, NCNP, Kodaira, Japan, 7CRBM, CNRS, Montpellier, France
Microtubules function as molecular tracks along which motor proteins transport cargo to appropriate destinations. In the nervous system, tubulins, pieces constructing microtubule, are highly polyglutamylated. Despite recent progress in the identification of tubulin polyglutamylases, the physiological significance of this post-translational modification has remained elusive. Here we demonstrate that polyglutamylation of α-tubulin is required for proper targeting of KIF1 into neurons and accounts for synaptic vesicle transport. ROSA22 mice lack functional PGCs1, a subunit of tubulin polyglutamylase. Loss of PGC1 function produced a striking and specific reduction in polyglutamyalted α-tubulin, which was normally enriched in neurons. Reduced α-tubulin polyglutamylation decreased the microtubule-binding affinity of muturotubulin-associated proteins including kinesins. In particular, KIF1A was reduced in neurons from ROSA22 mutants in

420
vitro and in vivo. The density of synaptic vesicles, a cargo of KIF1A, decreased in presynaptic compartments in the CA1 region of ROSA22 mutant hippocampus. Consistent with these findings, ROSA22 mutants showed more rapid depletion of synaptic vesicles than wild-type littermates. Our results provide the first evidence for a function of tubulin polyglutamylation in vivo; modulating synaptic transmission through regulation of trafficking of KIF1 kinesin and its cargo synaptic vesicles in neurons.

Interactions between EB1, Tubulin, and Microtubules: Implications for EB1 Function

K. K. Gupta,1 Z. Zha,2 E. S. Folker,2 S. B. Skube,1 H. V. Goodson1; 1Chemistry and Biochemistry, University of Notre Dame, Notre Dame, IN, 2Department of Anatomy and Cell Biology, Columbia University, New York, NY

EB1 and other plus-end tracking proteins (+TIPs) act at crucial interfaces between microtubules and other subcellular structures. While it seems clear that +TIPs regulate microtubule dynamics, their role in greater cell function remains obscure. EB1 is both an endogenous and conserved +TIP, and it binds to many other +TIPs. These observations suggest that EB1 is the core constituent of a +TIP network or "microtubule plus-end complex". To better understand the functions and activities of this network, we are investigating interactions between EB1, tubulin, and other +TIPs.

Two hypotheses have directed this work: 1) EB1 tracks by an end-loading mechanism driven by its having higher affinity for tubulin than for microtubules (Folker MBOC 15:256a 2004); 2) EB1 binds its own tail in an autoinhibitory conformation released by binding of the tail to partners such as CLIP-170 (Hayashi MolCell 19:449 2005). While many of our experiments are consistent with these ideas, others reveal additional complexity. First, removal of the EB1 C-terminal tail (the part involved in autoinhibition) significantly increases the apparent affinity of EB1 for microtubules. However, it does not interfere with EB1 plus-end tracking in vivo. These observations are difficult to reconcile with a straightforward end-loading mechanism. Second, the EB1 tail-minus mutant binds microtubules with surprisingly high stoichiometry (~4EB1/tubulin dimer). This suggests that EB1 has more than one binding site on tubulin, or that EB1 dimers self-associate. Moreover, CLIP-170 and the EB1 tail mutant (which lacks the CAP-GLY binding site) can bind microtubules simultaneously. We are working on models for interaction between EB1, tubulin, and other partners that are consistent with these data. In particular, we are investigating the possibility that EB1 can form higher-order structures influenced by tubulin and/or other +TIPs.

2295

Spatial Control of EB1 Dynamics during Neuron Polarization

D. Seetapun, D. J. Odde; Biomedical Engineering, University of Minnesota, Minneapolis, MN

Microtubule polarization requires the coordination of molecular processes to ultimately form axons and dendrites. Among these processes is the polarization of the microtubule array, since loss of dynamic microtubules (MTs) leads to polarization failure. Understanding the regulation of MT dynamics during neuron polarization is essential to understanding the control of axon specification. To investigate MT dynamics during neuron polarization, we performed time-lapse imaging of EGFP-EB1-transfected E7 embryonic chick forebrain neurons grown on polyethyleneimine-coated glass. These neurons undergo a stereotypical transition in vitro from having short, minor processes (stage 2) to having a single major process, the axon, along with a number of minor processes (stage 3), as observed for rat hippocampal neurons. Prior to axon specification (stage 2), we found that EGFP-EB1-tagged MT plus ends in minor processes (MPs) moved distally at a rate of 7.5 +/- 2.9 µm/min (N=56), similar to the rate observed in the cell body. After axon specification (stage 3), axonal Mts (AxMts) moved distally at a rate of 9.2 +/- 3.6 (N=70), again similar to the rate observed in the cell body. However, axonal growth cone MT plus ends (1.1 +/- 0.3 µm/min, N=12) and MPMT plus ends (6.8 +/- 3.41, N=47) moved significantly slower than AxMT and cell body MT plus ends. These preliminary results suggest that there is strong spatial control of MT plus end motion after axon initiation. Interestingly, axon elongation stages in 3 neurons were the same regardless of spatial location. This suggests that plus end polymerization was partially opposed by retrograde transport of Mts specifically in axonal growth cones and MPs, but not in the axon shaft or the cell body.

2296

The Importance of Tag Identity and Position on EB1 Behavior In Vivo

S. Skube, L. Chaverti, J. Goodson; Chemistry and Biochemistry, University of Notre Dame, Notre Dame, IN

In vivo studies are an integral part of investigating protein function and behavior. A common approach is to fuse proteins of interest to various tags that allow easier purification or detection. It is often assumed that the behavior of the tagged proteins reflects the behavior of the native protein, but this assumption can be problematic. For example, addition of a C-terminal GFP to EB1 inhibits proper binding to CLIP-170 (MBOC 16:533-2005) and interferes with CLIP-170 localization. As part of our studies of EB1 function, we have investigated the issue of EB1 tag identity and localization in more detail. We find that both N-terminal and C-terminal tags have significant effects on the behavior of EB1 and EB1 fragments. Moreover, larger tags (GFP) can have more significant effects than smaller tags (V5). For example, N-terminal tags significantly compromise the ability of expressed EB1/EB1 fragments to bind microtubules (MTs) and/or track MT plus ends. These constructs, like their C-terminally-tagged counterparts, also interfere with CLIP-170 localization, while untagged EB1 recruits CLIP-170 to MTs. As another example, N-GFP EB1-150kDa is cytosolic, while C-GFP EB1-350kDa and the untagged construct localize to mitochondria (the significance of this localization is unknown). These observations demonstrate that experiments performed using tagged EB1 constructs in vivo must be interpreted carefully. In addition to altering EB1 behavior, these tags interfere with CLIP-170 localization. Do they also interfere with localization of other EB1 binding proteins? These studies also raise concerns about the effects of tags on EB1 protein-protein interactions in vitro.

Regulation of Dynamics of Microtubule Plus End Binding Protein through Rho GTase Activity

C. L. Kilburn, R. Uhura, S. Gupoton, C. M. Waterman-Storer; Physiology Course, Marine Biological Laboratory, Woods Hole, MA

Microtubules establish polarity necessary for cell migration. (+)TIP proteins associate with growing microtubule plus ends and may help maintain polarity by modulating microtubule plus end assembly dynamics or localizing specific signaling molecules. These putative functions of (+)TIPs could be spatiotemporally regulated by their distribution on specific microtubules and their kinetics of microtubule association. The small Rho GTases are known to modulate microtubule assembly and stability in cells. Rac promotes microtubule growth to the leading edge by decreasing catastrophes, while Rhos promotes a stable subpopulation of microtubules. We sought to test the hypothesis that the distribution and microtubule affinity of the (+)TIPs, CLASP, EB1 and APC, are regulated by Rho GTase activity. We imaged GFP conjugates of these proteins in PTK1 epithelial cells by time-lapse microscopy and analyzed the kinetics of their interactions with microtubules using FRAP on a DeltaVisionRT Imaging System. As shown previously, Rac activation promoted (+)TIP behavior by CLASP. APC exhibits three behaviors in control cells, (+)TIP clusters, cortical clusters, and small clusters that move on the microtubules. Activation of Rac caused loss of cortical and (+)TIP clusters, and increased motile microtubule-associated clusters. EB1 localization was unaffected by Rac activity state; however, Rho activation promoted EB1 association with microtubule tips and Rho inhibition increased EB1 binding to microtubule lattice. FRAP experiments revealed that EB1 and EB1 were more stably associated with microtubules in cells expressing dominant negative or constitutively active Rac alleles, suggesting that Rho GTase cycling is critical for the dynamic association of these proteins with microtubule plus ends. Also, stability of EB1 and APC binding to microtubules was increased with constitutive Rho and Rac activity, respectively. Thus, Rho family GTPases modulate (+)TIP localization and microtubule affinity which may be critical to their role in cell polarization.

A New Role for Microtubule-plus-end Binding Protein EB1: Essential Participant in Skeletal Muscle Differentiation

T. Zhang1, K. J. M. Zaal1, G. G. Gundersen2, R. Uehara3, S. Gupton, C. M. Waterman-Storer; Physiology Course, Marine Biological Laboratory, Woods Hole, MA

Little is understood of the function or mechanism of the microtubule (MT) stabilization taking place during skeletal muscle differentiation. To investigate whether EB1 is involved, as it is in non-muscle cells, we first localized and quantified EB1 in the mouse muscle cell line C2 by immunofluorescence and immunoblotting. The typical EB1 rocket-like staining was found in both undifferentiated myoblasts and differentiated myofibers. Immunoblotting showed the expected 30 kDa band (EB1-30). An additional 20kDa band (EB1-20) appeared during differentiation and was the only other plus-end tracking protein in vivo, but was not found in fibroblasts. Overexpression of full-length EB1 had little effect but overexpression of the fragment EB1-C caused MT defects and formation of abnormally wide and short myotubes. We then silenced EB1 with different shRNA expression constructs. Compared with control cells, EB1-KD neither elongated nor fused. All indices of differentiation were suppressed or at least reduced: MT stabilization (appearance of Glu-MTs), expression of myogenin, p21, beta-catenin and cadherin, Golgi complex and centrosome reorganization. Interestingly, the inhibition of differentiation appeared preferentially linked to the disappearance of EB1-20. Reintroduction of wild-type EB1 led to partial rescue. Examination of cells that spontaneously reverted to an EB1-expressing phenotype in the EB1-KD suggested a cascade of events in which caderhin-catenin complex formation in the plasma membrane and MT stabilization in the cytoplasm happen at an early stage of muscle differentiation before myoblast elongation and fusion. We conclude that EB1 only plays a role in muscle MT stabilization but also is in fact indispensable for muscle differentiation, elongation and fusion. In addition, muscle seems to use two EB1 forms differentially.

2006 ASCB Annual Meeting Abstracts
EB3-mediated Microtubule Capture Is Required for Myoblast Elongation and Fusion

A. Straube,1 A. Merdes2; 1University of Edinburgh, Wellcome Trust Centre for Cell Biology, Edinburgh, United Kingdom; 2CNRS - Pierre Fabre, Toulouse, France

During muscle development, myoblasts undergo a series of biochemical and morphological changes that result in elongation and fusion into syncytial myotubes. This process is characterized by a complete remodeling of the cytoskeleton, but the underlying mechanisms are unknown. In this study, we focus on the role of microtubule plus-end binding proteins related to EB1. We demonstrate that expression of EB3, but not of other EB family members, increases during early differentiation of myoblasts, and that this protein is required for the regulation of microtubule dynamics at the cell cortex in differentiating myoblasts. Our data suggest that EB3-mediated microtubule capture is necessary to provide the cytoskeletal support for cell spreading, bipolar cell elongation and establishment of fusion competence. Expression of chimeric EB1/EB3 proteins on an EB3-depletion background indicates that EB3-specific functions are mediated by its amino-terminal calponin-like domain. We identified two amino acid changes between EB1 and EB3 that are essential for the myogenic function of EB3 and are exposed at the surface of the molecule opposite to the microtubule binding site. We therefore propose that an EB3-specific interacting protein mediates microtubule capture in differentiating myoblasts and we are currently in the process of isolating this factor. Our results suggest that EB3-mediated microtubule capture at the cell cortex is a crucial step during myogenic differentiation and might be a general mechanism in polarized cell elongation.

Identification of DDA3 as a Novel Microtubule Associated Protein That Interacts with EB3 and APC2

P. Hsieh, R. Chang, F. Wang; Institute of Biochemistry and Molecular Biology, National Yang-Ming University, Taipei, Taiwan

We have previously identified DDA3 as a novel mouse p53 transcriptional target. To explore the functional role of DDA3, we screened a mouse brain cDNA library by yeast two-hybrid assay, and identified EB1, a microtubule plus-end binding protein, as a DDA3 interacting protein. The mouse EB3 was cloned and shown to share 99% sequence homology with its human counterpart. Binding of DDA3 to EB3 was confirmed by GST pull-down assay, subcellular co-localization and co-immunoprecipitation, and the results indicated that the interaction of these two proteins within cells required intact microtubules. GST pull-down assay further mapped the domains of DDA3/EB3 interaction to amino acids (a.a.) 118-241 and 242-329 of DDA3 and the N- and C-termini of EB3. Immunofluorescence analysis showed co-localization of DDA3 with microtubules in various cell phases, and regions encompassing a.a. 118-241 and 242-329 contain microtubule-interacting and bundling activities. In vitro microtubule binding assay showed that DDA3 and EB3 associated directly to microtubules. In addition, DDA3 bound to the EB3 interacting partner APC2, a homologue of the tumor suppressor adenomatous polyposis coli (APC). By ectopic expression and suppression of endogenous DDA3 and EB3 levels in cells, we showed that the two proteins countered APC2 in the Wnt/TCF-dependent transactivation. Together our results indicate that DDA3 is a novel microtubule-associated protein that binds to EB3 and APC2, and suggest a role of DDA3 in the β-catenin-mediated pathway.

Adenomatous Polyposis Coli Is Phosphorylated during Early Stages of NGF Mediated PC12 Differentiation

H. Y. Caro-Gonzalez,1 W. J. Nelson,1,2 A. I. M. Barth;1 Molecular and Cellular Physiology, Stanford School of Medicine, Stanford, CA; 2Department of Biological Sciences, Stanford University, Stanford, CA

Adenomatous polyposis coli (APC) is a multifunctional protein that binds to microtubules (MT) and localize to clusters at sites of MT-cortex interactions during cell extensions in several cell types. APC localizes to tips of neurites and is needed for differentiation of rat pheochromocytoma (PC12) cells by nerve growth factor (NGF). APC function is in part regulated by glygogen synthase kinase 3β (GSK3β) activity, which increases APC’s affinity for β-catenin and decreases MT bundling. It has been shown that, during NGF signaling in fully polarized neurons, GSK3β activity is inhibited locally at the growth cone, which allows APC cluster formation at the leading edge and rapid axon extension. In order to understand how APC mediates neurite extension in response to NGF we are analyzing APC interactions during NGF induced neurite extension in PC12 cells. Here we show that APC is phosphorylated upon stimulation of PC12 cells with NGF. This phosphorylation correlates with the rapid formation of APC cortical clusters at cell extensions. This new phosphorylation seems to be GSK3β independent and independent of PI3K and MEK pathways. We are working on the characterization of this phosphorylation and its effects on MT dynamics.

Loss of the Adenomatous Polyposis Coli Protein Alters Cytoskeletal Organisation and Leads to Decreased Cell Migration

K. Kroboth,1 I. Newton,1 D. Dikovskaia,1 K. Kata,2 C. M. Waterman-Storer,2 I. S. Nähkä1; 1Cell & Developmental Biology, University of Dundee, Dundee, United Kingdom; 2Department of Cell Biology, Scripps Research Institute, La Jolla, CA

Truncation mutations in the adenomatous polyposis coli (APC) gene are common to most colorectal cancers. The APC protein supports the formation of a protein complex that controls the availability of β-catenin in a Wnt-regulated manner. β-catenin is crucial for cadherin-mediated cell-cell adhesion and also acts as a transcriptional regulator. In addition, APC regulates cytoskeletal proteins. It binds to microtubules directly and indirectly and also interacts with proteins that regulate F-actin dynamics. Truncation mutations of APC in tumours lack binding sites for cytoskeletal components suggesting that loss of these interactions also contribute to defects in APC-mutant cells. In this study we show that loss of APC results in decreased cell migration. This effect correlates with the disappearance of cellular protrusions and a reduction in microtubule stability that is accompanied by changes in post-translationally modified microtubules. Correspondingly, overexpression of APC induces the formation of cellular protrusions. Direct binding to microtubules, but not binding of EB1, determines the effect of APC on microtubule stability and also governs the dynamics of this interaction. Surprisingly, the ability of APC to stabilise microtubules is not required for APC-induced cell shape changes, highlighting the importance of APC interaction with other cytoskeletal proteins. Our data demonstrate that cell migration and microtubule stability are linked to APC status and reveal a weakness in APC-deficient cells with potential therapeutic implications.

Aneugenic Activity of Op18/stathmin Is Potentiated by the Somatic Q18->E Mutation in Leukemic Cells

P. Holmfeldt, K. Brännström, S. Stenmark, M. Gullberg; Molecular Biology, Umea University, Umea, Sweden

Op18/stathmin (Op18) is a phosphorylation-regulated microtubule destabilizer that is frequently overexpressed in tumors. The importance of Op18 in malignancy was recently suggested by identification of a somatic Q18->E mutation of Op18 in an adencarcinoma. We addressed the functional consequences of aberrant Op18 expression in leukemias by analyzing the cell cycle of K562 cells either depleted of Op18 by expression of interfering hairpin RNA or induced to express wild-type or Q18E substituted Op18. We show here that although Op18 depletion decreases microtubule density during interphase, the density of mitotic spindles is essentially unaltered and cells divide normally. This is consistent with phosphorylation-inactivation of Op18 during mitosis. Overexpression of wild-type Op18 results in aneugenic activities, manifest as aberrant mitosis, polyploidization, and chromosome loss. One particularly significant finding was that the aneugenic activity of Op18 was dramatically altered by the Q18->E mutation. The hyperactivity of mutant Op18 is apparent in its unphosphorylated state, and this mutation also suppresses phosphorylation-inactivation of the microtubule-destabilizing activity of Op18 without any apparent effect on its phosphorylation status. Thus, although Op18 is dispensable for mitosis, the hyperactive Q18->E mutant, or overexpressed wild-type Op18, exerts aneugenic effects that are likely to contribute to chromosomal instability in tumors.

Effect of Stathmin and MAP4 Expression in Breast Cancer Cells

V. E. Cucchiarielli,1 L. Hiser,1 J. J. Correia,1 S. Lobert1; 1Department of Biochemistry, University of Mississippi Medical Center, Jackson, MS; 2School of Nursing, University of Mississippi Medical Center, Jackson, MS

The efficacy of anticancer therapy is limited by drug resistance. Stathmin and MAP4 are known to influence microtubule dynamics and may play an important role in determining the sensitivity to the antimotic agents, taxanes and vinca alkaloids. p53 is thought to regulate the expression of stathmin and MAP4. Therefore, alterations in p53 expression might lead to resistance to tubulin-binding agents. We evaluated the effects of the absence of p53 on the cellular response to these drugs. The response to taxol and vinblastine was determined by IC50 measurements in two cell lines: MCF-7 SC expressing wild type p53 and MCF-7 KD or p53 knock down cells (derived from the human breast adenocarcinoma MCF-7 cells). We found that MCF-7 KD cells are 20% more sensitive to taxol as compared with MCF-7 SC cells; while no significant difference in response to vinblastine was observed, mRNA expression of stathmin and MAP4 was measured by q-real time RT-PCR before and after treatment with taxol. Contrary to expectations, stathmin and MAP4 mRNA levels were lower in MCF-7 KD cells, suggesting that...
in this system, p53 is an activator of statmin and MAP4 genes, or that other factors that regulate statmin and MAP4 expression have been altered by p53 knockdown. The lower level of statmin mRNA in p53 knock down cells is consistent with their increased sensitivity to taxol. Upon treatment with their correspondent taxol IC50 concentrations, we found a decrease in statmin mRNA levels. These data suggest p53 regulation of statmin and MAP4 may be altered by taxol. The same experiments are being carried out with cells treated with vinblastine.

Effects of Tau Pseudophosphorylation at Residues Ser262, Ser396, and Ser404 upon Microtubule Binding, Assembly, and Regulation of Dynamic Instability In Vitro

E. Kiris, M. R. Massie, M. A. Jordan, L. Wilson, S. C. Feinstein; Neuroscience Research Institute, University of California, Santa Barbara, CA

Tau is a neural specific microtubule-associated phospho-protein that is crucial for the proper development and maintenance of the nervous system. Mechanistically, it is well established that tau binds directly to microtubules, promotes microtubule assembly and regulates microtubule dynamic instability. Given that microtubules are central to many neural cell functions, it is not surprising that abnormal tau behavior has long been associated with numerous neurodegenerative diseases, including Alzheimer’s disease and related dementias; further, a large body of biochemical and genetic data implicate abnormal tau phosphorylation in pathological tau action. One technical strategy that has become widely used to overcome a variety of technical difficulties in studying protein phosphorylation is “pseudophosphorylation”, that is, the substitution of aspartic or glutamic acid residues to mimic phosphorylated serine, threonine or tyrosine. Here, we have used pseudophosphorylation to study the mechanistic effects of phosphorylation at three key phosphorylation sites in tau (ser262, ser396 and ser404). We assessed the effects of each individual pseudophosphorylation event upon the ability of tau to bind and assemble microtubules as well as to regulate microtubule dynamic instability. Consistent with a variety of cellular studies, pseudophosphorylation at ser404 has little effect on tau action in either 3-repeat or 4-repeat contexts. Alternatively, pseudophosphorylation at ser262 compromises the ability of tau to bind to microtubules at steady state by up to 2 fold in both 3-repeat and 4-repeat tau contexts. Finally, pseudophosphorylation at ser396 significantly compromises tau binding activity in 4-repeat but not 3-repeat tau. Ongoing studies of the ability of each molecule, as well as molecules harboring multiple pseudophosphorylated sites, to affect the ability of tau to assemble microtubules and to regulate microtubule dynamic instability should provide valuable insights into mechanisms of normal and pathological tau action. (Supported by NIH grants R01NS035010, R01NS13370 and R01CA57291)

Tau Impacts on Src-mediated Actin Remodeling

V. Sharma; Internal Medicine, University of Iowa, Iowa City, IA

Tau, the primary component of neurofibrillary tangles in Alzheimer’s disease, is now known to have functions beyond microtubule (MT) association. We have previously shown that tau interacts with the SH3 domain of Src family kinases (SFKs), non-receptor protein tyrosine kinases that regulate several biological functions, including cell cycle and growth factor signaling. A potential consequence of SH3 interaction is the upregulation of the tyrosine kinase activity. Here we investigate the activation of Src and Fyn by tau, both in vitro and in vivo. The presence of tau increased the tyrosine phosphorylation of tubulin by Fyn in in vitro assays and in transfected COS7 cells. Tau also upregulated the activity of Src in a kinase assay. In fibroblasts, Src is known to be activated by PDGF, leading to a dramatic reorganization of the actin cytoskeleton. We found that tau appeared to prime Src for activation following PDGF stimulation, as reflected by changes in Src-mediated actin remodeling. While majority of the non-transformed cells recovered actin stress fibers by 7h following PDGF stimulation, tau-expressing cells showed a sustained actin fiber breakdown, suggesting a sustained activation of Src kinase activity. MT stabilizing function of tau appeared not to be involved in this effect. The spatial localization of activated SFKs was also altered by the presence of tau. Results obtained by inhibiting SFK activity with a pharmacologic inhibitor, or by using a tau deficient mutant in Src interaction, implicated SFKs as mediators of the effect of tau on actin organization. Our results provide evidence that the interaction of tau with SFKs upregulates the tyrosine kinase activity. This interaction would be relevant during cytoskeletal reorganization in neuronal differentiation, and also in AD where aberrant activation of cell cycle mechanisms has been implicated.

Centrioles Are Essential for Ciliogenesis and Meiosis, but Not Mitosis and Fly Development

S. Blachon, J. Gopalakrishnan, A. Polyanovsky, T. Avidor-Reiss; 1Harvard Medical School, Boston, MA, 2Sechenov Institute, Russian Academy of Sciences, Petersburg, Russian Federation, 3Howard Hughes Medical Institute and University of California, San Diego, CA

The centriole has a dichotomous role in eukaryotic cell biology. During mitosis, as a component of the centrosome it radiates astral microtubules, while in interphase it becomes a basal body to the cell cilium. In Drosophila melanogaster, all cells have centrioles, however, centrioles are transformed to basal body only in sensory neurons and in male germ line. These basal bodies participate in the formation of motile and mechanosensory cilia as well as in male meiosis. To study basal body formation, we screened for the mutations that generate adult flies showing a characteristic proprioception phenotype of ciliary mutants, having immotile sperm flagellum and unable to carry out meiosis. We find three mutants in different genes that neither have basal bodies nor cilia. To study the failure to generate basal bodies, we have examined the centrioles in these mutants. Surprisingly, these mutants have either abnormal or no centrioles. These findings demonstrate that centrioles are not required for fly development but are essential for ciliogenesis. The proteins encoded by the candidate genes are localized specifically to the centriole and basal body, showing a distinct spatial and temporal localization and suggesting that they have indispensable role in different processes during centriole formation.

Identification of Basal Body Proteins That Interact with Delta and Epsilon Tubulin

S. K. Dutcher, L. Li, T. H. Giddings; 1Genetics, Washington University School of Medicine, St. Louis, MO, 2MCD Biology, University of Colorado, Boulder, CO

We employed a yeast two-hybrid screen to identify novel interaction partners of Bardet Biedl Syndrome Protein, Bbs5, for β-tubulin and two genes that interact only with β-tubulin. The first group includes translation initiation factor 3, several kinases, and five novel proteins. The β-tubulin interacting class contains a AMP phosphodiesterase, a DNA I motif containing protein, and a novel protein. The β-tubulin interacting class contains a RuvB-like protein and a novel protein. The novel protein encoded by STP1, which interacts with δ-tubulin, is found in all ciliated organisms. It localizes to the basal body region by immunofluorescence. Two independent RNAi strain have morphologically normal basal bodies, but assemble very short (< 0.5 μm) flagella when the protein amount is reduced. The basal body localization of Stip1 requires the presence of δ-tubulin; it is not localized in the δ-tubulin mutant, χm3-1. However, δ-tubulin is localized properly in the Stip1 RNAi strains. RuvBII is found in all eukaryotic organisms and is involved in chromatin remodeling and transcription complexes (Bellonta et al., 2005). In Chlamydomonas, RuvBII localizes to the basal body region and to the nucleus by immunofluorescence, but localizes only to the nucleus upon deflagellation. The gene is transcriptionally upregulated by deflagellation (6x-fold) as is RuvBII or pontin (5x-fold). Its localization is dependent on fully assembled basal bodies as it is not localized in a number of mutants (bd2, bd10, bd11). RNA interference studies are underway to examine the hypomorphic phenotype.

Bardet Biedl Syndrome Protein, Bbs5, for Tetrahymena Basal Body and Ciliary Function

C. G. Pearson, T. H. Giddings, M. Winey; MCDB, CU at Boulder, Boulder, CO

Human BBS5 gene mutations cause Bardet Biedl Syndrome (BBS), a disease characterized by retinal dystrophy, renal abnormalities, obesity, polydactyly, and other maladies. These phenotypes are likely associated with centriole, basal body and or/ciliary abnormalities. Loss of Bbs5 results in flagellate cells (Li et al, 2004), however, the functional role of Bbs5 in basal body and ciliary function is not understood. We have identified the Tetrahymena ortholog of the human BBS5 gene. The single BBS5 gene (TTBBS5) encodes a ~41 kDa protein with two conserved DM16 domains. Tetrahymena TTBBS5 tagged with GFP localizes at basal bodies. GFP-Bbs5 fluorescence was found along cortical rows in live cells and co-localized with the basal body marker centrin. Preliminary immuno-electron microscopy cross-section studies find GFP-Bbs5 at the lumen of the basal body, implicating this protein in early basal body duplication and assembly. We introduced into Tetrahymena several mutant alleles of GFP-bbs5 that mimic human disease mutations. In addition to elucidating human mutations that alter GFP-Bbs5 localization, we have identified TTBBS5 as a candidate for a Tetrahymena mutant that indicates that TTBBS5 is essential and protein depletion alters cellular motility and division, as expected for ciliary dysfunction. These studies further develop Tetrahymena as a model system for functional understanding of basal body and ciliary disease in human implication.
A Prefoldin-like Protein Provides a Link between the Core BBSome and the Chaperonin-like Proteins BBS6 and BBS10
A. V. Loktev,1 2 F. Bazan,3 D. Y. Nishimura,3 J. S. Beck,4 Q. Zhang,4 D. C. Slusarski,4 V. C. Sheffield,5 P. K. Jackson,3 2 M. V. Nachury3, 1 Department of Tumor Biology and Angiogenesis, Genentech, South San Francisco, CA, 2Department of Pediatrics and Howard Hughes Medical Institute, University of Iowa, Iowa City, IA, 3Department of Protein Engineering, Genentech, South San Francisco, CA, 4Department of Pathology and Stanford University School of Medicine, Stanford, CA, 5Department of Biological Sciences, University of Iowa, Iowa City, IA

Bardet-Biedl syndrome (BBS) is a pleiotropic disorder affecting retina, kidneys and body weight regulation. We have recently shown that seven of the eleven known BBS proteins are present in a highly conserved 450 kDa complex, which we named BBSome. Outside of the BBSome subunits, BBS6 and BBS10 stand out as type II chaperonin-like proteins present only in vertebrates, suggesting a link between BBS and protein folding. Yet, all evidence so far points to a role for the BBSome in membrane trafficking to and inside the primary cilium. We have now discovered stoichiometric amounts of a 10 kDa polyethylene (BBIP10) associated with the core BBSome. Bbip10 show an arrangement characteristic of prefoldins, a group of chaperones involved in transferring unfolded polypeptides to the canonical type II chaperonin complex. Like all other BBSome subunits, BBIP10 is conserved in ciliated organisms and is absent from plant genomes, thereby implicating BBIP10 in cilium function. This association is further highlighted by genome wide expression correlation data in the mouse eye showing that BBIP10 is better correlated to known BBS genes than 99.98% of all genes. Finally, we turned to the zebrafish system for functional validation. Loss of function of BBIP10 leads to malformations of the ciliated Kupffer’s vesicle, left-right asymmetry perturbations and defects in melanosome movement. The same defects were found upon depletion of BBP10, implying that BBP10 functions in the same molecular pathway as known BBS genes. In summary, we have found a novel prefoldin-like subunit of the BBSome that may provide a link to the cilia-chaperonin-like BBS proteins. A future challenge will be to identify and characterize the critical substrates of this novel folding pathway in order to uncover the missing link between BBS proteins and the variety of symptoms affecting BBS patients.

Tetrahymena thermophila Possesses Two SAS-6 Homologs That Function at Basal Bodies
B. P. Culver, T. Giddings, M. Winey; MCB, University of Colorado, Boulder, CO

Tetrahymena thermophila possesses two SAS-6 homologs that function at basal body Centrioles are a functionally and morphologically conserved organelle throughout most of the eukaryotic kingdom. SAS-6 was previously shown to be required for centriole duplication in C. elegans as well as in human cells (1,2). We have identified two SAS-6 homologs in ciliated protozoan Tetrahymena thermophila. We refer to these genes as SAS-6 like protein 1 and 2 (Sip1 and Slp2). While Tetrahymena do not possess centrosomes and associated centrioles, they do possess in abundance morphologically and compositionally similar basal bodies. Our study seeks to define a role for Slp1 and Slp2 at the basal body. We have found that both genes are expressed in dividing cells and that their GFP-tagged gene products localize to basal bodies. Slp1 and Slp2 like their homologs in other organisms have two identifiable motifs: a N-terminally located PISA domain and a centrally located coiled-coil domain (1, 2). We have shown that GFP-tagged truncations possessing the PISA domain localize to basal bodies. It therefore seems likely that the dividing cells and that their GFP-tagged gene products localize to basal bodies. Slp1 and Slp2 like their homologs in other organisms have two identifiable motifs: a N-terminally located PISA domain and a centrally located coiled-coil domain (1, 2). We have shown that GFP-tagged truncations possessing the PISA domain localize to basal bodies. It therefore seems likely that the presence of the PISA domain is sufficient for the localization of Slp1. References: 1. A Sea Urchin Sperm Flagellar Adenylate Kinase with Triplicated Catalytic Domains
M. Kimukawa,1 2 M. Nomura, 1 V. D. Vacquier; 1 Center for Marine Biotechnology and Biomedicine, Scripps Institution of Oceanography, University of California San Diego, La Jolla, CA, 2Shimoda Marine Research Center, University of Tsukuba, Shimoda, Japan

The mitochondrion of sea urchin sperm is located at the base of the sperm head and the flagellum extends from the mitochondrion for ~40 μm. These sperm have two known flagellar, non-mitochondrial enzymatic systems to phosphorylate ADP. The first involves the phosphocreatine shuttle, where flagellar creatine kinase (Sp-CK) produces phosphocreatine to rephosphorylate ADP. The second system, studied in this paper, is adenylate kinase (Sp-AK) that uses 2 ADP to make ATP + AMP. Cloning of Sp-AK shows that, like Sp-CK, Sp-AK has three catalytic domains. Sp-AK localizes along the entire flagellum and most of it is tightly bound to the axoneme. After solubilization from the axoneme by dialysis against EDTA buffer and sedimentation by sucrose density centrifugation, the characteristics of Sp-AK were studied. The Km of Sp-AK in the direction of ATP synthesis is 0.9 mM and the Vmax 16.6 μmol ATP formed/mg protein/min. The Sp-AK activity is uniform between phi 6-9. The specific Sp-AK inhibitor Ap5A, blocks enzyme activity with an IC50 of 0.41 μM. Flagellar motility was studied using deuterated spermidine and protein. In 1 mM ADP, flagella reactive motility in 5 min; 1 μM Ap5A completely inhibits this reactivation. No inhibition of motility occurs in Ap5A when 1 mM ATP is added to the reactivation buffer. Under in vitro conditions, when both enzymes are saturated with ADP as substrate, Sp-CK contributes ~60%, and Sp-AK ~40%, of all non-mitochondrial ATP synthesis in isolated flagella. However, under in vivo conditions the role of Sp-AK in ATP regeneration to support motility is questionable. An alternative hypothesis is that Sp-AK could be involved in removal of ADP, which is a potent inhibitor of dynein ATPase.

To Maintain Motility, the Na,K-ATPase Alpha4 Isomorf Is Necessary for Extruding from Sperm Intracellular Protons Leaking from Metabolically Active Mitochondria
A. Sengupta, S. Chakraborty, P. F. James; Zoology, Miami University, Oxford, OH

The Na,K-ATPase is a major ion transport protein found in higher eukaryotic cells that establishes and maintains electrochemical gradients across the plasma membrane by transporting three Na+ out of the cell and two K+ into the cell using the energy generated from the hydrolysis of ATP. The activity of the Na,K-ATPase is essential for establishing resting membrane potential and to support the activity of other membrane transporters which move other solutes into or out of the cell. Of the four known alpha isoforms of the Na,K-ATPase, only two, the ubiquitously expressed alpha1 isoform and the sperm-specific alpha4 isoforms, are expressed in sperm. Specific inhibition of the alpha4 isoform inhibits rat sperm motility suggesting a specialized role for this Na,K-ATPase isoform in maintaining sperm motility. Here we demonstrate, by alkalining the sperm cytoplasm with NHSI, that loss of sperm motility mediated by inhibition of the Na,K-ATPase alpha4 isomorf is due to acidification of sperm cytoplasm. In addition, we identify the mitochondria as the source of protons which accumulate during Na,K-ATPase alpha4 isoform inhibition; inhibition of H+ transport by the electron transport system with KCN or Antimycin A eliminates the necessity for the Na,K-ATPase alpha4-dependant pH regulatory mechanism to maintain sperm motility. This data demonstrates that the Na,K-ATPase alpha4-dependant pH regulatory mechanism is only required to support sperm motility in presence of metabolically active mitochondria.

Characterization of the Guanylate Cyclase in Cilia of Tetrahymena thermophila
C. A. Clement,1 2 C. F. Guerra,1 A. Awu, 1 2 A. Bell,3 P. Saiti,3 S. T. Christensen3; 1 BKA, Institute of Molecular Biology and Physiology, Copenhagen, Denmark, 2Albert Einstein College of Medicine, Bronx, NY

The cGMP production in the motile cilia/flagella in Tetrahymena thermophila may play an important role in regulating cilary beat frequency (CBF) and/or function in signal transduction systems that regulate cell survival and proliferation. We have studied the mRNA up-regulation and localization of the membrane bound cGMP-generating enzyme, guanylate cyclase (GC) in T. thermophila and further investigated possible interactions with GC and the IFT raft protein, IFT139, and kin 5, which is a homodimeric kinase-2-family IFT-motor protein. With RT-PCR technique we initially conducted an analysis of whether 14 putative GC genes in the Tetrahymena database are activated after deciliation. These results showed that three of these genes were up-regulated as a result of deciliation, suggesting that these genes encode GC’s that localize to the cilium. By immunofluorescence (IF) microscopy using an antibody directed against a conserved region of GC, we show that GC strongly and preferentially localized to the cilia in T. thermophila and in a punctate pattern along the entire length of the cilium. GC quickly localized to regenerating cilia in cells after deciliation. To investigate how GC is transported into the cilium in T. thermophila, we conducted co-immunoprecipitation experiments that showed that GC colocalized with IFT139 along the cilium. They structure support the conclusion that transport of GC into the cilary membrane of T. thermophila is via IFT utilizing the homodimeric kinase kin5.

Katanin Is Required for Assembly of Motile Cilia
N. Sharma, J. Bryant, D. Wogha, J. Gaertig; Cellular Biology, University of Georgia, Athens, GA

The cilia Tetr hymena thermophila has two genes encoding a catalytic subunit of the microtubule-severing protein, katanin (p60), KAT1 and KAT2, and one gene encoding a noncatalytic subunit of katanin (p80), KAT3. Using the “knockout heterokaryon” strategy, we produced gene disruption mutants at all these loci. Cells lacking either KAT1 (p60) or KAT3 (p80) were
immotile and displayed an arrest in cytokinesis, while cells lacking KAT2 appeared normal. Cells lacking Kat1p showed an increase in the microtubule content and accumulated stable hyperacetylated microtubules in the cell body. The cytokinesis arrest appeared to be caused by abnormally long cortical microtubules, which impeded the ingressing cleavage furrow. Thus, in the cell body, the phenotype of katanin deficiency is consistent with lack of microtubule severing activity. Moreover, overproduction of Kat1p led to depolymerization of most microtubules including some ciliary doublets. Ultrastructural analyses of KAT1−/− and Kat2−/− null cells revealed severe defects in cilium biogenesis. The basal bodies formed normally, but either remained uniliated or had only an excessively short immotile cilium and only 9+0 microtubules. GFP-Kat1p localized to cortical microtubules and basal bodies. Together with an earlier demonstration that the p80 subunit is needed for the central pair assembly in Chlamydomonas (Dymek and Smith, Eukaryot. Cell, 3, 2004), these results show that the catalytic activity of katanin is required for assembly of motile cilia. We propose that katanin assists in the assembly of cilia by generating ciliary tubulin precursors via severing of preexisting MTs inside the cell body. Importantly, the phenotype of katanin mutants is identical to the phenotype of a beta-tubulin mutant lacking sites of so-called polymodifications (glutamylation and glycylation). We suggest that katanin preferentially severs polymodified tubulins.

Protein Families of the Trypanosome Flagellum

N. Portman, H. Dawe, H. Farr, A. Baines, M. Ginger, K. Gull; Sir William Dunn School of Pathology, University of Oxford, Oxford, United Kingdom
We have recently produced a detergent and salt-extracted proteome for the Trypansomoa brucei flagellum. Bioinformatic investigation of the evolutionary distribution of these proteins reveals that a number of proteins encoded by a single gene in other eukaryotes exist as extended gene families in T. brucei and other kinetoplastids. Several known flagellar components such as RIB72, PACRG, PF2; Trypanin, Ectoin and MBO2 are members of small gene families in T. brucei, as well as hypothetical proteins such as DIGIT, AKR, TFI, and TAX-2 for which we have produced phenotype information. Family members are often found on different chromosomes with no conservation of flanking gene order, suggesting ancient gene duplications and subsequent divergence. We have analysed each family in terms of its domain architecture, localisation, and RNAi phenotype. In some families simultaneous RNAi ablation of multiple family members is required to produce a visible phenotype whereas ablation of a single member is sufficient in others, indicating that a requirement for functional redundancy cannot fully explain this phenomenon. We suggest that the lack of alternative splicing and introns in this extracellular parasite may favour gene duplication as a means of achieving protein diversity.

Identification of Novel Ciliary Proteins Using Microarray Data of In Vitro Ciliogenesis

A. Kubo,1 A. Kubo,2 S. Tsukita,3 S. Tsukita4; 1Dermatology, Keio University School of Medicine, Tokyo, Japan, 2Solution Oriented Research for Science and Technology, Japan Science and Technology Corporation, Tokyo, Japan, 3Cell Biology, Kyoto University Faculty of Medicine, Kyoto, Japan, 4School of Health Sciences, Kyoto University Faculty of Medicine, Kyoto, Japan
To identify the factors required for the formation of ciliary epithelial cells, we analyze the gene expression patterns during ciliogenesis in the mouse tracheal epithelial cells cultured in vitro. Our previous work identified the PC1-2 protein as a component of fibrous granules appeared in the beginning of ciliogenesis. In the course of ciliogenesis, the expression of ciliary precursor proteins, including PC1-2, is elevated first followed by the expression of basal body proteins and axonemal proteins sequentially. We identified two novel proteins in this study. One shows the expression pattern of axonemal proteins and localizes to the so-called ‘lateral spokes’ at the tip of motile cilia. Its expression is restricted to the organ that has motile cilia. The other shows the expression pattern of ciliary precursor proteins and localizes at the basal bodies and the fibrous granules. We named this protein PCM-2. PCM-2 is a ubiquitously expressed coiled-coil protein with a molecular mass of ~80 kD and co-localized with the cilidional satellites protein PC1-2 and the centrosome protein γ-tubulin in U2OS cells. HA-tagged full length PCM-2 localizes to the centrosome in the interphase. Interestingly, the centrosome localization of full length PCM-2 is observed only in ~20% of transfected cells at 24h post transfection, probably via cell cycle dependent integration of PCM-2 to the centrosome. The amino-terminal domain of PCM-2 binds to PCM-1, and the carboxy-terminal domain mediates centrosome attachment. Further characterization of PCM-2 is underway to determine the function of PCM-2 in ciliogenesis and ciliogenesis.

Nek1 Affects Stability of Centrioles and Cilia

M. C. White, L. M. Quarmby; Molecular Biology and Biochemistry, Simon Fraser University, Burnaby, BC, Canada
Mutations in Nek1 (NIMA-Related Expressed Kinase 1) have been identified as causal in the murine models of polycystic kidney disease katu and katu (Kidney Anemia Testis). Nek1 has proposed roles in the DNA damage response pathway and in chromosome condensation. Endogenous Nek1 is cytoplasmic and localizes to multiple spots adjacent to the centrosomes, however expression of carboxy-terminal truncations of Nek1 accumulate in the nucleus. The mechanisms and cellular significance of nuclear import and export of Nek1 remain poorly characterized. Here, we demonstrate that full-length Nek1 is cytoplasmic, but probably cycles through the nucleus. We have identified a repressive, leptomycin-B-sensitive, carboxy-terminal Nuclear Export Sequence (NES), and more than one sufficient Nuclear Localization Signal (NLS). Overexpression of truncated, eGFP-tagged mNek1 that lacks the NES region but retains the NLSs (residues 1-686) results in a depletion of γ-tubulin foci from the centrosome, and the loss of the primary cilia in the murine kidney epithelial cell line IMCD3. Expression of residues 1-686 of the putative kinase-dead mutant K33R does not deplete γ-tubulin foci or disrupt ciliogenesis. Furthermore, the truncated K33R protein localizes to the primary cilium, the centrosomes and the nucleus. The central coiled-coil domain of mNek1 is sufficient for localization to the primary cilium. To determine the domains sufficient for the disruption of γ-tubulin foci in wild-type, and primary cilium localization in the K33R mutant, we constructed eGFP-tagged truncations of mNek1 removing each of the four central coiled-coils. Coiled-coils 3 and 4 were dispensable for both these effects, whereas coiled-coils 1 and 2 were necessary. We propose that Nek1 has several kinase-depending activities related to the primary cilium and the centrosomes and that these activities are inhibited by the presence of Nek1’s carboxy-terminal domain which also inhibits nuclear accumulation of Nek1. This work is funded by a KFO6 operating grant to LMQ.

Extensive Polyglycylation of Tubulin Is Not Essential for Cilia Function in Mammals

S. J. Y. Dosso, R. Hallworth, Biomedical Sciences, Creighton University, Omaha, NE, USA
Glycopolymodification is a posttranslational modification that is unique to the alpha and beta subunits of tubulin in the microtubules of cilia and flagella. It has been shown that polyglycylation of tubulin in the cilia of tetrahymena contributes to cilary function and the loss of polyglycylation in beta-tubulin may result in lethality. However, the full effects and significance of polyglycylation are still unknown. We have explored the extent of polyglycylation in functional cilia of mouse tracheal epithelial cell cultures using two antibodies, TAP 952 and ANO 49, which are specific for minimal and extensive polyglycylation, respectively. We have found that although minimal polyglycylation was present along most of the cilia length, it was excluded from the tip. In contrast, little to no extensive polyglycylation occurred in our cultures at any stage. This suggests that while some glycylation is universal in mammalian cilia, extensive polyglycylation is not required for function. Supported by RR17417-01 to Creighton University and NSF-EPSCoR EPS-0346476 to RH. We thank Marie-Helene Bre for the gift of antibodies.

A Functional Component Analysis of Flagellar Motility in African Trypanosomes

P. W. Collingridge,1 E. M. Barnwell,2 N. Portman,3 M. K. Shaw,4 P. G. Mceean,1 K. Gull,4 M. L. Ginger1; 1Sir William Dunn School of Pathology, University of Oxford, Oxford, United Kingdom, 2Department of Biological Sciences, Lancaster University, Lancaster, United Kingdom, 3Department of Genetics, University of Cambridge, Cambridge, United Kingdom, 4Department of Biological Sciences, University of Oxford, Oxford, United Kingdom
We have used RNA interference (RNAi) and epitope-tagging strategies to interrogate the regulation of motility in Trypanosoma brucei. Based upon likely carbon source availability in the environments occupied by trypanosomes we have argued that intraflagellar energy homeostasis is maintained by flagellar adenylate kinase activity (J.Biol.Chem. 280:11781-9). Here, we show the presence of an axonemal trypanosome-specific glyceraldehyde-3-phosphate dehydrogenase (GAPDH)-like protein. The protein is unlikely to be catalytically active and we speculate that its presence in the trypanosomal structural flagellum is a reminder of when glycolysis could have been an intraflagellar pathway in the free-living flagellate ancestor from which the parasitic trypanosome lineage diverged. We argue that an important role for this gene is likely to play an important role regulating trypanosome motility, and provide new insight into the complexity and control of flagellar motility through the molecular characterisation of two novel trypanosome axonemal adenylate kinase-related (AKR) proteins. We show these proteins are important for motility and, moreover, form part of a flagellate-specific super-family containing unusually structured adenylate kinases and several classes of AKR protein. We suggest the trypanosome AKR proteins evolved following fusion of an adenylate kinase and a nucleoside diphosphate sugar epimerase. Although homologs are present in evolutionarily diverse taxa, no homology of the trypanosome AKR proteins is present in Chlamydomonas, but intriguingly other members of the AKR super-family are present and important for motility. In general, the phylogenetic distribution of AKR proteins supports a hypothesis that the trypanosome AKR proteins (and homologs in other flagellates) play a role in central pair dependent regulation of dynein arm activity. Using the ultrastructural phenotypes that arise following RNAi against various flagellar proteins (including radial spoke and outer arm docking complex components) for comparison, we provide arguments for both structural (passive) or regulatory (direct) roles for trypanosome AKR proteins in the control of flagellar motility.

Comparison of Motility in Primate Sperm Using Optical Tweezers
J. Nascimento, L. Shi, E. Botvinick, S. Meyers, P. Gagneux, M. Berns, 1, 2 Bioengineering, University of California, San Diego, La Jolla, CA, 3Anatomy, Physiology, and Cell Biology, University of California, Davis, CA, 4Glycobiology Research and Training Center, University of California, San Diego, La Jolla, CA, 5Beckman Laser Institute and Medical Clinic, University of California, Irvine, Irvine, CA

Laser tweezers have been used to trap sperm cells, determine their swimming forces, and relate these forces to sperm curvilinear swimming velocity, VCL (swimming force increases with VCL). After trapping a sperm, laser power is reduced using a polarizer until the sperm is capable of escape (escape power, Pesc, and VCL are recorded). Sperm from Rhesus macaques, whose mating system is multimale-multifemale, are found to be on average both the fastest (86.1 µm/sec) and strongest (93.2 µmN). Sperm from western lowland gorillas, known to be strictly monogamous, are found to be on average the slowest (23.5 µm/sec) and weakest (4.6 µN). Sperm from human males, considered from an evolutionary viewpoint to be at neither extreme, lie between the two other species (52.5 µm/sec, 16.5 µN). The VCL and Pesc distributions for each species are statistically different (P < 0.005). It is also found that the linear regression applied to the scatter plot of Pesc vs. VCL for human sperm is statistically the same as that for gorilla (t > 1.96). Both of these regressions are statistically different than that for Rhesus macaque (t > 1.96). These findings support the theory that primary sperm from multimale-multifemale mating systems compete within the female tract. Such high evolutionary pressures would lead to sperm that swim stronger and faster than sperm from monogamous primates.

Empirical Model of the Ciliary Waveform of Human Airway Epithelium Developed Using Video Microscopy
P. R. Sears, K. Thompson, C. Davis, Cystic Fibrosis Center, University of North Carolina, Chapel Hill, Chapel Hill, NC

Mechanical models of ciliary motion are validated by their ability to reproduce true ciliary waveforms. However, there is currently no empirical model of the ciliary waveform. Of particular interest are cilia beating in epithelial sheets where they are difficult to visualize. An empirical model was developed that parameterizes the ciliary shapes using two Gaussian functions to define the curvature. The waveform is constructed by visualizing the model superimposed on slowed videos of beating cilia and using 15 smoothed parameter sets that span one cycle. To acquire videos of beating cilia, cultures of human bronchial and nasal epithelial cells were wrapped around a #1 coverglass, placed between two coverglasses, and viewed in profile using a 60x oil objective (NA 1.4) fitted with a Bioptechs objective heater. The waveform was recorded using a Megaplus ES-310T camera at 250 frames per second. The ciliary waveforms were ranked according to their parameter values and the median waveform was used to calculate internal displacements. The displacement of the dyneins along B-tubules was determined for all dyneins over the entire cycle. Dynein displacement at the tip is 18 nm across tubelet sets 7-8 at the end effective stroke when the integrated curvature is greatest. But the central portion of the cilium, where the displacement relative to the base is similar to that at the tip, has a displacement of 36 nm relative to its position at the end of the recovery stroke. This region is also the only one to remain relatively straight for much of the cycle. This suggests that the central portion of the cilium has a critical role during the effective stroke and that processivity may be important since the net displacement of dyneins in this region is greater than four times the expected step size.

An Investigation of the Mechanical Properties of Passive Sea Urchin Sperm Flagella
D. W. Pelle, K. A. Lesich, C. B. Lindemann; Biological Sciences, Oakland University, Rochester, MI

Recently, we lab reported that passive, vanadate-inhibited (50 µM + 0.1 mM ATP), rat sperm flagella exhibit a phenomenon described as counter-bend formation (Lindemann et al. 2005 Biophys. J. 89:1165-1174). When the basal portion of the flagellum is bent with a glass microprobe, the portion of the flagellum distal to the probe contact point develops a bend in the opposite direction to the imposed bend. In this study, we confirm that a similar phenomenon is observed in sea urchin flagella. Therefore, the counter-bend phenomenon is integral to the basic 9 + 2 microtubular axoneme and is not derived from the special features of mammalian sperm morphology. We further determined that removing the end flagellum of the by micro-dissection eliminates the response, as does mechanocally splitting the flagellum longitudinally. If the axoneme is immobilized in the middle of the flagellum, bends imposed on the basal section result in a counterbend in the distal section, but manipulation of the distal portion does not produce a counterbend in the basal portion. All of these results confirm that the phenomenon depends on the generation of inter-doublet shear. Based on measurements under our experimental conditions the flagellum has a total stiffness of ~ 6.0 x 10¹⁰ Nm⁻². We used this value to calculate the torque produced in the counterbend and find a shear resistance of ~ 7.4 pNnm for the flagellate microtubules. On this basis, the shear resistance of the sea urchin flagellum would account for ~ 1/3 of the total stiffness of the passive axoneme. Supported by N.S.F. grant #MCB-0516181.

Disruption of Hydin in Tetrahymena Causes Defects in Swimming Speed and Ciliary Beat Frequency
A. Kabli, J. Zhao, M. L. Robinson; Zoology, Miami University, Oxford, OH

Conagential hydremas are a common birth defect with an estimated occurrence of 1 in 1000 live births in the United States. Hydin (Hydrocephalus-inducing) is a very large gene that contains 167 exons, spanning 400 kb, and is expressed throughout the nervous system in all organisms. Hyduperturbated cilia beat at a frequency of 33 beats/sec in wild-type cells. Although disruption of Hydin affects ciliary motility, mutants can alter ciliary activity in response to specific external stimuli. Both wild-type cells and Hydin mutants increase swimming speed when exposed to hyperpolarizing conditions and decrease swimming speed when exposed to mild depolarizing stimuli. Like wild-type cells, mutants also exhibit a transient reversal of ciliary beat direction when exposed to strong depolarizing stimuli. Our data suggest that Hydin is required for normal ciliary motility but is not required for at least some alterations in ciliary activity. Our data also suggest that mammalian Hydin mutants develop hydrocephalus because ciliary beating is affected. This work was supported by NIH AREA grant R15GM098553-3 to DGP.

The Rate of Microtubule Sliding: Its Stability and Load Dependency
S. Ishijima, Bioengineering, Tokyo Institute of Technology, Tokyo, Japan

Flagellar beat of Suncus, golden hamster, and monkey spermatozoa before and after hyperpolarization were analyzed using high-speed video microscopy and digital image processing in order to understand the sliding mechanism of the flagellar beating and the function of outer dense fibers of mammalian spermatozoa. Although these spermatozoa have a different morphology and movement characteristics, change in the flagellar beating during the hyperpolarization was almost identical; namely, sharp bends at the base of the flagellum and a low beat frequency. Flagellar bends in other regions of the flagellum appear to have a limited involvement in the hyperpolarization. The nonhyperpolarized (activated) spermatozoa exhibited nearly constant-curvature beating, whereas the hyperpolarized spermatozoa displayed nearly constant-frequency beating, suggesting that the hyperpolarization is a mode conversion from constant-curvature beating to constant-frequency beating. To examine the microtubule sliding of sperm flagella, shear angle, which is the angle of the tangent to the flagellar shaft with reference to the sperm head axis, was measured because the degree and the rate of the shear angle are proportional to the amount of microtubule sliding and sliding velocity, respectively. The sharp bends at the flagellar base were generated by the increase in the total length of the microtubule sliding. The sliding velocity of each species was statistically different (P < 0.005). A comparison of the sliding velocity of the flagellar beating of Suncus, golden hamster, and monkey spermatozoa with the moment of inertia of the cross section at the flagellae base revealed that relationship between these two parameters was expressed by an exponential equation, similar to the characteristic equation of the muscle contraction. Data from sea urchin sperm also reveal the same extrapolated values from the values of the mammalian spermatozoa, suggests that the same sliding microtubule system functions in both the mammalian and echinoderm spermatozoa.
Fiber Diffraction Study on Flagellar Axonemes from a Wild Type and Mutant Strains of Chlamydomonas

S. Toba,1 H. Ivamoto,2 H. Sakakibara,1 K. Oiwa,1 Kobe Advanced ICT Research Center, National Institute of Information and Communications Technology, Kobe, Japan, 3Japan Synchrotron Radiation Research Institute, SPring-8, Harima, Hyogo, Japan

We have carried out X-ray diffraction studies on whole flagella isolated from Chlamydomonas and have obtained structural information of the axoneme both with and without nucleotides. We used several types of flagella prepared each from strains of wild type, and mutants lacking the whole outer arm (oda1), spoke (pf14), central apparatus (pf18) and the α chain of the outer arm dynein (oda11). We aligned axonemes in a flow cell by continuous shear flow, and then obtained diffraction patterns with the synchrotron radiation x-ray of 0.9 Å wavelength at SPring-8, BL45XU. The diffraction pattern showed several distinct meridional and equatorial reflections. Compared under the same nucleotide conditions, the 24-nm meridional reflection of the wild type was stronger than that of oda1, suggesting that this reflection originates mainly from the axial repeat of the outer dynein arms. The weaker 32-nm meridional reflection of pf14 compared with the wild type suggests that this reflection mainly comes from the repeat of the spoke. The 19-nm equatorial and 16-nm meridional reflections of pf18 were weaker than in the wild type, and these changes were presumably caused by the lack of the central sheath in pf18. Diffraction patterns were also obtained in different nucleotide states: no nucleotide, AMP-PNP, ADP/V, and ADP. In the ADP/V state, the 24-nm meridional reflection of the wild type became over twice as strong as that in the no nucleotide state. Although the origin of the equatorial reflections is yet to be determined, the addition of ATP/V or ADP caused the 27-nm equatorial reflection to shift towards the meridian and the 21-nm one away from it, indicating some nucleotide-dependent axial / azimuthal motion of axonomal structures. These changes are not simply due to uniform shrinkage/expansion of the axoneme. Acknowledgement: We thank Dr. S. Kamimura for the use of his flow cell.

Analysis of Structure and Functions of Flagellar Microtubule Tektin/Tubulin Protifilament Ribbons

P. W. Setter,1 E. Malvezy-Dorn,2 W. Steffen,1 R. E. Stephens,1 R. W. Linck3; 1Genetics, Cell Biology & Development, University of Minnesota, Minneapolis, MN, 2All About Children Pediatrics, Eden Prairie, MN, 3Molecular and Cell Physiology, Medical School, Hannover, Hannover, Germany, 4Physiology and Biophysics, Boston University School of Medicine, Boston, MA

Flagellar microtubule protifilament and tektin filaments were analyzed to elucidate their polypeptide composition and structural interactions. Tripneustes gratilla seaurchin sperm flagellar axonemes were fractionated with 0.5% Sarkosyl into protifilament ribbons, and these in turn were fractionated with 3-3.5 M urea to obtain tektin filaments. These entities were analyzed by quantitative SDS-PAGE immunoblotting with monospecific, polyclonal antibodies to L. pictus echinoderm tektin, and with antiserum to protein phosphatase 2A. Results indicated that there are two equimolar isomers of tektin A (A1, A2) and that in 3 M urea-stable filaments the tektins were present in equimolar ratios: (A1+ A2)/B=C. Tektin filaments were then fractionated with 4.5 M urea to yield highly stable AB filaments and pure soluble tektin C. These fractions were crosslinked with bis(sulfosuccinimidy) suberate, demonstrating that tektins A and B were nearest neighbor heterodimers and higher oligomers in the extended polymer; whereas soluble tektin C exists as homodimers, trimers and tetratomers. Finally, by extracting axonemes with 1 M NaSCN, filamentous remnants were obtained that contained tektins in a unitary ratio plus tightly-bound tubulins equivalent to the tektins, i.e., n=(A1+ A2)/B=C, and residual dynein heavy chains. The tightly-bound tubulin and dynein could be extracted from tektins with Sarkosyl. By negative stain EM, the NaSCN remnants appeared as tektin filaments with semi-periodic globular elements that disappeared after Sarkosyl extraction. We conclude that NHE1 activity contributes to the generation of (i) a defined cell surface pH needed for adhesion and spreading and (ii) a longitudinal pH gradient needed for migration. The proton gradient in moving direction. The proton concentration was higher at the leading edge than at the rear end. This longitudinal gradient is not present when the Na+/H+ exchanger is inhibited. Stimulation of the Na+/H+ exchanger leads to the formation of numerous protrusions firmly attached to the extracellular matrix. The proton gradient is much lower than at the surface of the cell body (ΔpH 0.25 in the glycolaxis). We conclude that the longitudinal pH gradient at the outer surface of the plasma membrane of melanoma cells contributes to the dynamics of cell-matrix contacts and thereby to cell migration. The more acidic pH at the front favors the formation, and the more alkaline pH at the rear end of the cell matrix contacts.

Protons at the Cell Surface as Glue for Cell-Matrix Contacts in Migrating Melanoma Cells

A. Schwab, M. Mueller, S. Mally, C. Stock; Institute of Physiology II, University of Muenster, Muenster, Germany

Migration of melanoma (MVM3) cells (i) is based on a coordinated formation and release of focal adhesion contacts mediated by integrins, (ii) depends on extracellular pH and (iii) requires the activity of the Na+/H+ exchanger NHE1 in the lamellipodium. The Na+/H+ exchanger is part of focal adhesion complexes. We suggest, that protons extruded by the Na+/H+ exchanger create an extracellular pH nanoenvironment at sites of cell-matrix contacts. The local extracellular pH may then influence the strength of cell adhesion and thereby modulate cell migration. In order to test this hypothesis we measured the extracellular pH (pHeμ) within approximately the first 50 nm from the outer surface of the plasma membrane. We labeled the plasma membrane and the glycolaxis with pH-sensitive dyes (phosphoethanolamine and wheat germ agglutinin, respectively) and determined pHeμ by means of ratiometric video imaging techniques. pHeμ decreased or increased as soon as pH of the bulk solution was lowered or elevated. Cells establish a proton gradient in the direction of movement, with the extracellular proton concentration being higher at the leading edge than at the rear edge (ΔpHe 0.2 at the cell membrane and ΔpHe 0.1 in the glycolaxis). This longitudinal gradient is not present when the Na+/H+ exchanger is inhibited. Stimulation of the Na+/H+ exchanger leads to the formation of numerous protrusions firmly attached to the extracellular matrix. The proton gradient is much lower than at the surface of the cell body (ΔpH 0.25 in the glycolaxis). We conclude that the longitudinal pH gradient at the outer surface of the plasma membrane of melanoma cells contributes to the dynamics of cell-matrix contacts and thereby to cell migration. The more acidic pH at the front favors the formation, and the more alkaline pH at the rear end of the cell matrix contacts.
Increased numbers of stellate cells (PSC) around pancreas carcinoma (PAC) might be due to two factors: (i) increased proliferation of PSC (recently demonstrated by our group) and (ii) recruitment of PSC from surrounding areas. Here we show whether carcinoma cells stimulate motility of PSC and attract PSC towards tumor cells. In addition we investigated the molecular mechanisms of stimulated PSC motility. The effect of tumor cell (MiaPaCa2, Panc1 and SW580) supernatant on PSC motility was demonstrated by time-lapse microscopy using the wound-assay and an agarose-chemotactant assay. The molecular mechanisms of stimulated PSC motility were studied by immunofluorescence microscopy (F-actin, paxillin, phosphorylated focal adhesion kinase (p-F-AK), and total tyrosine-phosphorylation) and Western analysis (total tyrosine-phosphorylation, p-PDG-F-R, p-F-AK, P-ERK, P-Src). In addition the compounds SB203580 (p38MAPK), PD98059 (MEK) and Y27630 (Rock), AG1295 (PDGF-R), anti-PDG-F-bb, and LY294002 (PI3K) were used to inhibit PSC motility and to determine the signal transduction pathways. In the presence of 0.1, 1.0, 5.0 and 10 % fetal calf serum, respectively, TC-SN (25%, 50%, 75% final concentration) dose dependently stimulated PSC motility and chemotaxis. Within 5 min after addition of TC-SN to cultured PSC the formation of focal adhesions complexes and phosphorylation of PDGF-F-R, FAK, ERK and Src was observed. Preincubation of TC-SN with anti-PDG-F-bb or preincubation of cultured PSC's with AG1295, SB203580, PD98059, Y27630 and LY294002 reduced stimulated PSC motility. Strongest inhibition was obtained by the ERK-inhibitor PD98059. The PI3K inhibitor LY294002 almost completely blocked basal and stimulated PSC motility. Our data indicate that pancreas carcinoma cells release PDGF and stimulate hereby random motility and chemotaxis of PSC towards a PDGF-gradient. In vivo these mechanisms result in an increased number of PSCs around pancreas carcinomas. PI3K, ERK, and P38MAPK and seem to play a role in the PDGF-induced signal transduction pathway leading to stimulated motility of PSCs.

Does Cdk6 Induce Cell Migration through Integrin Pathways?

T. Baker, M. J. Grossel; Biology, Connecticut College, New London, CT

Previously thought to function solely by regulating the G1 phase of the cell cycle through phosphorylating retinoblastoma protein (pRb), evidence now implicates cyclin-dependent kinase 6 (cdk6) in the process of differentiation. Over-expression of cdk6 in cultured mouse astrocytes was recently shown to induce changes in motility, gene expression, and actin dynamics - processes known to be associated with differentiation. Interestingly, wound assays demonstrated that cdk6-expressing astrocytes showed enhanced motility on fibronectin- and collagen-coated plates, but not on laminin- or vitronectin-coated plates. This ligand-specific motile response may indicate that cdk6 is involved in an integrin-mediated pathway. These data support a model of cdk6 interaction with integrin pathways, which may be a factor in the increased migratory ability characteristic of glioblastoma multiforme.

PDEF Mediated Cytoskeleton Re-organization Inhibits Invasive Properties of Breast Cancer Cells

D. P. Tumelty; Pathology and Laboratory Medicine, Medical University of South Carolina, Charleston, SC

Breast cancer mortality is attributable to metastasis as cells migrate from the primary tumor and invade into the circulatory system to establish at alternative sites. In order to acquire the polarized morphology required for directed movement, metastatic cells must dissociate from normal cell-to-cell contacts, reorganize their cytoskeleton and transiently re-localize cell-matrix interactions. These processes require extensive alterations in gene expression profiles. Our work has demonstrated that the ETS transcription factor PDEF (prostate derived ETS factor) is a possible negative-regulator of metastatic potential through the transcriptional control of metastasis-associated genes. PDEF expression is reduced in human invasive breast cancer and is absent in invasive breast cancer cell lines. Constitutive and inducible PDEF expression in invasive cells results in the inhibition of migration, invasion and cellular growth. Correlated with these phenotypic changes is the altered expression of metastasis-associated genes including the serine protease aPAP (arokinase-type plasminogen activator) and the metastasis suppressor maspin. Morphological differences observed between control cells and cells expressing PDEF led us to examine possible changes in cytoskeleton organization. Cells not expressing PDEF display polarized morphology associated with a migratory, including a defined single leading lamellipodia, a distinct trailing edge and polarized focal adhesions. In contrast, cells expressing PDEF, no longer show polarized morphology; but displayed characteristics of a more stationary cell. Specifically, they were rounded in shape, displayed altered G-F actin ratios and had randomly localized focal adhesions. Gene ontology analysis confirmed the differential expression of known effectors and modulators of cell-cell and cell-matrix interaction pathways. Collectively, these data indicate that PDEF expression in invasive cancer cells alters the ability of motile cells to form the temporal structures required for efficient motility. These results provide new insights into the mechanisms whereby PDEF functions as a potential metastasis suppressor.

Using Mammalian and Yeast Systems to StudyMemo, a Novel ErbB2 Effector Protein.

M. Meira, R. Masson, N. Hynes; Friedrich Miescher Institute for Biomedical Research, Basel, Switzerland

The Neu/ErbB2 receptor tyrosine kinase plays an important role in cancer cell motility and metastases formation. ErbB2 is often overexpressed in human breast and ovarian tumors. Our studies focused on signaling molecules that interact with autophosphorylated tyrosine residues of ErbB2. We have discovered that two autophosphorylation sites, Tyr 1201(YC) and Tyr1227(YF) are crucial to restore the migratory phenotype and promote cell motility to breast carcinoma cells upon Heregulin (HRG) stimulation, whereas the receptor lacking the 5 major autophosphorylation sites is impaired in stimulating migration. A novel protein has been identified and named Mmo for Mediator of ErbB2-driven cell Motility. Mmo interacts with the phosphorylated Tyr1227(YD) and is essential for HRG induced motility (1). Based upon the fact that Mmo knock-down (KD) does not block the ability of cells expressing the Tyr 1201 add-back mutant to migrate, we hypothesized that two parallel pathways stimulate migration in the context of a wild type ErbB2 receptor. We have found that PLCγ1 binds to Tyr 1201, and KD of PLCγ1 blocks HRG-induced cell migration. Furthermore, PLCγ1 KD cells, like Mmo KD cells, show decreased mitochondria outgrowth and strengthened actin stress fibers. We are focusing on the mechanisms which mediate the effects of Mmo and PLCγ1 on motility. Mmo has been conserved protein and has an orthologue with 40% sequence identity in S. cerevisiae. Strains lacking the Mmo gene (YJR080W) are viable. Accordingly, we have performed a synthetic lethal screen (in collaboration with the group of Dr. Matthias Peter in Zurich) by mating a Mmo deleted strain to an ordered array of 4700 yeast strains containing non essential gene deletions. This has led to the identification of a few genes that give a synthetic phenotype. (1) Marone, R. et al. 2004. Nature Cell Biol. 6: 515 - 522

Investigating Cytoplasmic Functions of Cdk6 in Differentiation

Z. E. De la Cruz, H. Stanish, E. Elliot, M. J. Grossel; Biology, Connecticut College, New London, CT

Recent evidence implicates the cyclin-cyclop cellcycle cycle, cyclin-dependent kinase (cdk6) in the processes of differentiation. Over expression of cdk6 in cultured mouse astrocytes was recently shown to induce changes in motility, gene expression, and actin dynamics. To better understand the role of cdk6 in changes in these processes, the sub-cellular localization of cdk6 is under study in these cells. Indirect immunofluorescence (IF) performed in our lab has localized cdk6 to the nucleus and the cytoplasm of cdk6-expressing mouse astrocytes. Our studies show that astrocytes infected with cdk6 stained more heavily in the cytoplasm and perinuclear regions, as opposed to control AP cells, which stained primarily in the nucleus. Together these results suggest that cdk6 may be involved in cytoplasmic functions. Indeed, published studies have demonstrated a role for cdk6 in the αβ, integrin regulatory pathway (Fahraeus, 1999). Also, another cyclin-dependent kinase, cdck, has been shown to modulate cell migration together with αβ integrin (Manes, 2003). Cdk6 coexpressed cells plated on fibronectin and collagen showed an unusual change in morphology. These ECM proteins resulted in increased nodules in cytoplasmic extensions. To further investigate this, immunofluorescence was performed on astrocytes over-expressing cdk6 on fibronectin. After being seeded on fibronectin, cdk6 was localized to the cytoplasm of the astrocytes including cytoplasmic nodules. A differential response by cdk6 to ECM proteins in both migration and morphological changes implies an involvement by cdk6 in integrin-mediated pathways. Localization of cdk6 to the cytoplasm further supports this possibility. The mechanism of this involvement, however, is unknown. These studies are intended to determine the mechanism of cdk6 function in the process of differentiation.

Interaction of Non-receptor Tyrosine Kinase Jak3 with Cytoskeletal Protein Villin Regulates Intestinal Epithelial Restitution

N. Kumar, J. Mishra, C. M. Waters; 1Physiology, University of Tennessee, Memphis, TN, 2College of Pharmacy, University of Tennessee, Memphis, TN

Intestinal epithelial restitution is a process by which epithelial continuity is rapidly reestablished following various forms of injury. The integrity of these epithelial barriers is compromised during the course of various intestinal disorders including inflammatory bowel disease (IBD). Enhancement of reparative processes through different interleukins can be a viable therapeutic alternative for different intestinal disorders. Although involvement of various (i.e. cytoketamine) and hormonal (i.e. growth factors and cytokines) components has recently been documented the mechanism of humoral signaling regulating mucosal recovery are not understood completely. To understand the significance of humoral IL-2 activated tyrosine kinase in the regulation of intestinal epithelial restitution, post-confluent differentiated intestinal epithelial cell lines were used to study in-vitro wound healing in response to recombiant human IL-2. Application of exogenous IL-2 enhances the restitution of both Caco-2 and HT-29 CL-19A cells in a dose dependent manner. Activation by IL-2 led to redistribution and tyrosine phosphorylation of the non-receptor tyrosine kinase Jak3. In these cell-culture model Jak3 interacts with villin in an IL-2 dependent manner. The time course of Jak3 activation coincided with
the tyrosine phosphorylation of intestinal and renal epithelial cell-specific cytoskeletal protein villin. Inhibition of Jak3 activation resulted in loss of tyrosine phosphorylation of villin and a significant decrease in wound repair of the intestinal epithelial cells. Activation of with IL-2 also led to co-localization of Jak3 and villin to cell margin in the migrating cells. We have earlier reported that villin can regulate cytoskeletal dynamics through its binding to different ligands or tyrosine phosphorylation. Present studies show that Jak3 plays a significant role in the signal transduction pathways involved in intestinal epithelial restitution through its interaction with interleukin receptors and interactions with cytoskeletal component villin. *This study was supported by a Research Fellowship Award (RFA) from the Coshen’s Colitis Foundation of America to NK.*

**2338 Regulation of Epithin by TGFβ and Its Role in Epithelial-Mesenchymal Transition**

H. Lee, S. Kim, Y. Cho, M. Kim, D. Park; Seoul National University, Seoul, Republic of Korea, 2Cho In University, Incheon, Republic of Korea

Epithin (matriptase, MT-SP1 in human) is a type II transmembrane serine protease, expressed in epithelium-derived tumors and epithelial components of most normal tissues. Epithin is consistently overexpressed in epithelium-derived tumors, and it has been demonstrated that Epithin could promote cancer metastasis in several reports. From these reports, it is expected that epithin has important roles in tumorigenesis, tumor growth, and metastasis. But the regulation of Epithin expression and its roles in cancer progression remain unknown. We found that TGFβ upregulated Epithin by transcriptional activation. This is mediated by Smad-independent, p38 MAPK-dependent pathway. In addition, TGFβ can facilitate the shedding as well as activation of Epithin. Although TGFβ is a well-known potent growth inhibitor, it has also been shown to promote metastasis, especially through induction of epithelial-mesenchymal transition (EMT). We investigated whether Epithin is implicated in TGFβ-mediated EMT. To test this possibility, we produced the Epithin-knockdown stable cell line (Epi-KD-17) using small interference RNA for Epithin. The expression of EMT markers were reduced in Epithin-knockdown cell line, and TGFβ-induced cell migration was also inhibited by Epithin knockdown. These results suggest that Epithin plays a crucial role in TGFβ-mediated EMT.

**2339 Abl and Its Interaction Partners Regulate Membrane Dynamics and Rate of Cell Spreading during Attachment**

S. Antoku, K. Sakoela, B. Mayer; University of Connecticut Health Center, Farmington, CT, 1Haartman Institute, University of Helsinki, Helsinki, Finland

During attachment, the cell dynamically changes its membrane structure to adapt to the new environment. Cell attachment and spreading involve two actin-based protrusive membrane structures, filopodia and lamellipodia. The Abi family of non-receptor tyrosine kinases, Abi and Arg, induces filopodia during attachment to fibronectin-coated surfaces. However, how Abi regulates this filopodium formation and its significance remain elusive. To determine the mechanism whereby Abi enhances filopodium formation, we introduced mutations in various domains and motifs of Abi, and re-expressed the mutants in mouse embryonic fibroblasts lacking Abi and Arg. We found that Abi carrying mutations in the cluster of proline-rich (PxxP) SH3 binding motifs significantly reduced filopodium formation upon attachment. We used a phage display library containing all known SH3 domains to identify potential binding partners for the Abi PxxP motifs. To determine which of these were involved in Abi-mediated filopodium formation, we overexpressed each candidate protein in spreading cells. We found that Nck family adaptor proteins enhanced filopodium formation, while Crk family adaptor proteins reduced filopodium formation and enhanced lamellipodium formation. All other candidates had no effect in this assay. These data suggest that binding of Nck and Crk to Abi through its PxxP motifs regulates filopodium formation. We performed further experiments to up- and down-regulate the expression levels of Abi, Nck, and Crk in spreading cells to manipulate the dynamics of filopodia and lamellipodium formation. We consistently observed that the average cell area during attachment was increased under conditions where lamellipodium formation was enhanced, and decreased where filopodium formation was enhanced. This implies that the balance between filopodium and lamellipodium formation controls the spreading speed of the cell. Our data indicate that Abi plays a critical role in attachment by regulating the dynamics of these actin structures through its interactions with Nck and Crk.

**2340 The Biological Function of iNOS in Cell Migration by RNAi-mediated Gene Silencing**

S. Liu, S. Chung, P. J. Chu; Institute of Biomedical Sciences, National Chung Hsing University, Taichung, Taiwan

We have described a tumor-associated NADH oxidase (iNOS) and its constitutive activation in transformed culture cells. Certain anticancer drugs have been shown to inhibit preferentially the iNOS activity in transformed cells and the inhibition of activity is well correlated with the poorer survival of transformed cells and subsequently results in the induction of apoptosis. However, the precise function of iNOS in transformed cells has not been fully studied. To further identify the biological function of iNOS, we utilize RNA interference (RNAi) approach and generate a stable iNOS RNAi cell line in HeLa cells. The stable cell line is, therefore, used to study the loss-of-function phenotypes. The expression of iNOS protein is reduced in iNOS-RNAi cells when compared with wild type HeLa cells and the protein expression associates with the lower survival in RNAi-transfected HeLa cells. In addition, the iNOS-RNAi cells exhibits less ability to migrate as suggested in wound-healing assay. To further investigate the effect of iNOS knock down in cell migration, we examine the key regulators involved in the pathway such as Rac protein. Surprisingly, the Rac protein level is significantly decreased in iNOS-RNAi cells. The detailed mechanisms by which iNOS regulates cell migration is investigated. (Supported by grants from National Healthy Research Institute NIHRI-EX95-941 IBC and Taichung Veterans General Hospital and National Chung Hsing University TCVGH-NCHU-957615).

**2341 α6β4 Integrin-mediated AKT Signaling Regulates Slingshot and Cofilin Activity in Human Keratinocytes**

K. R. Klipp, P. DeBiasi, J. C. Jones; Cell and Molecular Biology, Northwestern University, Chicago, IL

The motility of keratinocytes is essential for wound healing and metastasis of skin tumor cells. In vitro, the specific motile behavior of keratinocytes is dictated by the assembly of laminin-332 tracks. The assembly of these tracks is dependent upon α6β4 integrin signaling to the actin cytoskeleton, namely to the actin severing protein cofilin. Here we have analyzed how cofilin phosphorylation is regulated by mediators downstream of α6β4 integrin signaling in human keratinocytes. In human skin cells, expression of either dominant negative Rac1 or dominant inactive Slingshot-1 (SSH-1) induces phosphorylation of cofilin and leads to assembly of aberrant arrays of laminin-332. Like cofilin, SSH-1 is inactivated by phosphorylation on serine residues at the C-terminus. One kinase that may regulate SSH-1 in keratinocytes is AKT. To assess whether AKT phosphorylates SSH-1 in skin cells downstream of Rac 1 activity, we first determined the level of active AKT in keratinocytes induced to express dominant negative Rac1. Expression of dominant negative Rac1 not only increases levels of phosphorylated cofilin, but also leads to an increase in phospho-AKT levels. Conversely, expression of constitutively active Rac1 leads to decreased levels of phosphorylated cofilin and phospho-AKT. Moreover, treatment of human keratinocytes with the PI3K inhibitor LY294002 leads to a decrease in phospho-cofilin levels, providing additional support that SSH-1 is a target of AKT. Taken together, these data define a molecular pathway mediating keratinocyte motility. In the pathway, the regulation of AKT by Rac1 is a key determinant of SSH-1 and cofilin activity. SSH-1 and cofilin govern laminin-332 matrix assembly and ultimately regulate precise keratinocyte motility behavior.

**2342 Regulation of TRIP6 Function in Cell Motility by PTP-L1 Phosphatase**

Y. Lai, F. Lin; Cell Biology, Univ. of Alabama at Birmingham, Birmingham, AL

TRIP6 is a zyxin family member that has been implicated in actin dynamics and signal transduction important for cell adhesion and migration. Previously we have shown that LPA stimulation induces the recruitment of TRIP6 to the activated LPA 2 receptor and promotes the association of TRIP6 with several components of focal complexes, including p130 cas, FAK and Src. TRIP6 is a zyxin family member that has been implicated in actin dynamics and signal transduction important for cell adhesion and migration. Here we further identify PTPL1 as a tyrosine phosphatase responsible for dephosphorylating TRIP6 in vitro and in cells. Overexpression of PTP-L1 inhibits LPA-induced tyrosine phosphorylation of wild-type TRIP6, but not a TRIP6 mutant lacking the C-terminal PTP-L1 binding domain. Furthermore, LPA-induced morphological changes and the turnover of TRIP6 at focal adhesion sites are retarded in cells overexpressing PTP-L1. Consistently, PTP-L1 reduces LPA-induced cell migration. Taken together, these results suggest that a coordinate regulation of TRIP6 phosphorylation and dephosphorylation by c-Src kinase and PTP-L1 phosphatase is important for TRIP6 function in LPA-induced cell migration.

**2343 Regulation of Sperm Motility by Unique C-Complex-encoded Inhibitory Subunits of PPE172**

J. Lu, L. Chen, C. Myers, D. Solar, R. Wadlow, S. Vijayaraghavan, S. Pilder; Anatomy and Cell Biology, Temple University School of Medicine, Philadelphia, PA, 2Biological Sciences, Kent State University, Kent, OH
Ppp1r11 encodes a heat-stable inhibitor of PPI1cy2, a protein phosphatase 1 catalytic subunit whose activity is inversely related to sperm motility. Mouse Ppp1r11 localizes to the c complex, a naturally occurring polymorphism of the proximal third of chromosome 17 represented by a family of closely related haplotypes that carry similar mutant alleles of genes implicated in sperm dysfunction. The mutated t-allele of Ppp1r11 is thought to code for one of several proteins whose expression in sperm from t/t males coincides with an aberrant motility phenotype strongly associated with sterility. The initial purpose of this study was to compare the pattern of PPP1R11 expression in sperm using protein purification, western blotting, pull-down assays, immunoprecipitation, and immunofluorescence. Results indicate that PPP1R11+ is highly expressed in testis and spermatozoa as multiple isoforms, including a 27-kDa isoform identified in numerous tissues, and a testis- and sperm-specific 55-kDa isoform. The wild-type 55-kDa polypeptide does not bind PPI1cy2 in the testis, but binds it quantitatively in motility-activated sperm. Its t-isoform is extremely volatile in both newly activated sperm and sperm capacitated in vitro. Interestingly, microcin pull-down experiments demonstrate that a large, N-terminally unique isoform of another inhibitory subunit of PPI1cy2, PPI1R2, mapping to the c complex, is abundant in motility-activated wild-type sperm, but absent from sperm produced by t/t males. Based on our findings, we hypothesize that interplay between PPI1cy2 and the t-isoforms of these two c complex-derived regulatory subunits promotes the onset and maintenance of sperm motility and hyperactivation, while the poor motility of t-sperm derives from the instability or absence of the t-isoforms of these PPI1cy2 regulators. Efforts are currently underway to determine the complete molecular identities of these sperm-specific, c complex-encoded isoforms of inhibitors of PPI1cy2.

Regulation of Actin Dynamics and Cell Motility by Chromophin, a Cofilin Phosphatase, during EGFR Stimulation
C. DerMardirossian, V. Delorme, T. Huang, G. Bokoch; Immunology, The Scripps Research Institute, La Jolla, CA
As a crucial mediator of actin dynamics and cell motility, cofilin is regulated by cycling between an inactive, phosphorylated form, mediated by LIM kinase, and an active unphosphorylated form that depolymerizes and/or severs actin. Dephosphorylation of cofilin is mediated by slingshot (SSH) and a previously uncharacterized phosphatase, chromophin (CIN). We investigated the contributions of CIN to growth factor-induced actin dynamics and cell motility. We show that in serum-starved MTLn3 carcinoma cells, overexpressed CIN is mostly diffusely distributed in the cytosol. In response to epidermal growth factor (EGF) stimulation, marked transient localization of overexpressed CIN at the leading edge of the lamellipodium occurs. Interestingly, neither inactive CIN (D25N) or SSH translocate to the cell edge. As a consequence of the translocation, CIN becomes active and decreases by 25% the P-cofilin level at the cell edge. We find that the EGF-induced re-localization of CIN to actin-rich ruffles and membrane protrusions is dependent on PI3-kinase and Rac activity. To assess the function of CIN, we measured actin dynamics in vivo using Fluorescence Speckle Microscopy (FSM). We show that CIN expression induces the formation of a unique region at the cell edge in which the F-actin undergoes a fast retrograde flow. Kinetic analysis indicated that CIN increases the rate of F-actin treadmilling in vivo and widens the region of F-actin polymerization at the leading edge, consistent with the increase of free barbed ends induced by CIN at 3 min post EGF stimulation. Finally, analysis of cell speed using phase-contrast microscopy revealed that MTLn3 injected with CIN migrated nearly twice as fast as cell controls. The effect of chromophin knock-down on P-cofilin levels, actin polymerization, and cell motility in EGF stimulated cells will be evaluated.

Hepatocyte Growth Factor-induced Motility through Transactivation of the Epidermal Growth Factor Receptor
J. K. Klarlund, J. K. Spis, E. R. Block, E. Y. Clay; Visual Sciences Research Center, University of Pittsburgh, Pittsburgh, PA
Signaling by HGF (hepatocyte growth factor or scatter factor) through its receptor c-MET has been implicated in epithelial wound healing. HGF/MET has also been found to play important roles in numerous forms of cancer. HGF was found to induce robust scattering of colonies of an immortalized line of human corneal limbal epithelial (HCLE) cells, and it accelerated healing of wounded areas in confluent sheets of the cells. Unexpectedly, HGF was also found to induce activation of the epidermal growth factor (EGF) receptor by immunoblotting with an antibody against the receptor phosphorylated on tyrosine 1173. Studies with neutralizing antibodies and inhibitors demonstrated that HGF-induced EGF receptor activation proceeds via the triple membrane-passing signal mode of activation. Activation of the EGF receptor was necessary for HGF induced scattering and healing of wounds in sheets of corneal epithelial cells. However, activation of the EGF receptor was not necessary for activation of ERK1/2 or for internalization of E-cadherin. Activation was inhibited by the src inhibitor pp2, suggesting a role for a src-family kinase in transactivation, but protein kinase C or phospholipase D did not seem to be involved. Importantly, the EGF receptor is also activated by HGF in epidermoid carcinoma A431 and in MDCK cells, suggesting a general role for transactivation of this receptor in HGF action. We suggest that the EGFR receptor may be a relevant therapeutic target for at least some cancers driven by aberrant HGF/MET signaling.

ARF6-dependent Activation of ERK and Rac1 Is Regulates Cytoskeletal Remodeling during Epithelial Tube Development
J. Tushir, C. D’Souza-Schorey; Biological Sciences, University of Notre Dame, Notre Dame, IN
Tubes are the building blocks of epithelial organs and form in response to cues derived from morphogens such as hepatocyte growth factor (HGF). Investigating the mechanisms and regulation of tube development or tubulogenesis, is important not only to define fundamental aspects of development but also to understand the cellular basis of a variety of disease states. Recently little is known about signaling pathways that orchestrate the cellular behaviors that constitute tubulogenesis. Tube ‘initiation’ is characterized by a partial EMT, which would allow ‘pioneer’ cells from a cyst to become invasive and project long basolateral membrane extensions into the extracellular matrix. Therefore, cytoskeletal remodeling events are likely vital to tubule extension. Here, using three dimensional cell cultures of MDCK cells we show that the ARF6 GTPase is a critical determinant of tubule initiation in response to HGF. ARF6 is transiently activated during tubulogenesis and perturbing the ARF6/GTP/GDP cycle by inducible expression of ARF6 mutants defective in GTP binding or hydrolysis, inhibits the development of mature tubules. The effect of ARF6 on tube initiation is twofold. We show that not only does ARF6 regulate the subcellular distribution of the Rac1 GTPase at tubule extensions, but that ARF6-induced ERK activation is required for Rac1 activation and consequently for cytoskeleton remodeling during tubule initiation. We also demonstrate that uPAR signaling downstream of the ARF6/ERK pathway is critical for Rac1 activation during tubule outgrowth. Importantly, we have identified a cellular apparatus downstream of HGF signaling which regulates membrane and cytoskeleton remodeling necessary for the early stages of epithelial tube development.

IRSp53 is Required for CSF-1 and Rac Dependent Membrane Ruffling and Cell Migration, but Not for Podosomes and Cdc42-mediated Filopodia Formation in Macrophages
W. G. Abou-Kheir, B. Isaac, H. Yamaguchi, D. Cox; Anatomy and Structural Biology, Albert Einstein College of Medicine, Bronx, NY
WAVE (Wiskott-Aldrich syndrome protein [ WASP] family g-actin homologous) proteins play a major role in Rac-induced actin dynamics, but Rac does not bind directly to WAVE proteins. While it was initially demonstrated that IRSp53 (Insulin receptor substrate protein 53) linked WAVE to Rac, it has recently been shown that Rac can also bind to a complex of proteins containing Abelin interaction protein 1 (Abi1). We have previously shown that WAVE2 is crucial for actin cytoskeleton remodeling and migration of macrophages in response to colony-stimulating factor 1 (CSF-1) and that Abi1 is required for WAVE2 protein stabilization and function. A role for IRSp53 in CSF-1-induced actin cytoskeletal reorganization has not been reported in macrophages. We found that IRSp53, WAVE2 and Abi1 were co-localized in CSF-1-induced F-actin rich membrane protrusions in primary macrophages and in Rac-induced (RacQ61L) protrusions in a murine monocyte/macrophage cell line (RAW/LR5). Moreover, immunoprecipitation experiments demonstrated that IRSp53, WAVE2 and Abi1 existed in a complex in RAW/LR5 cells over-expressing constitutively active RacQ61L. Depletion of endogenous IRSp53 by RNA-mediated interference (RNAi) in RAW/LR5 cells resulted in a significant reduction of CSF-1 or RacQ61L-induced membrane ruffles, although formation of CSF42L (activated)-induced filopodia was not affected by depletion of IRSp53. Consistent with previous results observed in RAW/LR5 cells with reduced WAVE2 expression, cell migration in response to CSF-1 in RAW/LR5 cells with reduced IRSp53 expression was also significantly impaired. However, IRSp53 and WAVE2 were not involved in the formation of podosomes (actin rich, dot-like adhesion structures) suggesting that IRSp53 is not required for all actin dependent events in macrophages. Altogether, these data suggest that IRSp53 links Rac to WAVE2 and its function is crucial for CSF-1-induced F-actin rich protrusions and cell migration in macrophages.

Cortactin Is Required for Lamellipodia Retraction and Substrate Adhesion in MTLn3 Breast Cancer Cells
A. Gatesam Ammer,1 L. C. Kelley,2 S. A. Weed;1 Dept of Neurobiology and Anatomy, West Virginia University, Morgantown, WV, 3West Virginia University, Morgantown, WV
Changes in the actin cytoskeleton are mediated by a variety of actin-binding proteins and are essential for many cellular processes, including migration, invasion, and adhesion. Cortactin is an F-actin binding protein and Src family kinase substrate that is enriched in lamellipodia and is required for tumor cell motility and invasion. Cortactin functions to stimulate Arp2/3-mediated actin polymerization necessary for lamellipodia formation and extension, and serves to stabilize Arp2/3-F-actin networks. In this study we have investigated the role of tyrosine and serine phosphorylation in regulating motility and cortactin function using MTLn3 breast adenocarcinoma cells, a model system for studying lamellipodia. Lamellipodia formation in MTLn3 cells stimulated with EGF was monitored using time-lapse video microscopy. MTLn3 cells expressing control siRNA displayed normal lamellipodial dynamics, with maximal extension at about 3-4 minutes, and retraction by 10 minutes. In contrast, MTLn3 cells transfected with cortactin siRNA exhibited normal lamellipodia extension, but were dramatically impaired in their ability to
Retract, resulting in increased lamellipod persistence. Rescue of cortactin-silenced cells by expression of GFP-tagged human cortactin partially restored the ability of these cells to retract the lamellae. Our data suggest that cortactin serves to regulate lamellipodia retraction, an essential requirement for productive cell motility. Additionally, the role of cortactin in substrate adhesion and cell migration was examined using Electric Cell-substrate Impedance Sensing (ECIS). Our results suggest that cortactin is necessary for both cell-substrate adhesion and cell migration, as a loss of cortactin resulted in a delay in MTA2 adhesion and a decrease in adhesion strength, as well as impaired cell migration in response to EGF stimulation. We are currently examining the function of several mutants of cortactin, including tyrosine (Y421F, Y470F, Y486F, and Y498F) and serine (S405A and S418A) mutations, to dissect the requirements of cortactin in lamellipodia extension and retraction, substrate adhesion, and migration.

Fascin Promotes Colon Carcinoma Cell Migration by Alterations to Leading Edge Protrusions
Y. Hashimoto,1 M. Parsons,2 A. A. Smith,1 J. C. Adams1; 1Cell Biology, Lerner Research Institute, Cleveland Clinic, Cleveland, OH, 2Randall Division of Cell and Molecular Biophysics, King's College London, Guy's Campus, London, United Kingdom

Despite major improvements in diagnosis and treatment, tumor invasion and metastasis remain major causes of cancer morbidity and mortality. The actin-bundling protein, fascin, is not expressed by most normal epithelia but is up-regulated in many carcinomas. With our clinical colleagues we have found that high fascin expression correlates retrospectively with poor survival in patients with colorectal carcinoma. To test the hypothesis that up-regulation of fascin contributes to tumor cell migration and invasiveness, inducible shRNA for fascin knockdown (KD) was introduced into SW480 human colon cancer cells, that have a high level of fascin, and cloned cell lines were derived. Fascin-KD cells were unchanged in their proliferation rate, content and localisation of E-cadherin and beta-catenin, surface expression of beta integrins and initial attachment to extracellular matrix components. Distinct changes in phenotype were apparent in migrating cells. Parental cells contained fascin in cell protrusions and in the cell body. In both parental and fascin-KD cells, the major adhesions were at the protrusive tips. On laminin matrices, fascin-KD cells were increased in maximum length and had thinner and fewer actin-containing protrusions. By timelapse microscopy, the velocity of fascin-KD cells was significantly decreased (p<0.0001), as was polarised cell migration and the turnover of cell protrusions. This correlated with an altered distribution of focal adhesion components and decreased sensitivity to inhibition of endogenous Rac function. Phosphorylation of fascin by protein kinase C is known to regulate its actin-bundling activity, and FRET/FLIM microscopy of living cells migrating on laminin revealed strong, trans and Rac-dependent interaction between GFP-fascin and mEFP-protein kinase C gamma, localised at leading edge protrusions. Our working model is that fascin contributes to the cellular aggressiveness of CRC by promoting the turnover of cell protrusions necessary for directional cell migration. Fascin could represent a novel therapeutic target in strategies to arrest carcinoma cell invasion.

Neural Crest Migration and Dorsal Root Ganglion Formation in Zebrafish erbB3 Mutants
Y. Honjo, J. S. Eisen; Institute of Neuroscience, University of Oregon, Eugene, OR

ErbB3 is a receptor-type tyrosine kinase that has been shown to have important roles in glial development and in sympathetic ganglion formation. Mice with a targeted mutation of ErbB3 lack sympathetogenic brain and dorsal root ganglion (DRG) development. However, raising the possibility that normal neural crest migration is defective. To learn whether erbB3 is required for normal neural crest migration, we have taken advantage of the transparency of zebrafish embryos and studied neural crest migration in erbB3 zebrafish mutants. Previous studies showed that in zebrafish, as in mice, erbB3 mutants have a defect in gla development (Lyons et al., 2005, Current Biology, 15:513). We found that erbB3 mutants also have a defect in DRG formation, as revealed by absence of neurogenin1-positive nascent DRG cells at 30 hours postfertilization and by absence of Hac/D-positive DRG neurons at 4 days postfertilization. However, markers that label migrating neural crest cells revealed no obvious defects in the pattern of neural crest migration in erbB3 mutants. To learn whether other aspects of neural crest migration are affected in these mutants, we followed neural crest migration in live transgenic embryos in which GFP expression is driven by the zebrafish soxx10 promoter (Wada et al., 2005, Development, 132:3977). Treating embryos with the ErbB receptor inhibitor, AG1478, did not appear to affect overall neural crest motility, but did appear to affect the ability of some migrating neural crest cells to stop near the position where the DRG normally forms. These results suggest that erbB3 may be involved in the ability of DRG progenitors to recognize their target position during migration.

A Special Function for Nckα Adapter: Maintaining Paxillin Level During Neuronal Differentiation
S. Guan; University of Southern California, Los Angeles, CA

Nck adapter has an evolutionarily conserved function in neuronal differentiation, in which it links cell surface cues to the actin cytoskeleton-orchestrated cellular events. However, the mechanism of Nck action remained little beyond speculation. We investigated the roles of Nckα (Nck/Nck1) versus Nckβ (Grb4/Nck2) in nerve growth factor (NGF)-induced differentiation of the rat adrenal pheochromocytoma cell line, PC12, and in fully differentiated rat primary neurons. Here we show that genetic silencing Nckα completely blocks NGF-induced neurite outgrowth. In contrast, down-regulation of Nckβ slightly enhances the effect of NGF. We provide evidence that the role of Nckβ is to maintain the steady-state levels of paxillin, a critical focal adhesion molecule. Down-regulation of Nckα causes subsequent down-regulation of paxillin at the post-translational level. Furthermore, the differentiation defects of Nckα PC12 cells can be duplicated by genetic silencing paxillin in PC12 cells and rescued by re-expressing a siRNA-resistant Nckβ, but not Nckα, in the Nckβ cells. Thus, this study unveiled a novel Nckβ-paxillin mechanism by which Nckβ is the Mother Nature selection to maintain cellular paxillin level during neuronal differentiation.

A “Traffic Control” Role for TGFβ3: Orchestrating Dermal and Epidermal Cell Motility during Wound Healing
W. Li; University of Southern California, Los Angeles, CA

Cell migration is a rate-limiting event in skin wound healing. In un-wounded skin, cells are nourished by plasma. When skin is wounded, resident cells encounter serum for the first time. As the wound heals, the cells experience a transition of serum back to plasma. We report here that human serum selectively promote epithelial cell migration and halts dermal cell migration. In

Extracellular Hsp90α Mediates Hypoxia Signaling to Promote Human Skin Cell Migration
W. Li; University of Southern California, Los Angeles, CA

Hypoxia is a microenvironmental stress in skin wounds, where it causes increased motility of epidermal keratinocytes and dermal fibroblasts. The mechanism was unclear. Here, we report that hypoxia promotes human dermal fibroblast (HDF) migration by inducing hypoxia-inducible factor-1alpha (HIF-1α), which in turn causes secretion of heat shock protein-90alpha (hsp90α) into the extracellular environment. Expression of a constitutively activated HIF-1α replaced hypoxia for promoting hsp90α secretion and HDF migration. Permanent down regulation or functional inhibition of several mutants of cortactin, including tyrosine (Y421F, Y470F, Y486F, and Y498F) and serine (S405A and S418A) mutations, completely blocks hypoxia- and HIF-1α-enhanced HDF migration. In contrast, PDGF-βBB-stimulated migration of the same cells was unaffected. Finally, recombinant hsp90α alone promoted HDF migration under normoxia as potently as hypoxia, even in the absence of its co-factors or ATP. Thus, this study demonstrates a novel mechanism of hypoxia > HIF-1 > extracellular hsp90α > cell migration. Considering to HDF migration into skin wounds to help wound healing and remodeling, identification of this novel function for extracellular hsp90α provides a potential therapeutic target for better management of human skin wounds.

Distribution and Fate of YFP-transfected Donor Cell Mitochondria in Cloned Porcine Embryos
Z. Zhong, M. Katayama, R. Li, L. Lai, Y. Hao, D. Wax, L. Spate, K. Whitworth, Q. Sun, R. S. Prather, H. Schatten; 1Veterinary Pathobiology, University of Missouri-Columbia, Columbia, MO, 2Division of Animal Science, University of Missouri-Columbia, Columbia, MO, 3State Key Laboratory of Reproductive Biology, Institute of Zoology, Chinese Academy of Sciences, Beijing, China
Production of live offspring from cloned embryos is still low in mammalian species (ca. 1-5%) compared to in-vitro produced embryos which has been linked to a variety of cellular incompatibilities between the donor cell nucleus and the enucleated oocyte. Here we investigated whether donor cell mitochondria may exert adverse effects on embryo development. We have previously shown that perinuclear mitochondria aggregation indicates low developmental potential in vivo and in vitro fertilized pig eggs while abnormal mitochondria distribution is associated with developmental failures in in vitro fertilized oocytes. Here we investigated whether abnormal mitochondria distribution may be a contributing factor to the low cloning efficiencies and whether donor cell mitochondria are integrated into the entire mitochondria population in reconstructed pig embryos. In cloned embryos, two mitochondria populations are typically present, one contributed by the oocyte and one contributed by the donor cell. During normal fertilization, the oocyte contributes all mitochondria while the sperm’s mitochondria are destroyed by ubiquitination. We used either CMXRos-preloaded pig fibroblast cells or YFP-mitochondria transfected 3T3 mouse fibroblasts as donor cells to reconstruct interspecies and intraspecies cloned embryos, respectively, and follow donor cell mitochondria distribution. Our results revealed that donor cell mitochondria always aggregated near the donor cell nucleus but shortly after nuclear transfer (NT) dispersed into the ooplasm of the reconstructed embryo. In early stage embryos, there are no obvious differences in mitochondria distribution between IVF and nuclear transfer (NT) embryos. In later stage NT embryos, donor cell mitochondria displayed decreased labeling intensity which may indicate degradation or compromised mitochondrial function. Further studies are underway to investigate whether donor cell mitochondria exert negative effects on development, perhaps by inducing abnormal patterns of apoptosis. Funded by NIH grant R03-HD43829-02.

An Intact Actin Cytoskeleton Is Important for CCN2 Expression in Chondrocytes

D. Pala, 1 K. M. Lyons, 1,2 F. Beier, 1 A. Leask 1; 1 CIHR Group in Skeletal Development and Remodeling, University of Western Ontario, London, ON, Canada, 2 Department of Biological Chemistry, UCLA, Los Angeles, CA

Connective tissue growth factor (CTGF, CCN2) is expressed by mesenchymal cells during mammalian development. Mice genetically deficient in CCN2 die immediately after birth, displaying severe bone defects, including an expansion of hypertrophic cartilage and a decrease in ossification. The molecular basis of this defect is not known. An examination of the mechanisms underlying the control of CCN2 expression in primary chondrocytes was undertaken. CCN2 is expressed in chondrocytes, correlating with their differentiation stage. Using a combination of promoter analysis involving deletion series and point mutations, inhibitors and further functional assays we have identified cis acting sequences and trans-acting factors involved with CTGF expression. Remodeling of the actin cytoskeleton is essential for the early stages of chondrogenesis; and it has been found that expression of CCN2 in primary chondrocytes is blocked by the actin depolymerising agent cytochalasin D. Our results have identified a key sequence in the promoter that is responsive to the actin cytoskeleton. These results suggest that CCN2 is required for early chondrogenic events, downstream of remodeling of the actin cytoskeleton.

The Hereditary Neural Amyotrophy Causing Sept9 Mutations Are Associated with Altered Interaction with Other Septins, and Resistance against Rho/Rhotekin-dependent Septin Filament Disruption

K. Nagata, H. Ito, I. Iwamoto, R. Morishita, T. Asano; Molecular Neurobiology, Institute for Developmental Research, Aichi Human Service Center, Kasugai, Japan

Single point-mutations in Sept9 were shown to cause hereditary neural amyotrophy (HNA) but the cellular consequences of the mutations in HNA have not been determined. Since Sept9 is thought to exert its functions through interaction with other septins and small GTPase Rho-mediated signaling, we analyzed biochemical and cellular biological properties of HNA-associated Sept9 missense mutants, S93F/Sept9-v3 (Sept9F) and R88W-Sept9-v3 (Sept9W). We show that 1) Sept9F, but not Sept9W, affects Triton-X100 solubility of Sept7 and Sept11 when co-expressed in COS7 cells. 2) Sept9W, but not Sept9F, has reduced affinity to the interactive partner Sept4 in the cells, 3) both mutants, but not the wild-type, coordinately forms filamentous structures with Sept7 in NMuMG cells, and 4) the septin filaments comprising the mutants are not affected by the Rho/Rhotekin signals in the cells. Taken together, HNA-causing mutations in Sept9 are likely to alter the biochemistry of properties of Sept7 and modes of interaction with its interactive partners in different manners, and consequently might contribute to the pathogenesis of HNA.

The Alteration of Cell Shape, Cytoskeleton, and the Adhesive Structures Induced by Antioxidants

L. V. Domina, O. Y. Ivanova; Laboratory of Mathematical Methods in Biology, A.N.Belozersky Institute of Phys.-Chem. Biology, Moscow State University, Moscow, Russian Federation

The aim of the work is investigation of the effect of antioxidant Mito Q (mitochondrial targeted antioxidant) which in very low concentration protects cell from H2O2-induced apoptosis. Human skin fibroblasts (HSF), rat fibroblasts (Rat 1), mouse normal and Ras-transformed fibroblasts, human epithelial carcinoma cells (HeLa) and rat epithelial cells (IAR 2) were used. The cells were incubated with mitochondria targeted antioxidant- mito Q for 7 days, 50-100 μM H2O2 was added for last 24 hr. The confocal microscope in combination with immunofluorescence were used to study cytoskeleton. and in combination with tetera metil rodamine to study mitochondria. Treatment of cells with the antioxidant mito Q led to significant increase in cell areas and number of focal contacts. In spite of cell area growing up - cell elongation decreased. These changes in Ras-transformed fibroblasts made them morphologically indistinguishable from the normal ones. Cytoskeleton alteration consisted of actin filament increase in number and size. O-Smooth actin appeared in 26-30% of the treated fibroblasts, that could be considered as the differentiation step. Consequently wound healing by these fibroblasts was 2 times more intensive than in the control cultures. Number of mitochondria increased in the cells treated with mito Q. Mito Q led to formation of mitochondrial network from separated mitochondria and protect the cells from H2O2-apoptosis.

Cdc42 Is Required in Glucose-induced Insulin Secretion and Rac1 Activation in Pancreatic Beta-cells

Z. Wang, E. Eh, D. C. Thurmond; Biochemistry & Molecular Biology, Indiana University School of Medicine, Indianapolis, IN

Cdc42 and Rac1, members of the Rho subfamily of small GTPases, have each independently been found to play important roles in glucose-stimulated insulin secretion from pancreatic islet β-cells. Although Cdc42 and Rac1 are presumed to function in actin remodeling and insulin granule mobilization to the plasma membrane, it is unknown whether they are linked in a common signaling pathway. Using the GST-Pak1-PBD binding assay, we demonstrated that glucose stimulation Cdc42 is rapidly activated at the plasma membrane (PM) within 3 min, while Rac1 is not activated until a later time point of ~20 min. Both Cdc42 and Rac1 are activated only in response to D-glucose, otherwise unresponsive to non-metabolizable analogs 2-deoxyglucose and 3-orthoethyl-glucose or KCl, suggesting a requirement for glucose metabolism or a metabolite therefrom for activation. Interestingly, depletion of Cdc42 resulted in impaired glucose-induced activation of Rac1 at 20-30 min, supporting the notion that Rac1 exists downstream of Cdc42 in a common pathway. Furthermore, the p21-activated-kinase 1 (Pak1) became phosphorylated within 5–10 min of glucose stimulation, and thus may mediate the link between Cdc42 and Rac1 in this pathway. Functionally, Cdc42 depletion specifically impaired the 2nd phase of glucose-stimulated insulin secretion from isolated mouse islets, consistent with the notion that 2nd phase secretion requires actin remodeling for granule mobilization. Together, these data support a new mechanism whereby glucose initiates the mobilization of insulin granules early in stimulus-secretion coupling via first activating Cdc42 which then leads to Rac1 activation, and may involve Pak1 as an intermediary protein to coaggle Cdc42 and Rac1. This mechanism is only responsive to metabolism of D-glucose, consistent with the known requirement for stimulation of 2nd phase secretion. Further experiments are needed to elucidate the mechanisms leading to activation of Cdc42 and linking to Rac1 to facilitate second phase insulin secretion.

Phosphopeptide Analogues of HSP20 Modulate TGFβ-1 Stimulation of Human Keratin Fibroblasts

L. B. Lopes, 1 P. Komalavilas, 1,2 C. R. Flynn, 1 A. Panitch, 3 E. Furnish, 1 C. M. Brophy 1,2; 1 Harrington Department of Bioengineering, Arizona State University, Tempe, AZ, 2 Carl T. Hayden Veterans Affairs Medical Center, Phoenix, AZ, 3 Weldon School of Biomedical Engineering, University of Purdue, West Lafayette, IN

Transforming growth factor β-1 (TGFβ-1) stimulation leads to stress fiber formation, myofibroblast phenotype, and extracellular matrix production in fibroblasts. Phosphorylation of heat shock related protein (HSP) 27 and 40 is associated with actin cytoskeleton stabilization and stress fiber formation. Treatment with a phosphopeptide analogue of HSP20 conjugated to a protein transduction domain (PTD-pHSP20) induces loss of stress fibers and coloifin dephosphorylation. We investigated whether TGFβ-1 induces the phosphorylation of HSP27 and coloifin in human dermal keratin fibroblasts, and whether fibroblasts were growth 80% confluenve, serum-starved for 48 hr, and subsequently stimulated for 24 hr with TGFβ-1 (2.5 ng/mL), in the presence or absence of PTD-pHSP20 (0.05 mM). Untreated cells were used as controls. Immunoreactive phosphorylated HSP27 and coloifin were increased 5 and 2.2 times (over control), respectively. TGFβ-1 stimulation, PTD-pHSP20 decreased the TGFβ-1-induced phosphorylation of HSP27 by 52.4 ± 6.8% (n=3) and of coloifin by 31.5 ± 5.9% (n=3). PTD-pHSP20 treatment also led to loss of actin stress fibers with only cortical actin remaining. In addition, the expression of collagen in TGFβ-1-stimulated cells was decreased by 44.8 ± 13.2% (n=4) after PTD-pHSP20 treatment. The results suggest that phosphorylation of HSP27 and coloifin might mediate stress fiber formation induced...
Hyperosmotic stress increases phosphoinositide levels, reorganizes the actin cytoskeleton and induces multiple acute and adaptive physiological responses. We have found that phosphatidylinositol 4,5-bisphosphate (PIP2) levels increases rapidly in HeLa and Cos cells during hypertonic treatment. Depletion of the human type 1 phosphatidylinositol 4-phosphate 5-kinase (isoform PIP5KIβ) by RNA interference (RNAi) impairs both the PIP2 and actin cytoskeletal responses. PIP5KIβ is recruited to membranes and activated by hypertonic stress through ser/thr dephosphorylation. Cycalcin A (a caly A, a protein phosphatase 1 inhibitor, blocks the hypertonicity-induced PIP5KIβ dephosphorylation/activation as well as PIP2 increases in cells. Urea, which causes a rise in osmolarity without inducing cell shrinkage, neither promotes dephosphorylation nor increases PIP2 levels. Disruption or stabilization of the actin cytoskeleton, or inhibition of the Rho kinase, does not block the PIP2 increase or PIP5KIβ dephosphorylation. Therefore, PIP5KIβ is dephosphorylated in a volume-dependent manner by a caly A-sensitive protein phosphatase, which is activated upstream of actin remodeling and independently of Rho kinase activation. Our results establish a cause-and-effect relation between PIP5KIβ dephosphorylation, lipid kinase activation and PIP2 increase in cells. This PIP2 increase orchestrates multiple downstream responses, including the reorganization of the actin cytoskeleton.

Cytoskeletal Reorganization in a Kidney Cell Line (LLC-PK1) under Hypertonic Stress

A. S. Khanna, S. Murphy, M. Kasschau; Biological Sciences, University of the Sciences in Philadelphia, Philadelphia, PA

Mammalian kidney cells are normally exposed to high extracellular salt concentrations as a consequence of their participation in the urinary concentration mechanism (Natalia et al., Fundamental and Molecular Mechanisms of Mutagenesis, 2005). Cell structure and volume dependent remodeling of cytoskeleton is known to be influenced as an adaptive response to withstand this hypertonic stress (Di Ciano et al., Am J Cell Physiol, 2002). In diuresis and anti-diuresis conditions in mammals, the kidney cells are exposed to fluctuating levels of NaCl, urea and ammonia (Bustamante et al., Am J Physiol Renal Physiol, 2003). In our laboratory the effect of NaCl induced hypertonicity on cytoskeletal rearrangement in kidney cells was assessed by fluorescence microscopy. In LLC-PK1 cells, the distal tubular epithelial cell line from the cortical region of Sus scrofa (pig) kidney, actin and tubulin reorganized with exposure to 1 hour of hypertonic medium (1530 mOsm) as compared to cells in isotonic medium (330 mOsm). More than 95% of the LLC-PK1 cells grown in isotonic DMEM displayed colocalized actin and tubulin cortical rings. In approximately 80% of the cells, the actin and tubulin cortical rings were disrupted when cells were treated with a hypertonic medium for 1 hour. The cytoskeletal rings were reorganized, within 3 hours as cells recovered from the hypertonic treatment. One possible reason for this cytoskeletal reorganization could be due to the cell shrinkage as a result of hypertonicity. Comparative studies with mIMCD-3 cells, the inner medullary collecting duct cell line from Mus musculus (mouse), will enable us to understand whether cells from different regions of the kidney respond to hypertonic stress in a similar fashion.

Role of HSP70 and the Cytoskeleton in Podial Formation in a Human Hematopoietic Cell Line under Hypertonic Stress

M. D. Dutt, M. Kasschau, S. Murphy; Biological Sciences, University of the Sciences in Philadelphia, Philadelphia, PA

We study podia formation under hypertonic conditions in a human hemopoietic cell line KG1. KG1a cells are derived from the bone marrow of a patient with acute myelogenous leukemia (AML). KG1a cells are known to be highly sensitive to osmotic stress and undergo acute and adaptive physiological responses. Focal adhesion kinase (FAK) and its downstream targets, p38 MAPK and JNK, are involved in the regulation of podia formation in KG1a cells. FAK activation in KG1a cells under hypotonic conditions is mediated by Src.

The Rho-specific GEF Net1 Interacts with Scaffolding Proteins of the MAGUK Family

R. Garcia-Mata,1 A. Dubash,1 L. Sharek,1 K. Burridge2,3; 1Cell and Developmental Biology, UNC-Chapel Hill, Chapel Hill, NC; 2Lineberger Comprehensive Cancer Center, UNC-Chapel Hill, Chapel Hill, NC

Neuropilin remodeling factor 1 (NET1) is a RhoA specific guanine nucleotide exchange factor which was originally identified in a screen for oncogenic genes. Unlike the majority of Rho-GEFs which reside in the cytosol, Net1 localizes into the nucleus at steady state. A deletion in its N-terminus redistributes the protein to the cytosol, where it activates RhoA and can promote cell transformation. Net1 contains a conserved PDZ binding motif at the C-terminus which is essential for its transformation properties. In this study we found the Net1 interacts through its PDZ binding motif with the tumor suppressor protein SAP97/DLG1, as well as with other members of the same family, including SAP102 and SAP97. Interestingly, interaction between Net1 and its PDZ partners promotes the translocation of the PDZ protein to the nucleus specifically to nuclear subdomains associated with PML bodies. Deletion of the PDZ binding tail in Net1 prevents the Net1-mediated translocation of the PDZ protein which remain in the cytosol. The oncogenic mutant of NET1, which lacks the nuclear localization signals, is unable to shuttle the PDZ proteins to the nucleus, although the proteins still associate as clusters in the cytosol. Our recent studies suggest that the interaction of the NET1 mutant to transform cells may be in part related to its ability to sequester tumor suppressor proteins like SAP97/DLG1 in the cytosol preventing them to perform their normal cellular function. In agreement with this, we observe that the transformation potential of oncogenic Net1 is reduced when it is co-expressed in NIH3T3 cells together with SAP97/DLG1 or SAP102. Taken together our results suggest that the interaction between Net1 and SAP97/DLG1 could play a role in the mechanism of Net1 mediated transformation. Supported by a Susan Komen Foundation postdoctoral Fellowship (RGM) and by NIH GM25860 (KB).

Stretched to the Limit: Actin Dynamics at Extreme Cell Deformations

K. L. van Beek,1 M. G. Coppolino,1 M. Skalski,2 M. J. Kean,2 D. S. Fudge1; 1Integrative Biology, University of Guelph, Guelph, ON, Canada, 2Molecular and Cellular Biology, University of Guelph, Guelph, ON, Canada

Recent work on the intermediate filament (IF) network in cells suggests that IFs are highly extensible, and that the network can passively withstand cell strains up to 140%. In contrast, actin filaments are known to be at least two orders of magnitude stiffer than IFs and not nearly as extensible. This suggests that the actin cytoskeleton cannot survive large scale cell deformations and likely undergoes dramatic reorganization at large strains. To test these hypotheses we seeded Madin-Darby Canine Kidney cells onto rectangular silicone rubber strips coated with collagen IV, and stretched them with a custom uniaxial stretching device. Using this device we achieved cell strains in excess of 100%, which is several fold higher than the vast majority of cell stretching studies, which typically have maximum uniaxial strains of 25%. Rhodamine-phalloidin staining of control and stretched cells revealed that large uniaxial strains lead to considerable disruption of stress fibers (SFs). Similarly, large strain followed by relaxation of the rubber substrate also led to disruption of SFs. Cells stretched and held at large strains for 30 minutes exhibited SF buckling when the rubber substrate was relaxed. When viewed under phase contrast, these cells exhibited dramatic "stretch marks" perpendicular to the direction of stretch, indicating a partial loss of adhesion during the time they were held in the stretched state.

Analyzing the Role of Tension in Focal Adhesion Dynamics and Maturation

A. M. Pasapera-Limon,1 A. Kirby,2 W. D. Shim,1 A. N. Murray,1 C. M. Waterman-Storer1; 1Cell Biology, The Scripps Research Institute, La Jolla, CA; 2Biology, Duke University, Durham, NC
Focal adhesions (FAs) play a central role in cell migration. They link the actin cytoskeleton to the extracellular matrix through transmembrane integrin receptors which in turn recruit a complex of anchoring proteins leading to the formation of Focal complexes which mature into FAs. RhGTPase-regulated myosin II contraction of the cytoskeleton linked to adhesion induces integrin clustering and FA “maturation.” We hypothesize that tension-induced maturation of FAs results in changes in protein composition and dynamics that may influence adhesion morphology, strength, and signaling, thus regulating cell migration. In order to understand the relationship between adhesion morphology, maturation and protein binding/dissociation in FAs, we perform FRAP analysis of GFP-conjugated FA proteins while manipulating cellular tension across cell substrates.

To analyze the array of structural and signaling of FA components, we plated MEFs on 5 and 10 μg/ml of fibronectin and transfected then with GFP-conjugates of integrin α5, FAK, paxillin, zyxin, talin, or vinculin that were plated. FRAP analysis of these proteins showed remarkable diversity in their dissociation kinetics; 1/2 of fluorescence recovery was fast for paxillin, FAK, zyxin, and talin (~25s) while vinculin and α5 integrin were more stably bound in FAs (1/2 >100s) and only recovered partially. To manipulate cell contractility we inhibited myosin II activity by using the MLCK inhibitor ML-7 (20 μM). This revealed that 1/2 for α5 integrin, vinculin and zyxin were reduced, indicating that contractility promotes tighter binding of these proteins to FAs.

2366 Evolution of Actin Filament and Focal Adhesion Organization in Micro-patterned Cells
Department of Cell and Molecular Biology, Northwestern University Medical School, Chicago, IL, and Department of Chemical and Biological Engineering, Northwestern University, Evanston, IL, Marine Biological Laboratory, Woods Hole, MA

Heterogeneity of cell morphology and behavior precludes clear-cut quantitative analysis of cytoskeleton organization and dynamics across cell populations. Here, we show that control of cell geometry allows effective analysis of structural and functional characteristics of one component of cell motility, namely focal adhesion actin reorganization. Cell shape was controlled by patterning cell-adhesive islands separated by non-adhesive regions with micro-contact printing (μCP) of self-assembled monolayers of alkanethiolates onto gold. We used geometrically-defined cells to analyze the evolution and dynamics of the actin bundle and focal adhesion organization. B16F1 mouse melanoma cells were fixed with 30-minute time intervals from 2 to 12 hours after plating on fibronectin-coated patterned islands of circular and triangular shapes (area 1,250 micron square). Actin and focal adhesion structures were visualized with fluorescent phallolidin staining and immunofluorescence staining for paxillin. The images obtained from 25 single cells for each time point were combined to yield intensity maps of average distribution of cytoskeleton in the cell population. In circular cells, actin filaments re-organized from initial uniform distribution across entire cell area to preferential enrichment at the cell periphery with concordant increase of actin polymer mass. In triangular cells, actin filaments radiating out of the vertices as internal bundles progressively aligned with triangle’s edges. The re-organization of actin filaments was correlated with increased accumulation of focal adhesions at the rim of circular cells and at the vertices of triangular cells. Modeling of experimental data will be used to understand the cooperation between re-organization of actin bundles and focal adhesions. Our approach provides a powerful framework for quantitatively analyzing complex dynamic cellular processes from simple read-out of time series of averaged static images. Supported by NIH Grant 1 U54 CA119341 (GBB), Camille and Henry Dreyfus New Faculty Award (BG), and DOD Breast Cancer Research Program Postdoctoral Fellowship W81XWH-05-1-0312 (KKG).

2367 Cytosplastic Dynamics of Ovarian Cancer and the Role of RhGTPases
M. S. Thompson, P. Panorchan, J. S. H. Lee, A. Shrestha, D. Wirtz; Chemical and Biomolecular Engineering, Johns Hopkins University, Baltimore, MD

Ovarian cancer is the most deadly gynecological disease and progresses through two distinct pathways, complicating the search for effective diagnostics and treatments. Using multiple particle tracking microscopy, we have discovered that the cells corresponding to the two pathways of ovarian cancer progression vary distinctly in their cytoplasmic viscoelasticity. Benign ovarian surface epithelium and high-grade carcinomas share similar viscoelastic profiles, while the low-grade carcinomas exhibit a much softer cytoplasm. Upon wounding, the cytoskeleton of all three cell lines become stiffer, with the low-grade carcinomas showing the greatest change in viscoelasticity with a profile nearly identical to the benign and high-grade forms. These differences are correlated with vastly different migration rates in which the low-grade carcinomas migrate at twice the speed of the benign cells. However, the high-grade carcinomas, which are the most lethal via intraperitoneal dissemination and invasion, migrated the least. Immunofluorescence revealed vastly different cytoskeletal structures among the benign epithelium, low-grade carcinomas and high-grade carcinomas, suggesting that mediators of cytoskeleton organization may be essential to regulating ovarian cancer migration. We found that the RhGTPases were differentially expressed in the benign, low-grade and high-grade forms of ovarian cancer. Inhibition of Rac1 decreased the highly motile nature of the low-grade malignant and abolished migration of the high-grade carcinomas.

2368 Active Stiffening and Contractility of Cytoskeletal Networks Driven by Molecular Motors
G. H. Koenderink, Z. Dogic, M. P. Hansen, C. P. Brangwynne, D. A. Weitz
Experimental Soft Condensed Matter, Harvard University, Cambridge, MA, Complex Fluids Group, Rowland Institute at Harvard, Cambridge, MA

The cytoskeleton is a highly dynamic network of interconnected protein filaments that lends cells their mechanical integrity, but also actively generates forces. The most important contribution to shape changes and cellular movements stems from the actin cortex underlying the cell membrane. This cortex is contractile due to embedded myosin motor assemblies, which slide actin filaments past one another and thereby build up tension in the cross-linked actin cortex. In this talk I will present recent experiments on simplified model networks of purified actin and myosin II, which are aimed at a quantitative, microscopic understanding of the contractile properties of active actin/myosin networks. We probe the network mechanics on different length scales ranging from macroscopic scales (using macrotaxis) to micron scales (using embedded fluorescent microtubules as microscopic probes). The networks macroscopically stiffen due to internal stresses generated by contractile myosin activity, provided that cross-linking proteins are present to anchor the filaments. On small length scales the motors generate contractile fluctuations that show up in large transient shape deformations of embedded microtubules. From a materials perspective, our model system is a unique, active soft material. At the same time, the system allows to quantitatively explore molecular mechanisms of active cellular processes.

2369 Mechanical Properties of a Prokaryotic Actin-like Filament
B. Tseng, S. Sen, D. Mullins
Physics Course, Marine Biological Laboratory, Woods Hole, MA, Chromosome and Cell Biology, Rockefeller University, New York, NY, Control and Dynamical Systems, California Institute of Technology, Pasadena, CA, Cellular and Molecular Pharmacology, UCSF, San Francisco, CA

Recent work has identified homologs of actin and tubulin in bacteria. As in eukaryotes, these protein forms polymerize to maintain cell shape; transport cargo through the cytoplasm; and organize intracellular compartments. Understanding the mechanical properties of the eukaryotic polymers has helped explain the molecular mechanisms underlying their cellular functions. At present, almost nothing is known about the mechanical properties of prokaryotic cytoskeletal polymers. Using fluorescence microscopy of labeled proteins, we measured the flexural rigidity of actin-like filaments in Caulobacter crescentus, leveraging the phage-encoded protein ParM. Assembly of ParM filaments pushes plasmids to opposite poles of rod-shaped cells in a process analogous to the chromosome segregation function of microtubules. We determined a persistence length of approximately 10 μm for freely fluctuating filaments formed from a non-hydrolyzing ParM mutant.

In addition, we determined a persistence length of 20 μm for ParM filament bundles formed in the presence of parC and ParR. The persistence length of an individual ParM filament is similar to that of a eukaryotic actin filament - approximately 4-5-fold larger than the length of a bacterium. This result suggests that individual filaments may be stiff enough to segregate pairs of plasmid subunits. To analyze the array of structural and signaling of FA components, we plated MEFs on 5 and 10 μg/ml of fibronectin and transfected then with GFP-conjugates of integrin α5, FAK, paxillin, zyxin, talin, or vinculin that were plated. FRAP analysis of these proteins showed remarkable diversity in their dissociation kinetics; 1/2 of fluorescence recovery was fast for paxillin, FAK, zyxin, and talin (~25s) while vinculin and α5 integrin were more stably bound in FAs (1/2 >100s) and only recovered partially. To manipulate cell contractility we inhibited myosin II activity by using the MLCK inhibitor ML-7 (20 μM). This revealed that 1/2 for α5 integrin, vinculin and zyxin were reduced, indicating that contractility promotes tighter binding of these proteins to FAs.

2370 Quantitative Morphological Cytometry for Measuring Shear Stress in Cellular Systems
D. Lenz, B. Bayraktar, S. Leavesley, J. Robinson, B. Rajwa; Bindley Bioscience Center, Purdue University, West Lafayette, IN

Shear stress is known to have a significant effect on the state of cellular differentiation. It also induces morphologic responses including changes to cytoskeletal organization subsequently leading to changes in cell shape. In fact, fluid shear stress caused by blood flow is a major determinant of vascular remodeling and can lead to development of atherosclerosis. The morphological changes are usually evaluated using boundary-based shape descriptors (e.g. form factor) or binary geometrical moments on manually segmented cells. Although any one of the many automated segmentation method could be employed, these techniques are known to be complex, time consuming, and often require user input to operate properly, which is especially problematic for high-content screening (HCS) systems processing thousands of images during a single run. Therefore, development of robust, quantitative morphological measurements that are not dependent on precision and reproducibility of segmentation is extremely important for a substantial improvement of shear-stress analysis. The goals of this study were to find simple
morphological descriptors that could be applied to cells isolated by tessellation in order to enable a high-throughput screening of morphological shear-stress response, and to determine the amount of fluid shear stress to which endothelial cells were exposed on the basis of changes in their morphology. The proposed technique is based on the monitoring of changes in cytoskeleton organization using texture descriptors, rather than on quantifying cell-boundary modifications. We showed that objects identified by Voronoi tessellation carried enough information about cytoskeleton texture of individual cells to create a robust classifier. Our approach provided higher discriminant and predictive powers, and better classification capability, than traditional boundary-based methods. The robustness of classification in the presence of segmentation difficulties makes the proposed approach particularly suitable for automated HCS systems.

Interaction between XB130 and Fish/Tks5 and Involvement in Podosome Formation
H. Xiao, M. Liu; Thoracic Surgery Research Laboratory, Toronto General Hospital, Department of Physiology, University of Toronto, Toronto, ON, Canada
Src family protein tyrosine kinases play an important role in tumor progression and metastasis. We recently cloned a new adaptor protein, XB130, from a human lung adenocarcinoma cell line, and found that XB130 can activate c-Src, and leads to Akt-P-1,SRE transactivation. Using yeast-two-hybrid system, we found 64 positive clones that potentially interact with XB130, of which five clones encode partial sequence of Fish (Five SH3 domain-containing protein), which is called Tks5 and is required for podosome formation in cancer cells. Endogenous XB130 and Fish expression was found in several thyroid cancer cell lines by RT-PCR and western blotting. Interactions among Src and XB130 and Fish in these cells were found by co-immunoprecipitation and western blotting. Cell lysates from XB130-transfected COS7 cells were incubated with GST fusion proteins containing each of the five SH3 domains of Fish. The last SH3 domain at the C-terminus of Fish was identified as the major binding site to XB130. This was further confirmed by using a single amino acid mutant (W1056A) of this SH3 domain. A group of constructs were generated to partially truncate or delete functional domains in XB130. The N-terminus of XB130 containing putative SH3 and SH2 domain binding sites was responsible for the binding to Fish. When GFP XB130 construct was transfected into v-Src transformed NIH3T3 cells, XB130 was clustered in the podosomes. With prolonged incubation podosomes in these cells became smaller and disappeared. The morphology of these GFP XB130 transfected cells also changed. We speculate that the adaptor protein XB130 may interact with Fish to participate in the regulation of podosome formation and other Src related signaling and functions. Keyword: Fish/Tks5, Src, podosome, adaptor protein, signal transduction

Involvement of MLCK in Actin Stabilization and Podosome Development in the Contracting A7r5 Smooth Muscle Cell
S. E. Thatcher, 1 M. E. Fultz, 1 H. Tanaka, 1 K. Kohama, 2 G. L. Wright 1; Physiology, Pharmacology, and Toxicology, Joan C. Edwards School of Medicine, Huntington, WV, 1Biology, Morehead State University, Morehead, KY, 2Molecular and Cellular Pharmacology, Gummer University, Maebashi, Japan
Myosin light chain kinase (MLCK) is a serine/threonine protein kinase that is responsible for phosphorylating the serine-19 position on the regulatory light chains of myosin. MLCK also contains actin-binding sites located within its N-term which provides binding and bundling of actin filaments. Colocalization imaging and fluorescence resonance energy transfer (FRET) analysis indicated n-actin/MLCK association in resting cells and in podosomes of phorbol 12,13-dibutyrate (PDBu)-stimulated A7r5 smooth muscle cells. By comparison, β-actin/MLCK association was observed in stress fibers and in diffuse distribution in the perinuclear region of both control and PDBu-treated cells. Downregulation of MLCK by siRNA transfection resulted in variable patterns of actin isoform reorganization in control cells. n-Actin formed a dense system of filaments at the cell periphery leaving the central region of the cells devoid of structure. In contrast, β-actin stress fibers disassembled with this isoform diffusely distributed in the cell. In PDBu-treated cells, transfection with MLCK-siRNA resulted in an approximate 70% reduction in the formation of podosomes. The introduction of a peptide containing the I-41 N-terminal amino acid sequence of MLCK by peptide-mediated uptake or microinjection resulted in loss of α-actin stress fibers from the central region of the cell. The results indicate that MLCK plays an important role in maintaining n- and β-actin stress fibers and in the phorbol ester-induced reorganization of these isoforms. Furthermore, this role appears to be related to the N-terminal actin binding properties of the kinase.

Large Scale Cytoskeletal Structures Support Grasshopper Oogenesis
K. A. Edwards, E. Murray, D. Whitman, K. Vadali; Biological Sciences, Illinois State University, Normal, IL
Much of our knowledge concerning the cellular and molecular mechanisms of insect oogenesis is derived from Drosophila genetic studies. However, Drosophila ovaries are rather small and do not encounter the extreme mechanical challenges faced by large insects such as the Lubber grasshopper Romalea microptera. We are studying the differences in ovariore structure and the behavior of the follicular epithelium in these two species, to better understand the evolution of oogenesis in response to size variation. We find at least five structures that are heavily reinforced by either actin or microtubules, and differ dramatically from the homologous structures in Drosophila; these include the cellular sheath surrounding the ovariole, the terminal filament, the interfollicular stalks, the basal cytoskeleton of the oocyte follicle cells, and the follicle cells that remain after egg laying. The observed cytoskeletal structures all require the coordination of filament orientation across multiple cells. In two cases (the sheath and terminal filament) the cytoskeletal structures appear to reside in syncytia: the filaments pass continuously alongside multiple nuclei. In the remaining cases, actin filaments are coordinated from cell to cell, presumably through cadherin complexes or focal adhesions. These observations indicate that supracellular actin networks provide mechanical stability during insect oogenesis, and suggest that similar structures may arise in other developing tissues.

Cytoskeletal Regulation of Cell Shape Changes during Xenopus Gastrulation
J. Lee, R. M. Harland; Department of Molecular and Cell Biology, UC Berkeley, Berkeley, CA
Cell shape changes, such as apical constriction, are essential to diverse processes during development and cancer, ranging from morphogenesis to epithelial-to-mesenchymal transitions. Despite its importance and apical, surprisingly little is known regarding the cytoskeletal mechanisms that regulate apical constriction. To study apical constriction in a developmental context, we are examining the role of the cytoskeleton during Xenopus laevis bottle cell formation. Bottle cells undergo shape changes typical of apically constricting cells, transforming from cuboidal-shaped to flask-shaped while simultaneously undergoing cell elongation. In Xenopus, these cell shape changes create a crenicle to direct the first steps of mesodermal involution. It has been suggested, but never shown, that actin and myosin drive bottle cell apical constriction, whereas microtubules may be involved in elongation but not for contraction. To test these hypotheses, we first examined the localization and function of actin, myosin, and microtubules. Significant levels of F-actin and activated myosin accumulate at the apical surface of bottle cells. When actin or myosin function was inhibited with pharmacological agents, bottle cells were either completely absent (actin inhibitors) or exhibited less constricted apices (myosin inhibitor). Microtubules also localize to the apical side, though in an apicobasally-directed filamentous array. Intriguingly, microtubule depolymerization did not interfere with cell elongation; instead, it inhibited full constriction of the apical surface, presenting a novel role for microtubules during apical constriction. Together, our results show that, and to a lesser extent myosin and microtubules, are required for discrete aspects of the cell shape changes associated with apical constriction. We are currently examining the role of additional actin-dependent mechanisms, investigating the regulation of myosin activity, and determining the mechanism by which microtubules contribute to apical constriction. Using Xenopus bottle cells as a model, we hope to gain broader insight into the cytoskeletal mechanisms controlling cell shape changes.

Co-ordination of Actin and Microtubules during Drosophila Dorsal Closure
T. Millard, B. Stramer, P. Martin; University of Bristol, Bristol, United Kingdom
Dorsal closure is a process occurring during Drosophila embryogenesis whereby two epithelial sheets sweep towards one another over dorsal surface of the embryo and fuse when they meet at the midline. Dorsal closure is a well-studied model of epithelial morphogenesis. Previous work has elucidated the dynamics and function of the actin cytoskeleton during dorsal closure as well as signals that regulate actin during the process. A contractile actin-myosin cable is observed along leading edge of the two epithelial sheets and filopodia and lamellipodia protrude beyond this cable, which are involved in ‘rappelling’ of the two epithelial sheets. We have performed experiments designed to observe the dynamics and function of the microtubule cytoskeleton during dorsal closure. We have used two-colour live imaging to simultaneously observe actin filaments and microtubules during dorsal closure. We find that actin and microtubules display clearly distinct arrangements during dorsal closure. Microtubules are highly dynamic and are arranged in parallel bundles perpendicular to the leading edge actin cable. Dynamic microtubules frequently make contact with the leading edge actin cable and protrusions. Depolymerisation of microtubules disrupts dorsal closure, resulting in a dorsal hole. Live imaging suggests that ‘rappelling’ of leading edge cells fails following microtubule depolymerisation, while amnioserosa contraction proceeds as normal. Our results suggest that the microtubule and actin cytoskeletons of epithelial cells co-operate to achieve dorsal closure.
Role of the Yeast RGS Protein Sst2p in Cell Morphogenesis

T. Yi,1 H. Tanaka,1 H. Kitano2; 1Developmental and Cell Biology, UCI, Irvine, CA, 2The Systems Biology Institute, Tokyo, Japan

Yeast (2). Here, we investigated the role of Sst2p in forming proper shmoo. The Sst2D cells exhibited morphology defects during late polarization. The hRGS4 cells also exhibited similar morphology defects, even though hRGS4 could rescue the pheromone supersensitivity phenotype in sst2D cells. To investigate the differences between Sst2p and hRGS4, we observed the localization of marker proteins including Spa2p, Ste18p (Gg), Fus3p, Ste20p and Cdc12p (septin). We noted interesting spatial dynamics in the hRGS4 cells. Finally, in contrast to the late polarization defects, mating and early polarization in hRGS4 cells were similar to wild-type cells. (1) Billingmaier S and Snyder M, JCB 164:207-218, 2004 (2) Spinavisa SP, Bernstein LS, Blumer KJ and Linder ME, PNAS 95: 5584-5589, 1998

2378 Alanine Scanning Mutagenesis of the Yeast Cdc11p Septin

M. S. Longtine, A. Rajendran; Cell Biology and Physiology, Washington University in St. Louis, St. Louis, MO

role of septins to localize, and sometimes activate, septin-associated proteins. Recent data suggest that septin GDP binding is important in the formation of septin complexes and, thus, in septin filament formation and localization. Cdc11p and Cdc12p interact directly and stoichiometrically and this interaction requires both proteins to be bound to nucleotide. To better understand septin function, we have carried out a systematic alanine-scanning mutagenesis of Cdc11p with the aim of identifying regions involved in the interactions of Cdc11p with Cdc12p and with septin-associated proteins. Using this approach, we have identified four mutations that disrupt Cdc11p function. First, we identified two dominant-negative mutations in Cdc11p which do not prevent the interaction with Cdc12p or localization to the cell cortex. However, these mutations result in dominant defects in septin localization to the neck of the mutated Cdc11p and other septins and in septin function. We are currently testing the idea that these mutations result in the formation of abnormal septin filaments. Second, we have identified two mutations that disrupt the interaction of Cdc11p with Cdc12p. These mutations may identify surface regions of Cdc11p involved in the interaction with Cdc12p.

2379 Structural Analysis of Septin 2, 6, and 7 Complexes

C. Low,1 M. Macara1; 1Biochemistry, University of Virginia, Charlottesville, VA

Complexes. Yeast septins localize to the yeast mother-bud neck, the site of cytokinesis and mutations in CDC3, CDC10, CDC11 or CDC12 result in defects in cytokinesis, cell-cycle progression, chitin deposition, and other processes, resulting in inviability. Septin function appears to involve the formation of a membrane-associated septin filament serving as a barrier at the neck that has required for cell differentiation and cytokinesis. Septin function also involves the ability of septins to localize, and sometimes activate, septin-associated proteins. Recent data suggest that septin GDP binding is important in the formation of septin complexes and, thus, in septin filament formation and localization. Cdc11p and Cdc12p interact directly and stoichiometrically and this interaction requires both proteins to be bound to nucleotide. To better understand septin function, we have carried out a systematic alanine-scanning mutagenesis of Cdc11p with the aim of identifying regions involved in the interactions of Cdc11p with Cdc12p and with septin-associated proteins. Using this approach, we have identified four mutations that disrupt Cdc11p function. First, we identified two dominant-negative mutations in Cdc11p which do not prevent the interaction with Cdc12p or localization to the cell cortex. However, these mutations result in dominant defects in septin localization to the neck of the mutated Cdc11p and other septins and in septin function. We are currently testing the idea that these mutations result in the formation of abnormal septin filaments. Second, we have identified two mutations that disrupt the interaction of Cdc11p with Cdc12p. These mutations may identify surface regions of Cdc11p involved in the interaction with Cdc12p.

2380 p115-RhoGEF Controls RhoA Activity downstream of Fibronectin Adhesion

A. D. Dubash,1 K. Wennerberg,2 R. Garcia-Mata,3 M. Menold,1 K. Burridge1; 1Cell and Developmental Biology, University of North Carolina at Chapel Hill, Chapel Hill, NC, 2Southern Research Institute, Birmingham, AL

In order to understand how Rho proteins control actin reorganization, there is little knowledge about which specific GEFs are involved in different RhoA activation pathways, and the mechanisms via which these GEFs are activated. The current study was therefore focused on identifying the specific GEFs involved in activation of RhoA downstream of the FN adhesion signal. Using the nucleotide-free mutant of RhoA (which has high affinity for activated GEFs), we demonstrate that adhesion of fibroblasts to FN causes an increase in activity of p115-RhoGEF (p115RG), a RhoA exchange factor. Importantly, knockdown of Lsc (the murine homolog of p115RG) greatly reduces the ability of FN to activate RhoA in fibroblasts. Further, fibroblasts overexpressing a catalytically inactive mutant of p115RG demonstrate spreading defects, an inability to form stress fibers and focal adhesions, and no increase in RhoA activity when presented with a FN stimulus. Our studies therefore support an important role for p115RG function in modulating RhoA activity downstream of FN stimulation. Supported by DOD BCRP 2005 Predoctoral Traineeship Award BC051092 and NIH grant HL45100.

2381 Role of the Yeast RGS Protein Sst2p in Cell Morphogenesis

T. Yi,1 H. Tanaka,1 H. Kitano2; 1Developmental and Cell Biology, UCI, Irvine, CA, 2The Systems Biology Institute, Tokyo, Japan

2382 Cytoskeletal Changes during Nuclear and Cell Divisions in a Freshwater Alga Zygnema cruciatum (Chlorophyta, Zygnematales)

M. Yoon1, J. W. Han1; 1Biological and Environmental Research, Korea Institute of Science and Technology, Republic of Korea

Cytoskeletal changes were observed during cell division of the green alga Zygnema cruciatum using FITC-conjugated Phallacidin for F-actin staining and FITC-anti-a-tubulin for microtubule staining, and time-lapse videography. The f-actin ring appeared as a cleavage furrow. During the metaphase, FITC Phallacidin staining appeared on the chromosomes and nuclear surface, but the F-actin ring reduced and then disappeared. At the telophase, FITC Phallacidin staining did not appear at all. FITC-anti-a-tubulin staining revealed that microtubules were arranged beneath the protoplasm during the interphase and then localized on the nuclear region at the prophase, and the mitotic spindle was formed at the metaphase. The microtubules appeared between dividing chloroplasts. To our knowledge, this is the first record on coordinate involvement of both actin and microtubules in nuclear division. Our results showed that the F-actin began to appear on the chromosome and nuclear surface at prophase and then disappeared at metaphase and, therefore, F-actin and microtubules play an important role during cell division in this species.

2383 Effectives of Rho-family GTPases and Ras on the Cell Contact-dependent Regulation of the Smooth Muscle Actin Promoter during Epithelial-Mesenchymal Transition

A. Sebe1,2 Z. Peteri1, L. Fan2, A. Thirone3, L. Rosiwall2, I. Musci1, A. Kapus1; 1Dept. of Pathophysiology, Semmelweis University, Budapest, Hungary, 2Dept. of Surgery, St. Michael's Hospital, University of Toronto, Toronto, ON, Canada

Epithelial-mesenchymal transition (EMT) of tubular cells into o-smooth muscle actin (SMA)-expressing myofibroblasts is a central pathomechanism in kidney fibrosis. Our recent studies have shown that an initial injury of intercellular contacts in LLC-PK1 tubular cells is a prerequisite for the transforming growth factor- (TGFβ)-induced EMT. We found that intercellular contact disassembly facilitates Rho activation and Rho kinase-mediated myosin light chain (MLC) phosphorylation, which in turn contributes to the translocation of serum response factor (SRF) and its cofactor, myocardin-related transcription factor (MRTF) into the nucleus, where they induce the activation of the SMA promoter. Dominant negative (DN) Rho, DN-MLC and DN-MRTF inhibited the contact disruption- and TGFβ-induced SMA promoter activation. The present study demonstrates that other Rho-family GTPases, Rac and Cdc42 also participate in the contact- and contactility-dependent regulation of the SMA promoter. Specifically, overexpression of constitutively active Rac1, Cdc42 and their downstream effector p21-activated kinase (PAK) led to MLC phosphorylation, nuclear accumulation of SRF and MRTF, and activation of the SMA promoter. Contact disassembly induced by Ca2+ removal enhanced PAK phosphorylation. Importantly, DN-Rac1, DN-Cdc42 or DN-PAK1 inhibited the contact disruption-induced nuclear translocation of MRTF and the activation of the SMA promoter. These data suggest that various Rho GTPases promote contact injury-provoked EMT, partially through actin/phosphomycin-dependent nuclear translocation of MRTF. In sharp contrast to Rho GTPases, wild type...
Ras inhibited the Ca<sup>2+</sup>-removal-triggered SMA promoter activation, whereas DN-Ras markedly activated the promoter. These results suggest that Rho GTPases and Ras are both involved in the contact-dependent regulation of the SMA promoter, exerting an opposite effect: Rho GTPases promote whereas Ras GAPase mitigates the process.

**2383 Regulation of PKL/GIT2 Complexes by Protein Kinase A**

A. K. Howe, L. C. Baldor, S. Campbell, P. B. Deming; Pharmacology and the Vermont Cancer Center, University of Vermont, Burlington, VT

The interplay between integrin and growth factor receptor signaling is critically important for regulating both anchorage-dependent growth and chemotactic cell migration. Previously, we have shown that the cAMP-dependent protein kinase (PKA) plays an important role in anchorage-dependent growth factor signaling and in chemotaxis. The p21-activated kinase-1 (PAK1) is an important regulator of cell migration and is a direct target for PKA in the regulation of anchorage-dependent growth factor signaling. To further investigate the ability of PKA to regulate PAK-associated functions, PAK-containing complexes were immunoprecipitated and incubated with purified PKA to identify other PAK-associated substrates for PKA. Among the substrates identified were previously described targets - including PKA itself, the adaptor protein Nck, and the Rac/Cdc42 exchange factor beta-PIX - as well as a prominent 95 kDa protein. This protein was identified as PAKL/GIT2, a multifaceted linker protein that couples PAK1 and beta-PK to the focal adhesion protein paxillin, binds G-protein coupled receptor kinases (GRKs), and exhibits Arf/GAP activity. Further analyses confirm that PKA phosphorylates PAKL both in vitro and in vivo and can mediate PAKL signaling events. Specifically, inhibition of PKA activity blocks the PDGF-stimulated interaction of PAKL with beta-PX, and activation of PKA directly induces PAKL-paxillin and PKL-GRK2 interaction, and is required for the induction of these complexes following PDGF stimulation. These biochemical data correlate with PKA-dependent regulation of GFP-PKL localization in growth factor-stimulated cells. Together, these data implicate PKL/GIT2-containing complexes as major targets for PKA in events coordinately regulated by integrins and growth factors.

**2384 The Effects of Ginseng Fibroblasts Carried SOS1 Mutation on 3-D Collagen Matrices**

S. Jang, E. Lee, D. Pallos, T. C. Hart; 1NIDCR-CRC, NIH, Bethesda, MD, 2NIAMS, NIH, Bethesda, MD. 3University of Tahoe T, Tahoe, Brazil

Mutation of the son of sevenless-1 gene (SOS1) is etiologic for hereditary gingival fibromatosis (HGF) (Hart et al., Am. J. Hum. Genet. 70:943-954, 2002), a rare autosomal dominant disorder characterized by benign, nonhemorrhagic, fibrous enlargement of gingival tissues. Previous studies of HGF fibroblasts grown in monolayer culture under starving conditions showed constitutive MAP kinase signaling activation compared to control fibroblasts. To determine how the mutant SOS1 affects the extracellular matrix and leads to gingival enlargement we used a physiologically relevant 3-D collagen matrix model to study cell-matrix interactions. When equal densities of normal control and HGF fibroblasts were embedded in 3-D, regardless of the matrix shape (rectangular or circular), the 3-D HGF fibroblasts contracted to half the size of the 3-D culture control after 4 days incubation. The degree of contraction correlated with cell density in both cell types but HGF samples contracted 8-times faster than normal controls. To determine if contraction was associated with the higher proliferation rate of HGF fibroblasts, SOS1 was depleted through siRNA. No contraction was observed in the HGF 3-D mutant SOS1 knock-down. Morphological differences were observed as early as 2 hr after seeding in 3-D and maintained under starving medium (DMEM-HEPES): while normal fibroblasts appeared dendritic in shape with long, slender extensions, HGF fibroblasts showed a stellate/bipolar morphology. These data suggest that the induction of HGF fibroblasts to higher proliferation of gingival fibroblasts through the rearrangement and result in global remodeling of the collagen matrix.

**2385 Galectin-8 Induces Phosphatidic Acid-dependent Decrease of PKA Activity Leading to Sustained ERK Activation and Apoptosis in Jurkat T Cells in Suspension**

C. Metz, A. Norambuena, L. Vicuña, C. Cárcamo, E. Pardo, C. Oyanadel, A. González, A. Soza; 1Reumatología, Fac. Medicina, and Centro de Regulación Celular y Patología, Fac. Ciencias Biológicas, Pontificia Universidad Católica de Chile, and MIFAB, Santiago, Chile, 2Neurología, Fac. Medicina, Pontificia Universidad Católica de Chile, Santiago, Chile

Homeostatic regulation of immune response includes apoptosis induced by repeated T cell activation. This apoptotic process is mediated by prolonged activation of ERK. In several adherent cells, the Ras/Raf/Mek/MAPK pathway induced by growth factors depends on integrin-mediated cell attachment and is not activated in cells in suspension. In T cells, MAPK activation has been observed during cell adhesion to either integrin or TCR ligands. In Jurkat T cells, activation of β1 integrins in suspension failed to increase the activity of ERK. Galectin-8 are a family of carbohydrate-binding proteins secreted by non-canonical genes and recently implicated in a variety of cellular processes, including T cell homeostasis. Galectin function is exerted by binding to cell surface glycoproteins, specially integrins. In Jurkat T cells, we found that galectin-8 (Gal-8) binds to specific β1 integrins and constitutes a strong stimulus of ERK, even in cells in suspension. Gal-8 provokes a maintained ERK activation for at least 1 hour. A pathway from integrins to ERK involves activation of Rac-1 GTPase. Gal-8 as matrix induced activation of Rac1, but not in suspension. Primary alcohol known to abrogate phospholipase D-derived phosphatidic acid (PA) inhibited Gal-8 induction of ERK. PA has been described to activate specific cAMP phosphodiesterases leading to decreased cAMP levels and PKA activity. Accordingly, Gal-8 inhibited the activity of PKA, which in adherent cells has been described to allow anchorage-independent activation of MAPK. As expected for a prolonged activation of ERK, Gal-8 provoked apoptosis within 6 h of stimulation. These results suggest that Gal-8 constitutes a novel extracellular stimulus for T cells, which induces ERK activation in cells in suspension by involving a nexus between PA and cAMP/PKA pathways, with modulating potential upon the immune response (Financiado in part by FONDECYT grant #1050715, FONDAP grant # 13980001 and Millenium Project, Ministerio de Planificación).

**2386 Autophagy-mediated Survival of Prostate Epithelial Cells on Laminin Requires Integrin-mediated Activation of the EGFR/Erk and Src Signaling Pathways to Maintain Bcl-ExL Expression**

M. Edick, L. Lamb, B. Knudsen, C. Miranti; 1Van Andel Institute, Grand Rapids, MI, 2Fred Hutchinson Cancer Research Center, Seattle, WA

In vivo the prostate gland basal epithelial cells adhere to laminin 5 (L5M) via α3β1 and α6β4 integrins. When placed in culture primary basal prostate epithelial cells (PECs) secrete and adhere to their own L5M-rich matrix. In this study we have elucidated the mechanism whereby integrin-mediated signaling regulates the survival of PECs on L5M-rich matrices. Survival of PECs on L5M requires α3β1, but not α6β4, and is dependent on integrin-mediated, ligand-independent activation of the epidermal growth factor receptor (EGFR) and the cytoplasmic tyrosine kinase Src, but not PI-3K. Integrin-mediated EGFR activation supports cell survival by signaling downstream to Erk, but not Akt. Both Erk and Src act to maintain elevated levels of anti-apoptotic regulator Bcl-XL. Down regulation of Bcl-XL by siRNA in L5M-adherent PECs is sufficient to induce cell death. Despite the dependence on Bcl-XL for survival, death induced by inhibition of EGFR or Src is not mediated through cytochrome C release or caspase activation. Blocking autophagy in L5M-adherent cells also induces cell death and caspase activation. However, blocking autophagy did not prevent cell death induced by blocking EGFR signaling, and cell death under these conditions was compromised by an increase in caspase activity. Together these data indicate that survival signals by integrins on L5M is regulated by at least two pathways, signaling through EGFR/Erk and Src to target Bcl-XL and through an autophagy survival pathway. In the presence of an intact autophagy survival pathway, death induced by blocking EGFR/Erk signaling is caspase-independent. However, in the absence of autophagy, inhibition of signaling through this pathway leads to caspase-dependent death.

**2387 Regulation of Raf-MEK-ERK Signalling Pathway in Primary Mouse Mammary Epithelial Cells Forming 3D-acinar Structures**

M. K. Gajewska, E. McCadle, F. Martin; Conway Institute, University College Dublin, Dublin, Ireland

Primary mouse mammary epithelial cells supported on a laminin-rich ECM form 3D-acinar structures that mature to form polarised monolayers surrounding a lumen. Using this three-dimensional culture system, we have previously shown that JNK activity is necessary for normal mammary acinus development. Inhibition of JNK activity with SP600125 results in failure of cell polarisation and lumen clearance leading to formation of "disorganised" spheres filled with surviving cells. We show that during early acinus formation the Raf-MEK-ERK signalling axis is active, but the activity falls in time. In addition, focal adhesion complex components, paxillin, Src and FAK, which are recruited downstream of ECM-integrin interactions, are activated/phosphorylated. In spheres treated with the JNK inhibitor, acinus maturation failed and phosphorylation of the focal adhesion complex components was decreased. Raf-1 and MEK1/2 phosphorylation was unaffected, however ERK1/2 exhibited sustained high levels of phosphorylation. This sustained phosphorylation of ERK1/2 is crucial to the effect of JNK inhibition as normal acinus formation could be rescued by its inhibition using PD98059. We hypothesized that control of ERK1/2 phosphorylation/activation may also be regulated, to a degree, downstream of the ERK-MAPK pathway. Indeed normal acinus formation is associated with JNK-dependent Erk-specific phosphatase (MKP-2/-3) expression. By regulating the extent of MAP kinase phosphorylation, MKP-2 and MKP-3 are expressed (MKP-2 particularly in nuclei), whereas JNK inhibitor treatment abolishes the expression of both phosphatases. In addition, broad inhibition of cellular phosphatases by pervanadate induced cell illisation, sustained high level of ERK1/2 phosphorylation and formation of disorganised acini. This could be partially rescued with the MEK1/2

*2006 ASCB Annual Meeting Abstracts*
inhibition by PD98059. Our data suggest that necessary control of ERK1/2 phosphorylation/activation during acinus formation may indeed be contributed to by the action of ERK-specific phosphatases.

Mechanical Stimuli Activation of Calpain Is Required for Myoblast Differentiation and Occurs via an ERK/MAP Kinase Signaling Pathway
A. Grossi, A. H. Karlsson, M. A. Lawson; Department of Food Science, The Royal Veterinary and Agricultural University - KVL, Frederiksberg C, Denmark
Myogenesis is a complex sequence of events, including the irreversible transition from the proliferation-competent myoblast stage into fused, multinucleated myotubes. During embryonic development, myogenic differentiation is regulated by positive and negative signals from surrounding tissues. Stimulation due to stretch- or load-induced signaling is now beginning to be understood as a factor which affects various signal transduction pathways, gene sequences and protein synthesis. Evidence of the involvement of mitogen-activated protein kinase (MAPK) cascade activation in myoblast fusion, cell membrane and cytoskeleton component reorganization due to the activity of ubiquitous proteolytic enzymes known as calpains has been reported. Whether there is a link between stretch- or load induced signals, the MAPK pathway and calpain expression and activation is not known. Using a magnetic bead stimulation assay and C2C12 mouse myoblasts cell population, we have shown that mechanical signals transmitted through the C2C12 cells interaction with laminin cause an increase in cellular differentiation. This signaling results in an increase in the number of myotubes formed in the cultures, with each individual myotube containing a reduced number of nuclei. Mechanical stimulation increases not only the expression of m-calpain but also the overall activity of calpain in the cells through the MAPK signaling cascade. Our findings underline that the mechanical modulation of MAPK signaling cascade enhances the expression and activity of m-calpain, which may play a pivotal role during myoblast fusion, strengthening the idea of its implication during the initial events of muscle development.

JNK-dependent Regulation of Polarization in Primary Mouse Mammary Cells
J. A. Whyte, L. Thornton, E. McAdze, F. Martin; School of Biomolecular and Biomedical Sciences, Conway Institute, University College Dublin, Dublin, Ireland
Primary mouse mammary epithelial cells organize as spherical acini when grown on laminin-rich ECM. Acini formation begins with the apico basal polarization of the outer cells of the assembly and the withdrawal of these cells from the cell cycle. Subsequently, the internal cells die by apoptosis to form a hollow lumen. Polarization in an epithelial sheet is initially established by the generation of an active ternary signaling complex consisting of the atypical PKCζ, Par3 and Par6. We have previously shown that JNK activity is necessary for functional acinus formation and we have recently demonstrated that PKCζ is phosphorylated (at Tyr140) and activated in the early stages of acinus formation in a JNK-dependent fashion. In addition, inhibition of PKCζ activity is sufficient to disrupt the assembly of polarized acini. We now investigate other downstream systems that are regulated by JNK and contribute to cell polarization in the acini. We observe an increase in expression of the basolateral polarity protein scribble during the early stages of acinus formation and this increase is significantly reduced in JNK inhibited spheres. The reduction in scribble protein expression is most likely though the repression of c-jun-mediated transcription. In JNK inhibited spheres the low levels of scribble protein remaining is mislocalized. Inhibition of JNK also ablated expression of the scribble binding protein, discs large (dlg) and significantly reduced the expression of the apical polarity complex protein pahl1. These findings highlight a role for JNK signaling in the regulation of multiple polarity proteins. We therefore propose that JNK regulates key molecular events leading to the activation of PKCζ and the expression of key polarity proteins, which are necessary for early events in cell polarization.

Low Substratum Rigidity Induces Ubiquitin Ligase Culll Mediated-c-Jun Degradation in Nucleus of Epithelial Cells
Y. Hu, Y. Wang, M. Tang; Physiology, National Cheng-Kong University, Tainan, Taiwan, 2Basic Medical Sciences, National Cheng-Kong University, Tainan, Taiwan
The proto-oncprotein c-Jun is a component of the transcription factor AP-1 (activator protein-1) involved in cellular proliferation, differentiation and death. Maintenance of c-Jun protein levels plays an important role in proliferation and survival of epithelial cells. Previous studies in our lab showed that epithelial cells cultured on collagen gel developed apoptosis due to low substratum rigidity. Low rigidity-induced cell apoptosis was mediated by degradation of c-Jun, which was observed only in epithelial, but not transformed cells. The purpose of my study was to delineate the underlying mechanism whereby low substratum rigidity induced degradation of c-Jun. The low rigidity-induced degradation of c-Jun could be reversed by 26S proteasome specific inhibitors. Here we showed that Cul1, a ring-domain ubiquitin ligase, had a specific physiological role in low rigidity-induced c-Jun degradation. Low substratum rigidity induced Cul1 neddylation and enhanced Cull1 mediated polyubiquitination. Under low substratum rigidity condition, Cull1 physically interacted with c-Jun. Immunofluorescence study showed that low rigidity induced the accumulation of Cul1 in the nucleus, which was associated with degradation of c-Jun. In addition, low rigidity also triggered translocation of 26S proteasome into the nucleus. Taken together, we demonstrate that low substratum rigidity induces Cul1 neddylation which triggers c-Jun polyubiquitination and results in c-Jun degradation through ubiquitin-proteasome proteolysis in epithelial cells.

Abl Tyrosine Kinase Inhibits Cell Spreading on Fibronectin
H. Jin, J. Wang; Division of Biological Sciences, University of California, San Diego, La Jolla, CA
Cell adhesion and spreading on extra cellular matrix (ECM) is an important process for cell growth, migration and differentiation. The non-receptor tyrosine kinases Abl is activated upon cell adhesion to fibronectin, which is a component of ECM. To determine the effect of Abl kinase on fibronectin-induced cell spreading, we prepared Abl-FKBP fusion proteins, which were activated by a cell-permeable dimerizer. Dimerization of Abl-FKBP in serum-starved and suspended 3T3 cells led to tyrosine phosphorylation and activation of Abl. When plated on fibronectin, cells with activated Abl-FKBP exhibited a significant reduction in the rate of spreading, and the degree of inhibition could be correlated with the level of Abl activation. We also found inhibition of endogenous Abl kinase with imatinib could induce an increase in the rate of cell spreading, and this effect was not seen in an imatinib-resistant Abl (AblT315I) stable expressing cells, as well as Abl and Abl related gene, Arg, double knock out cells. Lastly, we found Rac activation was not impaired in spreading cells by Abl. Taken together, these results suggest that consistent with its role in cell spreading, Abl exerts a negative effect on cell spreading through a pathway that probably lies downstream of Rac activation.

FAK FERM Domain-enhanced p53 Degradation Controls a p21-dependent Block in Cell Proliferation
There is an undefined role for the p53 tumor suppressor (p53) in promoting cell cycle arrest when integrin-matrix signals are disrupted. Here, we demonstrate a novel link between p53 and integrin-activated focal adhesion kinase (FAK) during development and in the control of primary mouse and human fibroblast proliferation. Genetic deletion of FAK results in mesodermal growth arrest by E8.5, p53 accumulation, and the inability of FAK−/−p53−/− embryonic cells to proliferate ex vivo. Loss of FAK was not associated with increased cell apoptosis. However, FAK−/− mesodermal cell proliferation block was reversed by genetic deletion of either p53 or the p53-responsive target, p21Cip/Waf1 (p21). Interestingly, p53 protein stability and nuclear localization levels are elevated in FAK−/−p21−/− compared to FAK−/−p21−/− primary fibroblasts. By re-expressing FAK or various FAK mutants in FAK−/−p21−/− fibroblasts, we find that the FAK N-terminal domain is required for p53 nuclear localization. The data further suggest that cytoplasmic localization of p53 is required for FAK to promote increased p53 transcriptional activity. FAK-FERM-mediated p53 degradation is blocked by MG132 and increased p53 ubiquitination in the absence of FAK-FERM is dependent on MDM2. Biochemical fractionation and fluorescent microscopy showed that FAK-FERM is strongly localized to the nucleus and G2/F-FAK is nuclear-localized upon leptotignin B addition. A series of point mutations within the FAK-FERM domain identified a functional bipartite nuclear localization sequence (NLS) for FAK-FERM, which is associated with p53 and promote p53 degradation. To determine whether FAK expression regulates p53 turnover and cell proliferation.

Role of Gelsolin in Cyclosporin-induced Inhibition of Collagen Phagocytosis

M. W. C. Chan, P. D. Arora, C. A. McCulloch; CIHR Group in Matrix Dynamics, University of Toronto, Toronto, ON, Canada

Background: Gelsolin (Gsn) inhibits collagen degradation by interfering with the ligand binding step of the phagocytic pathway. In rapidly remodeling connective tissues such as human periodontium this manifests as marked tissue overgrowth and loss of function. Previous data have shown that CsA inhibits the release of Ca2+ from internal stores, which is required for the binding step of collagen phagocytosis. As gelsolin is a Ca2+-dependent actin severing protein that is required for collagen phagocytosis, we determined if gelsolin is a CsA target. Objectives: To examine the role of gelsolin in collagen phagocytosis following CsA treatment. Methods: Gingival tissues from wild-type and gelsolin-null mice treated with CsA were analyzed by histological sections. Collagen-coated beads were used to study collagen phagocytosis and calcium signaling in fibroblasts following CsA treatment. Results: Compared to vehicle controls, CsA treatment of wild-type mice markedly increased collagen accumulation in periodontal tissues; equivalent increases of accumulation were seen in vehicle-treated gelsolin-null mice. Similarly, collagen degradation by phagocytosis in vitro was blocked by CsA or absence of gelsolin. This inhibition was attributable to the collagen binding step but not the internalization step. CsA blocked actin assembly, gelsolin recruitment to sites of collagen binding and collagen-induced Ca2+ fluxes subjacent to bound collagen beads. CsA inhibited gelsolin-dependent severing in wild-type and gelsolin-null cells showing low to into gelsolin-null cells, collagen binding was similar to that of cells treated with CsA. In cells loaded with a peptide that interferes with the PI(4,5)P2 regulatory site of gelsolin and that inhibits collagen internalization, CsA did not further reduce collagen internalization. Conclusions: One mechanism of CsA-induced accumulation of collagen in the extracellular matrix involves disruption of actin severing by gelsolin, thereby inhibiting the binding step of collagen phagocytosis.

Effect of Basement Membrane on Hox A5 Transcriptional Activity

Hox genes are transcriptional regulators which play key roles during embryonic development and differentiation, and in adults contribute to pathological tissue remodeling. We previously showed that HoxA5 blocks angiogenesis by down regulating pro-angiogenic genes including VEGFR2 and Ephrin A1 and up regulating anti-angiogenic genes including Thrombospondin-2. Moreover, in endothelial cells cultured in the presence of a three dimensional reconstituted basement membranes (3DhBM), HoxA5 promotes formation of stable capillary networks as siRNA against endogenous HoxA5 blocks tube formation and overexpression of HoxA5 leads to increased branching and formation of extensive adherens junctions. The HoxA5 mediated increases in capillary networks and adherens junctions is associated with increased expression and activity of Akt1. Interestingly, the increase in Akt1 mRNA in HoxA5 expressing endothelial cells is observed only when cells are plated in 3DhBM but not in conventional 2D tissue culture plastic, suggesting that signaling through the BM facilitates HoxA5 mediated transcriptional activation. Indeed, pre-incubation of HoxA5 expressing endothelial cells with function blocking antibodies against β4 integrin impaired the HoxA5 dependent increases in Akt1 mRNA expression. To determine whether culturing on 3DhBM impacts chromatin organization and/or accessibility of Hox A5 to target genes, we pre-treated cells cultured in the absence of 3DhBM with an inhibitor of histone deacetylases. Incubation with Trichostatin-A restored the ability of HoxA5 to activate Akt1 mRNA in the absence of 3DhBM. Together our results suggest that signaling through the BM cooperates with HoxA5 to promote accessibility to downstream target genes and the formation of stable capillary networks.

Interaction of Alpha Actinin 4 with NFkB in Human Keratocyes Depends on Extracellular Matrix Proteins

D. Tentler,1 L. Turoverova,1 V. Babakov,1 O. Petukhova,1 A. Bolshakova,1 K. Magnusson,2 G. Pinacv; 1Dept. of Cell Cultures, Institute of Cytology, Russian Academy of Sciences, St. Petersburg, Russian Federation, 2Division of Medical Microbiology, Linkoping University, Linkoping, Sweden

The NFkB protein complex is a second messenger, which activates transcription of a number of genes in various tissues. The most abundant form of NFkB protein complex is a heterodimer of the p55 DNA-binding subunit and the weak DNA-binding subunit p65. The p50/p65 complex also interacts with a number of other proteins regulating its activity. The inactive form of the NFkB complex translocates from the cytoplasm into the nucleus. The exact mechanism for this remains unclear. We have earlier demonstrated that p65 subunit can interact with the actin-binding protein alpha actinin 4 (actn4), which proposes an important role of the cytoskeleton in the NFkB translocation. In order to elucidate a possible role of actn4 in the NFkB function, we investigated its distribution in nuclear keratocytes complexes. The complexes were purified by the immuno-precipitation with p65 antibodies from normal and transformed (epidermoid carcinoma cell line A431) human keratocyes cultured on different substrates such as plastic, collagen 1, collagen IV, laminin 2/4 and fibronectin. Western blot analysis of the actn4 in the purified complexes showed that not all of the complexes containing p65 had actn4. The distribution of the nuclear complexes with both p65 and actn4 depended on the substrate, and changed after the EGF treatment. Moreover, the amount of complexes with p65 and actn4 was different in the normal and transformed cells. The data provide evidence that the extracellular matrix may regulate NFkB activity through the actin cytoskeleton. The differences in distribution of p65/actn4 complexes between normal and transformed keratocytes may also signify that there is a mechanism of NFkB pathway regulation specific for cancer cells.

Does Discoidin Domain Receptor 2 Recognize the Fibrillar State of Collagen?

D. Garbellini, C. Mihal, G. Agarwal; Dorothy Davis Heart and Lung Research Institute, The Ohio State University Medical Center, Columbus, OH

Discoidin domain receptors (DDRs) are widely-expressed cell surface receptors belonging to the tyrosine kinase family. Earlier studies have shown that collagen are their ligand and their activation leads to up-regulation of matrix-metalloproteases (MMPs). It has also been noted in earlier observations that the activation of the DDR kinases by collagen follows a delayed time course relative to conventional growth factor receptors. This delay could be due to that time it takes for collagen to achieve a particular fibrillar state. What remains to be explored is if DDR-activation leads to up-regulation of matrix-metalloproteases (MMPs). It has also been noted in earlier observations that the activation of the DDR kinases by collagen follows a delayed time course relative to conventional growth factor receptors. This delay could be due to that time it takes for collagen to achieve a particular fibrillar state. What remains to be explored is if DDR-activation leads to up-regulation of matrix-metalloproteases (MMPs). In this study we employed cell-based assays and stimulated DDR2-transfected cells with collagen in fibrillar or non-fibrillar form. Our results show that activation of DDRs was enhanced when collagen was in a fibrillar state as compared to a monomeric state. Further, our in-vitro binding assays confirm that DDR2 binding is enhanced when collagen is in a fibrillar state. These observations together with our earlier results [1-2] may provide new insights on how DDR2 influences the deposition of collagen and the process of fibrosis. Ref: [1] Agarwal G. et al "Binding of DDR2 to Collagen type 1", Biochemistry, 2002 Sep 17;41(37):11091-8 [2] Mihal C. et al "DDR2 inhibits fibrillogenesis of collagen type 1" JMB
proteins. After the screening of 4 × 10^7 colonies, 133 positive clones were selected. While NSP is an intracellular protein, 52% of the clones encoded genes for extracellular matrix proteins, including Collagen type 1 alpha2 (Col1a2), 30%; Col1a1, 5%; Fibulin 2 (Fbn2), 4%; Laminin receptor 1 (Rpsa), 4%. Coimmunoprecipitation experiments using in vitro translated proteins confirmed binding of NSP-N to the fibrillar collagens C-terminal domain (COL2A1). Although the physiological significance of the interactions is currently under investigation, these results revealed that NSP interacts with fragments of extracellular matrix proteins at least under the tested condition.

2399 An α-Dystroglycan Binding Peptide Derived from the Laminin α2 Chain
M. Nomizu, T. Yoshimura, N. Suzuki, S. Urasuhita, Y. Kikawa; Tokyo Univ. of Pharm. and Life Sci., Hachioji, Japan
Laminins, consisting of α, β, and γ chains, are major components of basement membranes and have diverse biological activities. The laminin α2 chain, which is a component of laminin-2/4/12, is mainly expressed in skeletal muscles or peripheral nerves and interacts with dystroglycan and heparan sulfate proteoglycans. Here, we focused on the laminin α2 chain LG4-5 module and to identify their heparin and dystroglycan binding activities to better understand the biological function of the molecule. We prepared a recombinant laminin α2 chain LG4-5 module (res-α2LG4-5) using 293T cells. The rec-α2LG4-5 showed heparin and α-dystroglycan binding activities. To identify the binding sites in the laminin α2 chain LG4-5 module, we synthesized 42 overlapping peptides covering the entire molecule. First, we examined the effect of the peptides on the heparin binding of rec-α2LG4-5. The A2G78 peptide (GLIFYMARINHA, mouse laminin α2 chain 2796-2807) inhibited the heparin binding of rec-α2LG4-5. A2G78 showed heparin binding activity in a solid phase binding assay. The minimal active sequence of A2G78 for heparin binding was found to be LLYFMAR1. Next, we tested the α-dystroglycan binding activity of the A2G78 sequence. The A2G78 peptide showed inhibitory effect on α-dystroglycan binding to the rec-α2LG4-5 protein. These results suggest that the A2G78 site plays an important role in the interaction of rec-α2LG4-5 with heparin/heparan sulfate and α-dystroglycan and the peptide is useful to investigate the α-dystroglycan mediated biological functions.

2400 Receptor for Advanced Glycation End Products (RAGE) Signaling Stimulated by S100A4 Increases Chondrocyte Matrix Metalloproteinase-13 Production
R. Yammani; Molecular Medicine, Internal Medicine, Wake Forest School of Medicine, Winston-Salem, NC
S100A4 belongs to a family of 100 calcium binding proteins which function both intracellularly and extracellularly. In the current study, treatment of chondrocytes with exogenous S100A4 was found to increase production of MMP-13. Soluble RAGE and AGE-BSA blocked the production of MMP-13 suggesting a role for RAGE. A pull down assay found that RAGE co-precipitates with S100A4, confirming S100A4-RAGE association. Increased production of MMP-13 was found associated with increased phosphorylation of MAP kinases and NF-κB. Pretreatment with MetTAP, an antioxidant, followed by S100A4 stimulation blocked the production of MMP-13, suggesting the role for ROS in S100A4 stimulation of MMP-13. BAPTA-AM, an intracellular calcium scavenger also inhibited MMP-13 production upon stimulation with S100A4. However, nifedipine, an L-type calcium channel blocker had little inhibition suggesting a role for intracellular calcium levels. Pyk-2, a non-receptor calcium dependent tyrosine kinase was also found phosphorylated upon S100A4 stimulation. Inhibition of phosphorylation of Pyk-2 by either BAPTA-AM or triflupin A9 blocked the downstream activation of MAP kinases especially JNK and the transcription factor NF-κB with subsequent inhibition of MMP-13 production. This suggests a major role for Pyk-2 along with ROS in S100A4-RAGE mediated production of MMP-13. Our study also found that chondrocytes express S100A4 and its expression was up regulated in osteoarthritic (OA). Taken together, we conclude that in chondrocytes, S100A4 serves as a RAGE ligand and activates a signaling cascade leading to increased production of MMP-13. Since both S100A4 and RAGE are up regulated in OA cartilage, this signaling pathway could contribute to cartilage degradation in OA.

2401 Undersulfation of Chondroitin Sulfate Proteoglycans Results in Reduced Chondrocyte Proliferation via the Indian Hedgehog Signaling Pathway
M. Cortes,1 A. Baria,2 J. Henry,2 N. B. Schwartz;1 1Biochemistry and Molecular Biology, University of Chicago, Chicago, IL, 2Pediatrics, University of Chicago, Chicago, IL
The functional role of heparan sulfate proteoglycans (HSPGs) in regulating signaling pathways such hedgehog (Hh), Wingless-type (Wnt) and fibroblast growth factor (FGF) has been previously described. In contrast, the role of chondroitin sulfate proteoglycans (CSPGs) in these signaling pathways remains elusive. PAPS synthetase 2 (PAPSS2) is one of the two isoforms responsible for the synthesis of PAPS, the universal sulfur donor. The brachymorphic (bm) mouse is a PAPSS2 kinase mutant characterized by preferential undersulfation of CS chains and 50% reduction in limb length. In situ hybridization analysis of the bm mouse growth plate with various markers, performed to determine whether signaling pathways regulating chondrocyte proliferation and differentiation are affected by undersulfation, revealed reduced mRNA levels of Indian hedgehog (Ihh), and Patched (Ptc). Immunostaining with Ihh and Parathyroid hormone related peptide (PTHrP) antibodies showed decreased extracellular diffusion of both signaling molecules in the bm mouse growth plate compared to wildtype. Consistent with reduced Ihh signaling, BrDU labeling experiments of post-natal day 6 growth plates showed a significant decrease in chondrocyte proliferation, specifically in the proliferative zone. In order to determine if CSPGs directly interact with Ihh, binding experiments with N-Ihh AP-fusion protein and various forms of chondroitin sulfate (CS) and heparan sulfate (HS) chains revealed that HS-C, CS-4, CS-6, and CS-0 interact with Ihh with decreasing binding affinities, via hedgehog’s proteoglycan binding domain. Mutations of the Indian hedgehog proteoglycan binding domain result in complete loss of binding to both HS and CS chains. In sum, undersulfation of CSPGs in the brachymorphic mouse results in reduced chondrocyte proliferation due to diminished Ihh signaling, and sulfation of CSPGs is required for Ihh interaction via its conserved proteoglycan binding domain.

2402 C-Src Signaling Promotes Phagocytosis of αvβ5 Integrin-bound Photoreceptor Particles
S. C. Finneman,1 Y. Chang,1 M. Anand1; 1Dyson Vision Research Institute, Weill Medical College-Cornell University, New York, NY, 2Dyson Vision Research Institute, Graduate Program in Physiology, Weill Medical College-Cornell University, New York, NY
Retinal pigment epithelial (RPE) cells are among the most actively phagocytic cell types. Every morning, each RPE cell in the retina engulfed and digests numerous outer segment fragments (OS) shed in a circadian rhythm by adjacent photoreceptor neurons. Daily, synchronized OS clearance by RPE cells is critical for vision. Mechanistically, phagocytosis of OS by RPE cells is similar to engulfment of apoptotic cells by other phagocytes. OS recognition by apical (OS) shed in a circadian rhythm by adjacent photoreceptor neurons. Daily, synchronized OS clearance by RPE cells is critical for vision. Mechanistically, phagocytosis of OS by RPE cells is similar to engulfment of apoptotic cells by other phagocytes. OS recognition by apical OS shedding by photoreceptor neurons is essential to trigger particle engulfment. Here, we test whether and which Src family kinases (SFK) link OS-phagocytosis to MerTK activation and retinal phagocytosis. Furthermore, they show that FAK activation requires c-Src activation to promote phagocytosis. In contrast, active c-Src is sufficient to stimulate phagocytosis independently of FAK.

2403 14-3-3ζ Up-regulates MMP-2 (type IV Collagenase) Expression
E. Lee, S. Park; Pathology, Inha University, Incheon, Republic of Korea
14-3-3ζ is a highly conserved acidic protein family, composed of seven isoforms in mammals and involved in cellular processes like signal transduction, cell cycle arrest, and apoptosis. In this study, we demonstrate that the expression of 14-3-3ζ gene up-regulates the expression of MMP-2 gene independent of TIMP-1 levels. MMP-2, 72kDa enzyme, degrades multiple ECM components, including gelatins, type IV and V collagens. Overexpression of 14-3-3ζ protein induced MMP-2 mRNA and its protein expression in both NIH3T3 fibroblast and human keratinocyte cells. In addition, expression of 14-3-3ζepilson increased the secretion of MMP-2 and MMP-9. These up-regulations of MMP-2 by 14-3-3ζepilson were partially blocked by p38 MAPK inhibitor SB203580. These results strongly suggest that 14-3-3ζ induces MMP-2 expression via p38 MAPK signaling pathway.
Adhesion-induced Actin 1 and Actin 4 Redistribution in A431 Cells Spread on Fibronectin and Laminin 2/4
A. Bohlakova,1 Q. Petukhova,1 L. Turoverova,1 V. Babakov,2 D. Tenler,1 K. I. Magnusson,2 G. Pinacev;1 1Cell Cultures, Institute of Cytology, St. Petersburg, Russian Federation, 2Medical Microbiology, Ludwig Institute, Cape Town, South Africa
2404
Alpha-actinin 1 and 4 belong to family, originally described as actin-binding proteins in non-muscle cells. They share about 80 % of homology but play different roles in cell motility and adhesion. Actinin 4 is more abundant in highly motile cells especially in the dorsal ruffle. In contrast to actin 1, actin 4 is prone to the nuclear translocation and interaction with transcription factors. To delineate functional differences between the actinins, we assessed actinin redistribution after EGF stimulation in A431 cells, conventionally cultivated on plastic or spread on either fibronectin or laminin 2/4, using confocal microscopy and Western-blot. Both actinin 1 and 4 colocalized with cytoplasmic F-actin in spread cells and reorganized with F-actin after EGF stimulation. Moreover, actinin 1 accumulated near the nuclear membrane, and actinin 4 in the nucleus. A truncated form of actinin 4 resided in the cytoplasm of conventionally grown cells and truncated actinin 1 appeared after cell spreading, which was diminished with cytochalasin D. In nuclear extracts the antibody to actinin 4 precipitated full-size actinin 4, a truncated actinin 4 different from the cytoplasmic one, and an unknown, high molecular weight protein. These were found both in the nuclear protein fraction with transcription factors, and in the chromatin fraction. The redistribution between these nuclear fractions differed between normally cultivated cells and cells spread on fibronectin or laminin 2/4. This suggests that differences in the sub-cellular distribution of actinins can be explained by the appearance of truncated actinins regulated by the cell adhesion. Thus, the function(s) of actinin 4 in the nucleus could be regulated by specific cell adhesions, also affecting its partitioning between the chromatin- and transcription factor- containing protein pools. Beta-1 Integrin Regulates Epithelial Polarity through Rho GTPases
W. Yu, M. Zegers, K. Mostov;1 1Anatomy, University of California, San Francisco, San Francisco, CA, 2Surgery, University of Cincinnati, Cincinnati, OH
2405
The kidney is primarily comprised of epithelial cells. Epithelial cells are highly polarized and their plasma membrane is divided into discrete domains. The apical surface faces the lumen and the basolateral surface interacts with other cells and underlying extracellular matrix. Establishment and maintenance of polarity is critical to the functioning of epithelial cells. Most work on epithelial polarization has used cells grown on artificial filter support. We have used a three dimensional culture system in which is closer in vivo to study how β1 integrin and Rho GTPases coordinate to control the epithelial polarization. Individual Madin-Darby canine kidney (MDCK) cells grown in collagen gel from cyst spherical cysts comprising a monolayer of cells surrounding a hollow lumen. The cells are polarized. The β1 integrin function-blocking antibody A7B2 gives rise to cysts with inverted polarity. We showed that normal polarity is restored by either expression of constitutively active Rac or expression of exogenous laminin. We also found that inhibition of ROCK, a major effector of RhoA, or inhibition of myosin not only revert β1 integrin blocking induced phenotype, but also polarize the expression induced by expression of dominant-negative Rac. These findings indicate that β1 integrin orients polarity through Rho GTPases and laminin assembly.

Epithelial-Mesenchymal Transition via Actin Organization in Integrin α5-Expressing Cells
M. Oh, J. Lee;1,2 1Department of Tumor Biology, Cancer Research Institute, College of Medicine, Seoul National University, Seoul, Republic of Korea, 2Department of Molecular and Cell Oncology, Cancer Research Institute, College of Medicine, Seoul National University, Seoul, Republic of Korea
2406
Cell adhesion receptor integrins are well-known to transduce signaling activities leading to actin reorganization on integrin-extracellular matrix (ECM) protein engagement. This integrin-mediated actin reorganization is prerequisites of diverse cellular functions including epithelial-mesenchymal transition (EMT) and cell migration. In this study, the significance of integrin α5β1 signal transduction in actin reorganization leading to regulation of EMT and cell migration was explored by using normal rat intestinal epithelial cells. Whereas ectopic expression of integrin α5β1 wildtype responded to an actin-disturbing reagent by showing an EMT and severe retraction in morphology depending on c-Src and PI3K activities, cytoplasmic tailless mutant α5β1 caused no such changes and retarded migration. Expression of tailless α5β1 resulted in more focal adhesions and actin fibers along the cell-cell contacts, irrelevant to c-Src and PI3K inhibition. PKCδ inactivation via rotlinn or dominant negative adeno-PKCδ infection of wildtype α5β1-expressing cells abolished the actin disruptor-mediated EMT. Adeno-PKCδ wildtype infection to tailless α5β1 cells rendered the sensitivity to actin disruptor for EMT. Altogether, these observations indicate that integrin α5β1, but not tailless mutant α5β1, regulates dynamically actin organization especially along the cell-cell contacts sites leading to efficient regulation of migration.

Tension Induces a Conformational Change in α5β1 Integrin-Fibronectin Bonds That Controls Downstream Signals

Integrin β3 Integrin Ligand Binding Is Regulated by Serine Phosphorylation of the β3 Cytoskeletal Tail
A. M. Gonzalez, J. C. R. Jones; Cell and Molecular Biology, The Feinberg School of Medicine at Northwestern University, Chicago, IL
2408
Previously we demonstrated that integrin α5β1 antagonists negatively regulated α5β3 integrin-ligand binding in endothelial cells. To determine the mechanism regulating α5β3 integrin activation, we performed vitronectin binding assays on endothelial cells in suspension. Vitronectin binding was significantly inhibited upon β1 integrin clustering using antibody 656, indicating that 656-modulated α5β3 integrin affinity. Since talin is known to regulate integrin affinity, we assessed whether over-expression of talin would abrogate the impact of β1 integrin clustering on α5β3 integrin-ligand binding. It did not. Rather, β1 integrin clustering resulted in a two-fold increase in protein kinase A (PKA) activity and serine phosphorylation of β3 integrin. Inhibition of PKA activity rescued cell adhesion in the presence of β1 integrin antibodies and blocked β3 integrin serine but not tyrosine phosphorylation. These results indicated that affinity modulation of α5β3 integrin involves β3 integrin serine phosphorylation. β3 integrin contains a serine residue at position 752. To confirm the importance of this residue, we mutated it to alanine (β3S752A) or aspartic acid (β3S752D), expressed wild-type and mutated proteins in CHO cells and assessed cell adhesion to α5β3 integrin ligand. Cells expressing wild-type or β3S752A integrin attached robustly to ligand. Cells expressing β3S752D integrin did not. Since the β3 cytoskeletal tail lacks a PKA consensus site, it was unlikely that PKA is acting on β3 integrin. Rather, we tested the hypothesis that PKA inhibits the calcineurin/inhibitor-1 pathway, blocking the activation of protein phosphatase 1 (PP1) that, in turn, regulates β3 phosphorylation. In support of this, blocking PP1 activity in the presence of β1 integrin and PKA antagonists inhibited α5β3 integrin adhesion and resulted in β3 integrin serine phosphorylation. These results indicate a novel mechanism via which clustered β1 integrin negatively modulates α5β3 integrin-ligand binding. In this mechanism, PKA and PP1 play antagonistic roles in regulating 4 residue of α5β3 integrin.

Integrin α6β4 Chelation

We have previously identified a structural variant of the α6 integrin (Laminin receptor) called α6p. The α6p variant is a 70 kDa form of the full-length α6 integrin (140 kDa) that is paired with either the β1 or β4 subunit on the cell surface. α6p is produced by removal of the extracellular β-barrel domain while the receptor is on the cell surface. Urokinase-type plasminogen activating
(uPA) cleaves the α6 integrin directly without the involvement of plasmin. Using site directed mutagenesis we have determined the site of cleavage on the α6 integrin. In order to determine whether α6p occurs in tissue, we have found that α6p is present in mouse papillomas and squamous cell carcinomas induced by DMBA, TPA and MNNG treatments. Subcutaneous injection into athymic nude mice of a malignant mouse keratinocyte derived cell line (6M90) that is α6p negative, results in the development of tumors that contain α6p integrin. Taken together, these data suggest that the cell surface clipping of the α6 integrin occurs in tissue and may be an important step during skin tissue remodeling and during carcinogenesis. We are currently investigating the distribution of α6p in human and mouse tissues, using immunohistochemistry approaches.

2410 Oscillation of GPIIb/IIIa Surface Expression on Platelets
Y. Ma, K. Wong; Research and Development, Canadian Blood Services, Edmonton, AB, Canada

Background. It was observed that GPIIb/IIIa expression on platelets fluctuated to varying extents between samples or platelet rich plasma preparations. An objective of the present study was to show that such fluctuations were due to more than assay noise. Method. The expression of GPIIb/IIIa on platelets was studied by flow cytometric analysis of platelet rich plasma (PRP) sampled periodically, fixed and tagged with fluorochrome-conjugated, anti-GPIIb mAb. Results show that GPIIb/IIIa fluctuations of live platelets were significantly greater than that of prefixed cells. Periodicity in GPIIb/IIIa time series was not discerned but fluctuations in GPIIb/IIIa and forward scatter were positively correlated. Surface GPIIb/IIIa amplitudes subsided with storage within 140 min but increased with vigorous agitation of PRP. The former correlated with transient activation of platelets in PRP induced by processing. PAC-1 mAb binding shows that GPIIb/IIIa oscillated concomitantly at a low level between active and inoperative conformations. The average amplitude of such oscillations declined similarly after 140 min. Compared with room temperature results, PAC-1 binding oscillated with greater amplitudes at 4°C, an activating milieu for platelets. Surface GPIIb/IIIa increased slowly in washed platelets after > 6 h storage at room temperature. Cytochalasin B inhibited this rise in GPIIb/IIIa while exposing an underlying oscillation. Conclusions. GPIIb/IIIa surface expression and activation oscillated at a low level in nominally resting platelets. Present results suggest that GPIIb/IIIa oscillated between an inner and outer compartment independently of actin filament polymerization. It is proposed that subacute activation of platelets reduced cytoskeletal restraints on integrin movements, and GPIIb/IIIa interconversion between active and inoperative conformations.

2411 The Role of Calcium on the Reassociation of the Glycoprotein IIa-IIIb Complex in EDTA-treated Platelets
Y. Ma, K. Wong; Research and Development, Canadian Blood Services, Edmonton, AB, Canada

Incubation of platelets with EDTA at 37°C at alkaline pH causes GPIIb-IIIa (integrin, dIb/III) to dissociate into monomeric subunits. The objective of this study was to demonstrate that this dissociation and consequent loss of function were reversible. GPIIb-IIIa was measured by flow cytometric analysis of platelets labeled with fluorophore-conjugated mAbs specific for the glycoprotein complex or a monomer. In agreement with previous studies, EDTA chelation of extracellular calcium, [Ca^2+]_, caused the heterodimer to dissociate in a time and temperature dependent manner. Resuspension and incubation of platelets in nM [Ca^2+]_ allowed reassociation of GPIIb-IIIa in a manner dependent on [Ca^2+]_. While complete GPIIb-IIIa reassociation was induced by thrombin independently of [Ca^2+]_, Suppression of rises in cytosolic calcium concentration by BAPTA blocked the effect of all three agonists. Thus, internal Ca^2+ release was necessary and sufficient for the thrombin effect while Ca^2+ influx was necessary for the collagen and ADP effects. The aggregatory response of EDTA-treated platelets was inhibited differently depending on the agonist and was not correlated with the extent of GPIIb-IIIa reassociation. In conclusion, EDTA-induced changes in platelets were variably reversed depending on the agonist used and the cellular parameter measured.

2412 MyH9 (Non-muscle Myosin Heavy Chain-IIA) Provides a Key Mechanical Link between Integrin LFA-1 and the Cytoskeleton during T Cell Migration
N. A. Morin,* Y. Hyan,* P. W. Oakes,* J. X. Tang, E. Y. Chin,* J. S. Rechiner,* M. Kim; Surgery, Brown Medical School, Rhode Island Hospital, Providence, RI, *Physics, Brown University, Providence, RI

The process of cell migration involves at least three interdependent events including attachment of active integrin at the leading edge, cell contraction, and integrin detachment at the trailing edge. To identify key cytoskeletal molecules that allow LFA-1 de-adhesion from ICAM-1 during efficient T cell migration, LFA-1 was immunoprecipitated selectively from adherent human primary T cells on ICAM-1 substrate. Mass spectrometry analysis revealed that MyH9 is recruited to LFA-1 together with αL, β2 integrin, and the cytoskeleton during T cell migration. MyH9 transfected T cells showed the distinct distribution of MyH9 at the uropod of migrating T cells. Blebbistatin, a highly specific inhibitor of class II myosin ATPase activity, blocked MyH9 association with LFA-1 and resulted in extreme uropod elongation, defective tail detachment, and reduction in overall migration on ICAM-1 substrate. Dynamic LFA-1 activation by SDF-1, distribution of active LFA-1 at the leading edge, and periodic contraction of lamellipodia of migrating T cell were not affected by blebbistatin, suggesting MyH9 recruitment to LFA-1 is necessary for the collagen and ADP effects. The aggregatory response of EDTA-treated platelets was inhibited differently depending on the agonist and was not correlated with the extent of GPIIb-IIIa reassociation. In conclusion, EDTA-induced changes in platelets were variably reversed depending on the agonist used and the cellular parameter measured.

2413 EHD1 Regulates Beta-1 Integrin Endosomal Transport: Effects on Focal Adhesions, Cell Spreading, and Migration
M. Jovic,* N. Naslavsky,* D. Rapaport,* M. Horowitz,* S. Caplan; *University of Nebraska Medical Center, Dept. of Biochemistry and Molecular Biology, University of Nebraska Medical Center, Omaha, NE, *Dept. of Cell Research and Immunology, Tel Aviv University, Ramat Aviv, Israel

Beta-1 integrins bind to the extracellular matrix and stimulate signaling pathways that lead to a variety of critical cellular functions, including proliferation, apoptosis, cell spreading and migration. Consequently, control of beta-1 integrin function depends upon its subcellular localization, and current research aims at unravelling the complex regulatory mechanisms involved in beta-1 trafficking. Recent studies have identified the C-terminal EH domain-containing protein, EHD1, as a regulator of endocytic recycling for receptors internalized either through clathrin-coated pits or in a clathrin-independent manner. Furthermore, it has been shown that EHD proteins functionally interact with ARF6 and coordinate recycling events with Rab6 and Rab11, both of which are known regulators of integrin trafficking. Our current objective is to further elucidate the role EHD1 plays in regulating beta-1 integrin transport. Recently we have shown that the RNAi knockdown of EHD1 results in impaired recycling of beta-1 integrins and their accumulation in a transferrin-containing endocytic recycling compartment. The role of EHD1 in beta-1 integrin recycling was further assessed by using embryonic fibroblasts derived from EHD1 knockout mice (MEF-/-). These cells exhibited decreased levels of beta-1 integrins on the plasma membrane and longer, more prominent focal adhesions, resulting from slower kinetics of focal adhesion disassembly. The delay in beta-1 integrin recycling and the decreased rate of focal adhesion turnover impaired the ability of MEF-/- cells to migrate and spread on fibronectin. These defects could be similarly induced by EHD1-RNAi treatment of normal MEF +/- cells. They could also be rescued by transfection of wild-type EHD1 into MEF-/- cells. Our data supports a role for EHD1 in the recycling of beta-1 integrins, and demonstrates that loss of EHD1 impairs integrin-mediated downstream functions.

2414 Stimulation of Clearance Phagocytosis by the Tetrapsin CD81 Requires αvβ5 Integrin
Y. Chang,1 S. C. Finnemann 2,3; 1Dyson Vision Research Institute, Graduate Program in Physiology, Biophysics and Systems Biology, Weill Medical College of Cornell University, New York, NY, 2Dyson Vision Research Institute, Department of Ophthalmology, Weill Medical College of Cornell University, New York, NY, 3Graduate Programs in Cell and Developmental Biology, and Physiology, Biophysics and Systems Biology, Weill Medical College of Cornell University, New York, NY

Retinal pigment epithelial (RPE) cells are among the most active phagocytes in the body. Every morning, circadian shedding of photoreceptor outer segment fragments (POS) activates a prompt phagocytic response by RPE cells that is critical for vision. RPE cells employ αvβ5 integrin to recognize POS and to stimulate Mer tyrosine kinase (MerTK) activation that is essential to trigger POS engulfment. RPE cells lacking MerTK bind POS via αvβ5 but fail to internalize bound POS. In contrast, RPE cells lacking αvβ5 show greatly decreased POS binding. Like αvβ5, the tetrapsin CD81 is abundantly expressed at the apical, phagocytic surface of the RPE. Here, we test whether CD81 contributes to POS uptake. CD81 overexpression increased function of CD81 protein down-regulation by RNA silencing decreased binding but not internalization of isolated POS by RPE cells. Conversely, CD81 overexpression by transient transfection increased POS binding. These effects were specific for CD81 as similar experiments expressing or inhibiting function of CD9, another tetrapsin at the phagocytic surface of RPE cells, had no effect on POS uptake. Wild-type RPE cells and RPE cells lacking the engulfment receptor MerTK equally reduced and increased POS binding in response to CD81

2006 ASCB Annual Meeting Abstracts
inhibition and CD81 overexpression, respectively. In striking contrast, neither CD81 inhibition nor CD81 overexpression had any effect on POS binding by RPE cells lacking αvβ5 integrin. Furthermore, CD81 and αvβ5 formed a complex at the apical surface of wild-type RPE cells and shared similar detergent resistance. Taken together, our results identify a novel role for CD81 in POS binding by the RPE. They demonstrate that CD81 does not function as phagocytic receptor by itself but increases particle binding through functional and possibly physical interaction with αvβ5 integrin. To our knowledge, this is the first report of transsialin function in integrin-dependent phagocytosis by any cell type.

Cell Surface Proteoglycans in αβ1 Integrin-mediated Cell Adhesion to Collagen

K. Vuoriluoto, J. Ivaska; VTT Medical Biotechnology, University of Turku, Turku, Finland

We have investigated whether cell-surface proteoglycans play a role in cell-collagen interactions. Collagen receptor null Chinese hamster ovary (CHO) cells transfected to express αβ1 integrin became able to bind to and spread on type I collagen. Interestingly, proteoglycans are also required for αβ1 mediated adhesion to collage, since mutated CHO cell lines lacking HS and chondroitin sulfate (CS) glycosaminoglycan chains show impaired αβ1 mediated adhesion to collage. Importantly, this requirement applies to other cell types as well since enzymatic disruption of HS and CS from MDA-MB-231 human mammary carcinoma cells results in defects in αβ1-mediated adhesion to collagen. Impaired adhesion to type I collagen in cells lacking glycosaminoglycan chains is reflected in their inability to assemble integrin containing focal adhesion and in dramatic changes in the actin cytoskeleton. The requirement for proteoglycans applies only to adhesion to monomeric collagen since HS and CS disruption influence adhesion to fibronectin and fibrillar collagen only moderately. Furthermore, adhesion to the specific αβ1 recognition sequence, FGOGER, is not affected by the absence of HS and CS glycosaminoglycan chains, suggesting that proteoglycan co-receptors are required only for adhesion to full-length collagen. Integrin αβ1 is a known regulator of matrix metalloproteinase-1 (MMP-1) gene expression. Using a luciferase reporter construct, we show that αβ1 mediated activation of MMP-1 is also dependent on proteoglycans since MMP-1 activation in response to collagen is impaired in CHOαβ1 cells lacking HS. Finally, wound healing experiments have shown that CHOαβ1 cells lacking HS have a decreased migratory ability when plated on type I collagen. In summary, our results suggest that proteoglycans function as co-receptors with integrins in collagen adhesion, migration and cell signalling.

Dominant-Negative β1 Integrin Mice Have Region-specific Myelin Defects Accompanied by Alterations in MAPK Activity and Oligodendrocyte Behavior

K. K. Lee,1,2 Y. De Repentigny,1 R. Saulnier,1 P. Rippstein,3 W. B. Macklin,4 R. Kothary1,2,5; 1Molecular Medicine, Ottawa Health Research Institute, Ottawa, ON, Canada, 2Cellular and Molecular Medicine, University of Ottawa, Ottawa, ON, Canada, 3Department of Neurosciences, The Lerner Research Institute, Cleveland, OH, 4Department of Medicine, University of Ottawa, Ottawa, ON, Canada

Myelination is a process by which oligodendrocyte precursor cells proliferate, migrate and differentiate into mature oligodendrocytes within the CNS, and eventually form a myelin sheath. Recent studies have demonstrated the importance of β1 integrin in oligodendrocyte maturation in vitro. Here, we demonstrate the importance of β1 integrin in myelination in vivo. We have generated a transgenic mouse line that expresses a dominant-negative β1 integrin ΔC transgene under the control of the protocoll protein (PLP) promoter that drives expression of the transgene specifically to CNS tissues. The dominant-negative β1 integrin ΔC transgenic mice have hypomyelinated and increased numbers of unmyelinated axons in the spinal cord and the optic nerve, however the corpus callosum remains unaffected. The dominant-negative β1 integrin ΔC transgenic mice, under a demyelination and remyelination model, demonstrated significantly reduced number of remyelinated axons within the corpus callosum when compared with wild type mice. The defects in myelination and remyelination in the dominant-negative β1 integrin ΔC mice were attributed to the disruption of the MAPK signaling pathway. Histological and immunohistochemical analysis on sections of tissues from the central nervous system is allowing us to determine whether the numbers of proliferating oligodendrocyte progenitors and/or mature oligodendrocytes are affected in the dominant-negative β1 integrin ΔC mice. Our work highlights the importance of β1 integrin-mediated signalling in CNS myelination and remyelination in vivo.

NGF as a Ligand for α9β1 Integrin Initiates Progression of Glioblastoma

I. Staniszewska,1 M. Higgins,1 P. Lazarowicz,2 C. Marcinkiewicz2; 1Department of Neuroscience, Temple University, Philadelphia, PA, 2Department of Pharmacology, Hebrew University, Jerusalem, Israel

The α9β1 integrin is characterized as receptor for ligands including VCAM-1, tenasin-C, osteopontin, TSP-1 and certain ADAMs family members and two growth factors, VEGF-C and VEGF-D. In presented studies we found that α9β1 integrin is a receptor for nerve growth factor (NGF). Adhesion and ELISA assays revealed that this integrin is a high affinity receptor for NGF, similar to previously characterized trKA. NGF also induced signal transduction in cells expressing α9β1 integrin, including phosphorylation of MAPK Erk1/2 and paxillin. Using adhesion, flow cytometry, immunocyto staining and immunoprecipitation assays we found α9β1 integrin expressed on the surface of grade IV astrocytoma cell line, LN229, whereas normal human astrocytes and grade III astrocytoma cell lines showed no presence of this integrin. This finding indicates that expression of α9β1 integrin may be related to malignancy of glioblastoma multiformes (GBM), although another grade IV glioma cell line, LN18, does not express this integrin. We found that NGF induced proliferation of LN229 cells, whereas it inhibited proliferation of LN18 cells. This phenomenon could be explained that NGF-promoted proliferation is related to its binding to α9β1 integrin, but in the absence of this integrin NGF binds to low affinity receptor p75NTR. We found this receptor on both cells, however, in the absence of high affinity pro-survival receptor, α9β1 integrin, p75NTR, dominates and following interaction with NGF leads to induction of apoptosis, which blocks of proliferation of LN18 cells. NGF was also potent chemotactant for LN1229 cells in the Boyden chamber, in the contrast to LN18 cells. The pro-attractive and pro-migratory ability of LN229 cells induced by NGF was abolished following silencing of α9 integrin subunit using siRNA method. Moreover, specific inhibitors of α9β1 integrin such as disintegrin, VLO5 and monoclonal antibody V9A2, blocked NGF interaction with α9β1 integrin in adhesion, proliferation and migration assays.

The Integrin Alpha9Beta1 Contributes to Granulopoiesis by Modulating G-CSF Receptor Signaling

C. Chen, X. Huang, D. Sheppard; Lung Biology Center, UCSF, San Francisco, CA

The integrin α9 subunit forms a single heterodimer, α9β1, and is widely expressed on neutrophils, smooth muscle, hepatocytes, endothelia and some epithelia. We found that integrin α9-deficient mice had a dramatic defect in neutrophil development, with decreased numbers of circulating neutrophils, decreased numbers of granulocyte precursors in bone marrow, and impaired differentiation of bone marrow cells into granulocytes. In response to the neutrophil growth and differentiation factor, granulocyte colony stimulating factor (G-CSF), α9-deficient bone marrow cells or human bone marrow cells incubated with α9β1 blocking antibody demonstrated decreased phosphorylation of STAT5, an early target of G-CSF receptor signaling, and decreased phosphorylation of the G-CSF receptor. Ligation of integrin α9β1 in the hematopoietic cell line, BaF3, enhanced G-CSF-induced phosphorylation of Erk1/2 and STAT3 but had no effects on activation of STAT5 or Akt. These effects both depend on the presence of an intact α9β1 subunit cytoplasmic domain and the distal region of G-CSF receptor cytoplasmic domain. We conclude that integrin α9β1 is required for granulopoiesis and that integrin ligation enhances activation of a specific subset of signaling intermediates downstream of the G-CSF receptor.

Fatty Acid Binding Proteins (FABPs) as Modulators of Integrin Function in Breast Cancer Cells

J. B. Nero, J. Ivaska; Centre for Biotechnology, University of Turku, Turku, Finland

The cells need to connect to each other and to the surrounding matrix to form tissues. Integrins are major cell surface receptors mediating cell-cell and cell-matrix interactions and play a critical role in many vital cellular functions like cell migration, adhesion, tissue organization, and the regulation of cell survival, differentiation and proliferation. The role of integrin β subunit in cell signalling has been studied in detail, whereas very little is known about the signaling functions mediated by the integrin α cytoplasmic tails. I have been involved in screening for protein-protein interactions with the yeast-two hybrid method using the α cytoplasmic tails of the collagen binding integrins α11, α21, α31 and α111 as baits. Members of fatty acid-binding protein (FABP) multilamily have emerged from three independent screenings. FABPs are known to be small cytosolic proteins that mainly facilitate the solubility and intracellular transport of free fatty acids. I have studied in detail the biological effects of FABPs on integrin function. Interestingly, FABP3, also known as MDGI (mammary derived growth inhibitor), is found to down-regulate integrin mediated cell adhesion to type I collagen in several breast cancer cell lines. Most breast cancer cell lines have lost FABP3 expression, and our data demonstrates that one of the functions of this breast cancer tumor suppressor protein is to influence cell proliferation possibly via attenuated cell matrix interactions and integrin signalling.

2006 ASCB Annual Meeting Abstracts
Regulation of Inflammatory IL-6 and INOS by Substratum and Cell-Cell Interaction in Mammary Epithelial Cell Lines
S. W. Maalouf,1 D. C. Borger,1 R. S. Talhouk,2 F. L. Schanbacher1; 1Animal Sciences, The Ohio State University, OARDC, Wooster, OH, 2Biology, The American University of Beirut, Beirut, Lebanon
Recent studies linking chronic inflammation to the risk of cell transformation and cancer likely would apply to the mammary gland and breast cancer. Mammary epithelium is comprised of secretory and myoepithelial cells in close contact, represented by SCp2 and SCg6 cell lines respectively; both derived from the CID-9 mouse mammary cell line. From our previously described response of SCp2 cells to inflammation induced by bacterial endotoxin (ET), we further investigated the effect of exogenous extracellular matrix (ECM) or co-culture of secretory SCp2 with myoepithelial SCg6 mammary cells (mimicking cell organization in the mammary epithelium) on inflammatory responders interleukin-6 (IL-6) and nitric oxide (NO) in response to ET. SCp2 cells were cultured on plastic +/- extracellular matrix (ECM) or on a monolayer of SCg6 cells. ET-induced IL-6 secretion and NO production were monitored by ELISA immunoassay and Griess reaction assay respectively. Endotoxin induced a 4-7 fold increase in IL-6 secretion in SCp2 cells independent of ECM addition. However, in the absence of ET the co-culture of SCp2 with SCg6 cells induced a surprising 10 fold increase in secreted IL-6 compared to that of cells on plastic +/- ECM. ET treatment of the co-cultured cells further doubled IL-6 secretion. Unlike IL-6, NO production was dependent on ET treatment regardless of substratum. However, co-cultured SCp2 and SCg6 cells gave only 1/3 the NO production as SCp2 cells alone after ET treatment. These results suggest that NO induction is dependent on ET-induced inflammation in mammary epithelial cells. However, IL-6 secretion by mammary cells is drastically increased not only by ET but also by cell-cell interaction in the absence of ET, suggesting a potential role of IL-6 in mammary cell growth or differentiation independent of its pro-inflammatory role.

tg-beta Effects on Desmosomal Components in MCF10A Cells
S. A. Keim, Genetics, Cell Biology and Anatomy, University of Nebraska Medical Center, Omaha, NE
Epithelial to mesenchymal transition (EMT) is a normal part of embryonic development, and is a potential mechanism in carcinoma progression. During EMT, epithelial cells decrease cell-cell interactions and acquire an invasive phenotype. Epithelial cells interact with one another via several junctional complexes including the adherens junction and the desmosome. Changes in the adherens junction have been characterized during EMT, but desmosomes have received only limited attention. We have previously characterized the desmosomal components in MCF10A cells when they undergo TGF-beta induce EMT. Immunofluorescence and western blot analysis showed that the general trend is a decrease in the desmosomal components at the protein level by days three and four of TGF-beta treatment. We are now interested in the mechanism that causes the decrease in the desmosomal components. Quantitative Real Time PCR showed that mRNA levels of the desmosomal components are not significantly decreased with TGF-beta treatment suggesting that the decrease is due to a posttranscriptional mechanism. Since the plakophilins are greatly reduced at the protein level after TGF-beta treatment, we sought to determine if the proteins would be stabilized by the proteasome inhibitor MG-132. When MCF10A cells were treated with both TGF-beta and MG-132, the fates of plakophilins 2 and 3 differed from one another. Plakophilin 3 levels did not decrease with treatment, while plakophilin 2 levels where similar to those cells treated with only TGF-beta. These results suggest that the decrease in plakophilins during TGF-beta induced EMT contribute to the disassembly of desmosomes.

down-regulation of ras/erks cascade in scattered cells renders the egfr phosphorylation-dependent formation of cell-cell contacts
E. Kang,1 J. Lee2; 1Department of Molecular and Cellular Oncology, Cancer Research Institute, College of Medicine, Seoul National University, Seoul, Republic of Korea
Epithelial-mesenchymal transition (EMT) plays important roles in the development and dissemination of cancer cells from a primary tumor body. The reversal of EMT, mesenchymal-epithelial transition (MET) can occur at metastatic sites, although its regulation mechanisms are unclear. In this study, we observed MET as determined by cell-cell contact formation between scattered rat intestinal epithelial cells after treatment with a specific MEK inhibitor (U0126). U0126 treatment-mediated MET correlated with increased EGFR phosphorylation, in a ligand-independent manner, since the phosphorylation still occurred in the absence of serum or in cells preincubated with neutralizing anti-EGF antibody. Moreover, pretreatment with EGFR kinase inhibitor abolished U0126 treatment-mediated EGFR phosphorylation and MET, and the expression of H-Ras N17 dominant negative mutant allowed EGFR phosphorylation and MET even without U0126 treatment. Furthermore, the expression of a nonphosphorylatable EGFR Y5F mutant abolished U0126-mediated MET. U0126 treatment also caused less efficient wound healing by keeping monolayer intact, compared to control untreated cells. This U0126-mediated reduction in wound healing was further altered either by pretreatment of EGFR kinase inhibitor or expression of H-Ras N17 or EGFR Y5F. Taken together, this study supports a unique mechanism of cell-cell contact formation through MEK/Erks inhibition-mediated EGFR phosphorylation.

Subcellular Localization of RhoA/Rho Kinase Signaling in Endothelial Cells
G. P. van Nieuw Amerongen, J. Hodzic, C. M. L. Beckers, R. J. P. Musters, M. A. Engelse, V. W. M. Van Hinsbergh; Faculty of Medicine, Department of Physiology, VU Medical Center, Amsterdam, The Netherlands
We have previously shown that thomrin is a potent activator of RhoA. Thomrin is vascular hyperpermeability-inducer. It disturbs endothelial barrier integrity by a contractile mechanism, involving activation of RhoA and its downstream target Rho kinase. Rho kinase on its turn inactivates the Myosin Phosphatase (MP). Here, we investigated the subcellular localization of RhoA-mediated signaling. To visualize Rho kinase activity in endothelial cells, a phosphospecific antibody against the myosin phosphatase targeting subunit (Thr^422/Thr^423/Thr^425) was used as a surrogate marker for Rho kinase activity. Upon stimulation with thomrin, enhanced Rho kinase activity at contractile F-actin stress fiber was observed by 3D deconvolution fluorescence microscopy. In addition, live cell imaging using a fluorescence resonance energy transfer (FRET)-based probe for RhoA activity, confirmed an increase in RhoA activity in cytosolic areas upon thomrin stimulation Unexpectedly, at sites of thomrin-induced gap formation RhoA activity decreased, as was evidenced by a FRET probe that localized mostly at the plasma membrane by means of a K-Ras4B carboxy-terminal region. Furthermore, a basal activity of both RhoA and Rho kinase was observed in junctional areas of nonstimulated cells, suggesting a contribution of basal RhoA/Rho kinase activity to maintenance of cell-cell contacts. Indeed, inhibition of basal Rho kinase activity attenuated endothelial barrier integrity, opposing previously observed protection from the thomrin response. In conclusion, we provide evidence for dual role of RhoA/Rho kinase signaling in regulation of endothelial barrier function: 1) a basal activity injurious areas that contributes to maintenance of cell-cell adhesion, and 2) an enhanced RhoA/Rho kinase activity in cytosolic regions upon thomrin stimulation, resulting in barrier disruption.
Cerebral cavernous malformations type 1 (CCM-1), a disease associated with defective endothelial junctions, results from autosomal dominant CCM-1 mutations that cause loss of KRIT-1 protein. KRIT-1 (Krill Interaction Trapped-1) was discovered through its interaction with Rap1A in a yeast two-hybrid screen. We now demonstrate that KRIT-1 protein binds tightly to GTP-loaded Rap1A but not to the nucleotide free form to nor to activated H-Ras, establishing that it is an authentic Rap-specific effector. Furthermore, we developed anti-KRIT-1 monoclonal antibodies and used them to establish that Rap1 can regulate the conformation of KRIT-1 thus unmasking its FERM domain. The KRIT-1 FERM domain was masked through an interaction with a sequence in the KRIT-1 N-terminus. FERM domains often mediate interactions with the cytoplasmic tails of transmembrane proteins; we find that integrin β tails are such a membrane protein ligand for the KRIT-1 FERM domain and that Rap1 regulates the KRIT-1-integrin interaction. In addition, KRIT-1 protein is expressed in cultured arterial and venous endothelial cells and is present in both the nucleus and cell-cell junctions. We now find that the junctional localization of KRIT-1 is mediated by the FERM domain and that activation of Rap1 enhances this localization. Thus, these studies establish that KRIT-1 is a Rap1 effector located at cell-cell junctions, and provide a molecular explanation for aspects of the CCM phenotype.

Connexin 43 May Be Involved in IL-1β-mediated Cell Survival in Human Tenocytes
J. Qi,1 L. Chi,1 D. Bynum,2 A. J. Banes1; 1Flexcell International Corporation, Hillsborough, NC, 2Joint Department of Biomedical Engineering, North Carolina State University, Raleigh, NC, Orthopaedics, University of North Carolina at Chapel Hill, Chapel Hill, NC. Joint Department of Biomedical Engineering, University of North Carolina at Chapel Hill, Chapel Hill, NC

Introduction - Interleukin-1β (IL-1β) is a proinflammatory cytokine that is up-regulated by mechanical loading. IL-1β treatment increased cell survival in mechanically loaded human tenocytes by relaxing the cytoskeleton and decreasing the Young’s modulus. Overexpression of connexin 43 (Cx 43) increased cell survival in neuron cells. Cx 43 is the major connexin expressed in human tenocytes. To further investigate the mechanism of cell survival under mechanical loading, the effects of IL-1β on the Cx 43 expression were studied. Method - Primary tenocytes (HTFPs) were isolated from discarded human tendon tissue as described previously. HTFPs from passages 2 to 4 were used in this study. HTFPs were grown in three-dimensional type I collagen gels in the presence of 2% fetal bovine serum with or without 100 pM IL-1β. Cells were collected at 1, 8 and 24 h post-addition of IL-1β and total RNA was extracted with an RNaseasy mini kit (Qiagen), CDNA was synthesized with SuperScriptII (Invitrogen) and real time PCR for Cx 43 was carried out using a SYBR premix Ex Taq kit from Takara. For a dose-localization study, cells in type I collagen gels were treated with 1, 10 or 100 pM IL-1β for 24 h. Results - IL-1β up-regulated the expression of Cx 43 in human tenocytes in a dose-dependent manner by 24 h post-addition of 100 pM IL-1β. Conclusion - These results indicate that up-regulation of Cx 43 to increase cell-cell communication may be a potential mechanism by which IL-1β increases cell survival after mechanical loading in connective tissues. The latter action would be important in the compliant wound tissue during convalescence post-injury.

Exosomes Released by Activated T Cells May Contribute to Atherogenesis by Promoting Monocyte Cholesterol Accumulation and TNF-α Production
L. Zakharova, M. Svetlova, A. F. Fomina; Physiology and Membrane Biology, University of California, Davis, Davis, CA

Activated T lymphocytes release vesicles, termed exosomes, enriched in cholesterol and exposing phosphatidylserine (PS) at their surface. Although CD4+ activated T lymphocytes infiltrate an atherosclerotic plaque, the effects of T cell exosomes on the atheroma-associated cells have not been studied. Transformation of monocytes and macrophages into cholesterol-loaded foam cells is a hallmark of atherosclerosis. Therefore, we investigated the effects of T cell exosomes on cholesterol accumulation and cytokine production by human monocytes and PMA-activated THP-1 cells. Resting CD4+ T lymphocytes were purified from the peripheral blood of healthy volunteers and were activated in vitro with phytohaemagglutinin P to stimulate exosome production. Exosomes were isolated from T cell culture supernatants using the high speed centrifugation method. Purified exosome preparations were added to the cultured human monocytes or PMA-activated THP-1 cells. After overnight incubation, the total cholesterol content in monocyte whole-cell lysates was determined with an enzymatic cholesterol-detection assay. We found that exosomes strongly stimulated cholesterol accumulation in both cultured human monocytes and THP-1 cells. This effect was abolished by anti-PS receptor antibodies, indicating that this receptor may be involved in exosome internalization. Staining with filamin and Nile Red, the specific markers for free and esterified cholesterol respectively, revealed a number of lipid droplets composed of esterified cholesterol or cholesterol ester and free cholesterol in the cytosol of exosome-treated monocytes. The enhanced production of proinflammatory cytokine TNF-α in monocyte cell cultures was observed in parallel with cholesterol accumulation. We conclude that within an atherosclerotic plaque, the effects of T cell exosomes on rupture. Events tagged KIR molecules are being used to monitor KIR interactions during clustering and upon zinc binding. Preliminary results indicate that FRET decreases upon chelation of zinc. Analysis of NK Cell Inhibitory Receptor Clustering by FRET
P. Srinivasan, E. O. Long; National Institute of Allergy and Infectious Diseases, National Institutes of Health, Rockville, MD

Natural killer (NK) cells defend the body against intracellular pathogens via cytokine production and destruction of infected cells. NK cell activation is regulated by inhibitory receptors such as KIR (killer cell immunoglobulin-like receptor) that recognize MHC Class I molecules on target cells. KIR2DL1, an inhibitory receptor specific for the class I molecule HLA-C, accumulates at the interface of NK cells and resistant, HLA-C-expressing target cells. The divalent metal zinc contributes to KIR clustering at NK cell immune synapses, and to the inhibitory signal delivered by KIR2DL1. FRET (fluorescence resonance energy transfer) is being used to analyze dyeimerization and clustering of KIR, in order to define the role of zinc in the inhibitory function of KIR. KIR2DL1 has been tagged at the cytoplasmic tail with CFP and YFP. In addition, CFP and YFP have been fused to the N-terminus of KIR, adjacent to the putative zinc binding site. These tagged KIR molecules are being used to monitor KIR interactions during clustering and upon zinc binding. Preliminary results indicate that FRET decreases upon chelation of zinc. Events recorded on live cells will provide further insights into the role played by zinc in KIR2DL1 signaling.

Killer Cell Ig-like Receptor Promotes Clustering of Activation Receptors at Inhibitory NK Cell Immune Synapses
M. E. March,1 N. Schleiniz; 1Molecular Cellular Immunology Section, NIH/NIAD, Rockville, MD, 2Centre d’Immunologie, Institut National de la Santé et de la Recherche Médicale/Centre National de la Recherche Scientifique de Marseille Luminy, Marseille, France

Activation of NK cells by contact with target cells is controlled by inhibitory receptors for MHC class I, which include the human killer cell Ig-like receptors (KIR) specific for HLA-C. Inhibitory KIR accumulate at the site of contact with HLA-C-expressing target cells, and prevents phosphorylation of activation receptor 2B4 and its recruitment to detergent-resistant membrane domains. The hypothesis that KIR blocks activation receptor signaling by preventing anti-non-written receptor accumulation at immune synapses was tested here. Using primary human NK cells in contact with target cells expressing defined combinations of ligands for NK cell receptors, we show that accumulation of KIR correlated with exclusion of LFA-1 from the NK-target cell interface. In contrast to the exclusion of LFA-1, activation receptors CD2 and 2B4 were not excluded from inhibitory NK cell immune synapses, but accumulated and colocalized with KIR. In fact, KIR promoted the clustering of CD2 and 2B4 at inhibitory synapses by lifting the requirement for actin polymerization in CD2 and 2B4 accumulation. Therefore, inhibitory KIR does not prevent CD2 and 2B4 signaling by blocking actin-dependent accumulation at NK cell immune synapses, but by blocking the ability of activating receptors to signal within inhibitory synapses.

Regulation of Erzin Localization by Rac1 and Pipkin in Human Epithelial Cells
E. Auvinen,1 N. Kivi,1,2 A. Vaheri1; 1Department of Virology, HUSLAB Clinical Microbiology, HUS Helsinki, Finland, 2Department of Virology, Haartman Institute, University of Helsinki, Helsinki, Finland

Regulation of erzin and other ERM proteins is not completely understood, but the involvement of Rho GTPases seems crucial. In this work, expression plasmids encoding full-length, deleted or truncated ezrin were constructed and coexpressed with Rac1 GTPase in HeLa human epithelial cells in order to elucidate the mechanisms of ezrin activation and function. We observed induction of actin stress fiber formation by ezrin constructs harboring the F-actin binding site but devoid of sequences required for intra- or intermolecular binding. Stress fiber-inducing ezrin mutants were localized at cell-cell adhesions and also colocalized with F-actin in stress fibers. This localization required the activity of Rac1 and phosphorylidyinositol-4-phosphate 5-kinase and involved RhoA. We suggest that Rac regulates ezrin localization at cell-cell adhesions.
Thrombomodulin Cytoplasmic Domain Interacts with α-Melanocyte and Ezrin

G. Shi, G. C. Huang, C. Kuo, F. Lin, M. Chen, H. Wu
Department of Biochemistry and Molecular Biology, National Cheng Kung University, Tainan, Taiwan, 2Institute of Medical Sciences, National Taiwan University, Tainan, Taiwan

Thrombomodulin (TM), a type I integral membrane glycoprotein, is a well-studied potent anticoagulant factor. However, expression of TM in nonvascular cells such as epithelial squamous keratinocytes highly suggests that TM may possess other functions beyond its anticoagulant activity. Previously we have reported that TM functions as a novel cell-cell adhesion molecule which mediates cell aggregation. To be an effective adhesion molecule, cytoplasmic domain of TM needs to associate with cytoskeleton either directly or indirectly through linkage proteins. To investigate molecules involved in this interaction, by employing pMACS magnetic isolation we identified two candidates, ezrin and α-actinin, potentially associated with TM cytoplasmic domain. Co-immunoprecipitation analysis further proved their interaction with TM. In vitro binding assay provided evidence that both the ezrin N-terminal and α-actinin spectra domain bound to the TM cytoplasmic domain directly without the requirement of other proteins. We also studied the regions in the TM cytoplasmic domain implicated in the binding to ezrin and α-actinin. By truncating and mutating TM cytoplasmic domain we showed that the ezrin- and α-actinin-binding sequence was located in the positively charged juxtamembrane region KRRKQGAARAR. Immunohistological data in cultured cells revealed that TM colocalized with ezrin in actin-rich microvilli and membrane ruffles while α-actinin overlaid TM at the leading edges of lamellipodia and cell-cell contacts. Moreover, mutation of the positively charged binding sites for ezrin and α-actinin on TM prevented surface protrusions and cell aggregation phenotype. We therefore conclude that the positively charged residues in juxtamembrane region among TM cytoplasmic domain directly interact with ezrin and α-actinin which link membrane protein to actin filaments.

Thrombomodulin-mediated Cell Adhesion, Cytoskeletal Rearrangement, and Morphological Conversion

C. W. Huang, G. Y. Shi, H. Y. Yang, H. C. Huang, H. P. Chen, H. L. Wu

Podocytes are highly differentiated kidney epithelial cells responsible for maintaining the selective permeability barrier of the glomerulus. They form specialized modified adherens junctions that are important for maintaining the selective permeability barrier of the glomerulus. They form specialized modified adherens junctions that are important for maintaining the selective permeability barrier of the glomerulus. They form specialized modified adherens junctions that are important for maintaining the selective permeability barrier of the glomerulus. They form specialized modified adherens junctions that are important for maintaining the selective permeability barrier of the glomerulus.

Effects of Changing Endogenous Alpha-Catenin Localization on Cell Adhesion and Migration

J. Nelson, Biological Sciences and Molec. Cell. Physiology, Stanford University, Stanford, CA

α-Catenin regulates cell-cell adhesion and migration in vertebrates and invertebrates. It is generally accepted that strong cell-cell adhesion is mediated through cadherin binding to cytoplasmic α-Catenin is a protein essential for cell migration. In addition, we found that α-Catenin localization to F-actin cell-cell contacts and cell migration has been extensively investigated, but whether and how cadherin function is directly affected, as well as the role of the underlying actin cytoskeleton, remain less well understood issues. Ep8, a substrate of receptor tyrosine kinases, in a complex with Ab1 and Sos-1 induces Rac activation leading to actin cytoskeleton remodeling. Recent studies have shown that Ep8 regulates the growth of actin filaments by capping their barbed ends, an activity essential for cell motility. Here, we report that Ep8 localizes to cell-cell junctions, potentially regulating the interaction with the N-terminus of p120 catenin. Through the use of RNAi and the reconstitution with mutants selectively defective for Ep8 capping activity, the latter is shown to be required for normal cadherin-dependent adhesion, cortical actin organization, epithelial cell migration and HGF-driven cell scattering. This study provides novel functional information on Ep8 as a cell-cell adhesion regulator and increases our understanding of the roles of cell cing proteins in cell adhesion.
Beta-catenin Directly Regulates Bacteria-induced Inflammation In Vivo

Y. Duan, A. Liao, S. Kupipreddi, M. J. Ciancio, J. Sun
Pathology, The University of Chicago, Chicago, IL, The Inflammatory Bowel Disease Research Center, Department of Medicine, The University of Chicago, Chicago, IL
Wild-type (WT) Salmonella typhimurium cause acute intestinal inflammation by activating the nuclear factor kappa B (NF-kappaB) pathway. Interestingly, WT Salmonella typhimurium infection also causes degradation of beta-catenin, the regulator of cell proliferation and differentiation. Regulation of beta-catenin and the inhibitor of NF-kappaB, IkappaBalpha, are strikingly similar, involving phosphorylation at the same N-terminal serine sequence sites, ubiquitination by the same E3 ligase complex, and subsequent proteasomal degradation. However, how beta-catenin directly regulates the NF-kappaB pathway during bacteria-induced inflammation in vivo is unknown. The purpose of this study, therefore, was to investigate the role of beta-catenin in modulating the pro-inflammatory response mediated by NF-kappaB subsequent to Salmonella infection in vivo. Using streptomycin-pre treated mice challenged with WT Salmonella typhimurium entericenter, we demonstrated that WT Salmonella stimulated beta-catenin degradation and decreased the physical association between NF-kappaB alpha and beta-catenin (NF- kappaB-alpha/beta-catenin complex) in intestinal epithelial cells by Western blot and immunoprecipitation assays. Accordingly, WT Salmonella infection decreased the expression of c-myc, a beta-catenin-regulated target gene and increased the levels of IL-6 and TNF-alpha, the NF-kappaB-regulated target genes. Bacterial infection directly stimulated phosphorylation of beta-catenin, both in vivo and in vitro. In conclusion, we demonstrated that the transcription factor c-myc, a beta-catenin-regulated gene, is important in the regulation of the pro-inflammatory response in intestinal epithelial cells by WT Salmonella infection.

The Formin Homology Protein Dia1 Is Required for the Integrity of Cell-Cell Junctions in Epithelial Cells

L. Carramusa, A. Bershadsky; Molecular Cell Biology, Weizmann Institute of Science, Rehovot, Israel
Recent research demonstrated that Zipcode Binding Protein 1 (ZBP1) inhibits translation of beta-actin mRNA, until the mRNA reaches its destination at the leading edge of fibroblasts. To investigate the physiological significance of this process in living cells, we utilized a live-cell imaging assay to determine the spatial distribution of beta-actin mRNA. Experiments with GFP-fused Dia1 constructs demonstrated that junctional localization of Dia1 depends on the N-terminal domain of the Dia1 molecule, which contains the Rho-binding domain. Thus, constitutively active GFP-Dia1 mutants truncated at the N- terminus did not demonstrate junctional localization, while a mutant preserving the N-terminal domain but lacking the C-terminal autoinhibitory domain (GFP-Dia1-deltaDAD) was enriched at the junctions. As expected, constitutively active RhoA mutant, RhoA-V14, did not rescue formation of adherens junctions in the cells with down regulated Dia1, but enhanced recruitment of beta-catenin at the cell-cell contact area in GFP-Dia1-deltaDAD expressing cells. Moreover, coexpression of RhoA-V14 with full length GFP-Dia1 strongly promoted localization of GFP-Dia1 to the cell-cell junction, which was accompanied by greatly increased recruitment of E-cadherin to the junctional area. Thus, we propose that Dia1 localizes to adherens junctions in a RhoA-dependent manner, and is required for the proper junctional localization of beta-catenin and associated proteins, for which further studies are needed.

The Recruitment of Adherens Junction Components Requires Zipcode Mediated Local Translation of beta-Actin

A. J. Rodriguez, S. Burke, A. L. Wells, S. M. Shenoy, J. Condeelis, R. H. Singer; Anatomy and Structural Biology, Albert Einstein College of Medicine, Bronx, NY
Recent research demonstrated that Zipcode Binding Protein 1 (ZBP1) inhibits translation of beta-actin mRNA, until the mRNA reaches its destination at the leading edge of fibroblasts. To investigate the physiological significance of this process in living cells, we utilized a live-cell imaging assay to determine the spatial distribution of beta-actin mRNA. Experiments with GFP-fused Dia1 constructs demonstrated that junctional localization of Dia1 depends on the N-terminal domain of the Dia1 molecule, which contains the Rho-binding domain. Thus, constitutively active GFP-Dia1 mutants truncated at the N-terminus did not demonstrate junctional localization, while a mutant preserving the N-terminal domain but lacking the C-terminal autoinhibitory domain (GFP-Dia1-deltaDAD) was enriched at the junctions. As expected, constitutively active RhoA mutant, RhoA-V14, did not rescue formation of adherens junctions in the cells with down regulated Dia1, but enhanced recruitment of beta-catenin at the cell-cell contact area in GFP-Dia1-deltaDAD expressing cells. Moreover, coexpression of RhoA-V14 with full length GFP-Dia1 strongly promoted localization of GFP-Dia1 to the cell-cell junction, which was accompanied by greatly increased recruitment of E-cadherin to the junctional area. Thus, we propose that Dia1 localizes to adherens junctions in a RhoA-dependent manner, and is required for the proper junctional localization of beta-catenin and associated proteins, for which further studies are needed.

The Role of the Beta-1 Subunit of the Na,K-ATPase and Its Glycosylation in Cell-Cell Adhesion

O. Vagin, E. Tolkhtseva, G. Sachs; Physiology, UCLA, Los Angeles, CA
OBJECTIVE. The goal of this study is to identify the role of the Na,K-ATPase beta1 subunit in cell-cell adhesion. METHODS. YFP-linked fusion proteins of the Na,K-ATPase beta1 subunit and its glycosylation-deficient mutants were stably expressed in MDCK cells. Distribution and endogenous subunits of the Na,K-ATPase and adherens junction proteins was studied by immunohistochemistry, confocal microscopy and surface-selective biotinylation followed by Western blot analysis. RESULTS. In polarized monolayers of MDCK cells, the Na,K-ATPase alpha1 and beta1 subunits were detected exclusively in the sites of cell-cell contact and were resistant to Triton X-100 extraction suggesting association with the cytoskeleton. The Na,K-ATPase was co-localized with the markers of adherens junctions, beta1 Na,K-ATPase, directly underneath the tightest adhesion. Co-localization with the adherens junctions was retained before the tightest adhesion. The association of the Na,K-ATPase with the adherens junction proteins and cytoskeleton occurred when cell-cell contact initiated. Upon disruption of intercellular contacts by incubation of cells in a Ca++-free buffer, the Na,K-ATPase was internalized along with beta1-catenin. Mutagenic removal of N-glycosylation sites of the Na,K-ATPase beta1 subunit dissociated the pump from the adherens junctions and cytoskeleton as inferred from a significant removal of the mutated beta1 subunit and the endogenous Na,K-ATPase alpha1 subunit from the lateral membrane and loss of co-localization with beta1-catenin after treatment of cells expressing the mutant with Triton X-100. Incubation of attached MDCK cells with an antibody against the extracellular domain of the Na,K-ATPase beta1 subunit inhibited cell-cell adhesion. CONCLUSIONS. The Na,K-ATPase beta1 subunit is involved in intercellular adhesion and is responsible for association of the heterodimeric alpha1,beta1 Na,K-ATPase with the adherens junctions. N-glycosylation of the Na,K-ATPase beta1 subunit is essential for the stable association of the pump with the adherens junctions and hence the cytoskeleton.

A Possible Role for Cno/AF-6 in Linking Actin to Adherens Junctions during Morphogenesis

J. K. Sawyer, C. Beattie, M. Peifer; Biology, UNC-Chapel Hill, Chapel Hill, NC, Laboratory of Development Neurogenetics, Rockefeller University, New York, NY
Cell-cell adhesion is critical for development. Adherens junctions (AJs) were thought to form mechanical attachments between cells by linking actin in neighboring cells together through the cadherin-catenin complex. However, recent work from the Nelson and Weis labs questions whether this linkage is direct. Additional proteins are recruited to AJs whose function is less well understood. We hypothesize that these may act partially redundantly to regulate junctional plasticity by regulating connections to actin and to signal transduction machinery. To test this hypothesis we are defining the function of Cno (Cno) in AJs. Cno is a scaffolding protein that is thought to bring together multi-protein complexes to modulate adhesion. In mammals, AF-6 and the cell adhesion molecule nectin form a multi-protein complex that exists in adherens junctions. Our model predicts that these complexes regulate the formation and function of AJs by providing a link between AJs and actomyosin contractile ring.
A Role for Rap1 in *Drosophila* Morphogenesis

N. J. Harris, J. K. Sawyer, M. Feifer; University of North Carolina at Chapel Hill, Chapel Hill, NC

Animal development is dependent on proper cell-cell interactions, which are mediated in part by adherens junctions (AJs). These junctions mediate cadherin-based adhesion and also help organize the cortical actin cytoskeleton within cells. In addition to the cadherins and catenins at these junctions, other proteins are recruited to AJs which are thought to have additional functions. Our lab has been investigating the function of canon (cno), the *Drosophila* homolog of mammalian Afadin/AF-6, and its role in morphogenesis. Cno has a number of binding partners, among which is the small GFP-tagged Rap1. Mammalian Rap1 has been recently proposed to regulate integrin adhesion, while *Drosophila* Rap1 is suggested to regulate cadherin localization in imaginal discs. Rap1 has functions in early morphogenesis, but how it functions with cno to regulate adhesion or other intercellular events is not well understood. Currently, we are investigating Rap1’s role in cell-cell adhesion by analyzing maternal/zygotic mutants, and looking for possible genetic interactions with other proteins that localize to the AJ or are predicted to bind Rap1 based on work in other organisms. In addition, we are examining a GFP fusion of Rap1 from Nick Brown to learn more about its localization inside the cell during embryo morphogenesis.

Long-term Effects of Limited p120-ablation in the Mouse Intestine

W. G. Smalley, 1 P. E. Burnett, 1 M. A. Davis, 1 M. K. Washington, 2 S. Robine, 4 D. L. Guumcu, 2 R. J. Coffey, 2 A. B. Reynolds, 1 Cancer Biology, Vanderbilt University, Nashville, TN, 2Dermatology, Vanderbilt University, Nashville, TN, 3Pathology, Vanderbilt University, Nashville, TN, 4Institut Curie-CNRS, Paris, France, 5University of Michigan Medical School, Ann Arbor, MI, 6Gastroenterology, Vanderbilt University, Nashville, TN

We have established a novel mouse model for determining the long-term effects of p120-ablation in the small intestine and colon. In our first generation model, p120 ablation was induced by crossing p120 floxed mice to villin-Cre transgenic mice provided by D. Guumcu. A mosaic p120 knockout was observed in approximately half of epithelial cells from the stomach to the anus, with no other tissues affected. The damage, however, was severe, and animals bled to death by 3 weeks of age due to widespread epithelial shedding and inflammation. To examine long-term effects of p120 ablation, we have crossed our animals to a new villin-Cre-Ert2 transgenic mouse from S. Robine’s laboratory, and established tamoxifen dosing conditions to limit p120 loss to less than 10% of epithelial cells in the intestine and colon. Interestingly, morphologic and adhesive defects are similar to those characterized previously but are limited to fields of cells derived from individual p120-null stem cells. E-cadherin is significantly downregulated in p120-null regions, and cell morphology and adhesion is perturbed, but animals do not suffer the early health problems associated with the full knockout. By two months of age, however, all animals develop numerous cyst-like villi within villus structures in the intestines. This new model will allow detailed analysis of the long-term fate of these unusual structures.

Dissecting the Role of ALP-1 in *C. elegans* Epidermal Morphogenesis

H. Han, 1,2 C. R. McKeown, 2 M. C. Beckerle 1,2; 1Oncological Sciences Department, University of Utah, Salt Lake City, UT, 2Huntsman Cancer Institute, Salt Lake City, UT

The epidermis is a multilayered epithelial tissue that provides mechanical support and regulates drug transport. Despite its importance, very little is known about the molecular mechanisms that control epidermal morphogenesis. In this study, we have investigated the role of ALP-1, a protein that binds to the cadherin-catenin complex and cooperates with the adherens junction to regulate cell adhesion and morphogenesis. ALP-1 is an adhesion molecule that interacts with multiple proteins, including cadherins, catenins, and integrins. In *C. elegans*, ALP-1 cooperates with proteins in the catenin-cadherin complex to regulate cell adhesion and morphogenesis. Our data suggest that ALP-1 plays a role in cell adhesion and morphogenesis by interacting with the cadherin-catenin complex. ALP-1 also interacts with integrins, suggesting that it may function as a scaffold for protein assembly at cell-cell contacts. Our results provide new insights into the molecular mechanisms that control epidermal morphogenesis and suggest that ALP-1 may have a conserved role in cell adhesion and morphogenesis across multiple species.
Regulation of Adhesion by the Intracellular Trafficking of DE-cadherin during *Drosophila* Morphogenesis

J. F. Roeth, M. Peifer; Biology, University of North Carolina at Chapel Hill, Chapel Hill, NC

Adhesions junctions (AJ)s are critical to normal cell adhesion (mediated by intercellular homophilic interactions between Cadherin molecules on adjacent cells). It is generally thought that AJs must maintain a high level of plasticity to accommodate cell shape changes during morphogenesis and cell division. Studies in cultured mammalian cells suggest that the intracellular trafficking of E-Cadherin is an essential determinant of adhesion. Rab proteins form a family of small GTPases that act as key regulators to orchestrate multiple stages of protein transport. Rab5 mediates fusion of internalized vesicles with early endosomes, and may also play a role in clathrin-mediated endocytosis. Rab11 is thought to regulate vesicle transport at the sorting/recycling endosome, and can help to target proteins to the plasma membrane from either the endocytic or exocytic pathway. We hypothesize that the balance between endocytosis and recycling of AJ proteins is a potential mechanism to rapidly modulate epithelial cell adhesion, and that AJ proteins are actively transported via Rab5- and Rab11-dependent endosomal pathways. Using the GAL4-UAS system in *Drosophila*, we have expressed dominant Rab5 and Rab11 mutants in specific regions at various developmental stages during *Drosophila* embryogenesis and examined the consequences. In epidermal cells, constitutively active Rab5 induced the formation of enlarged endosomes that accumulate DE-Cadherin and recruit F-actin. Both constitutively active and dominant negative Rab5 mutants inhibited apical constriction and cell shape changes necessary for proper epithelial cell migration during dorsal closure. Finally, expression of a dominant negative Rab11 mutant resulted in the breakdown of apical AJs, and eventually led to major defects in epithelial integrity. Thus, the endosomal trafficking of AJ proteins in epithelial cells is important for normal embryonic development. We currently are investigating how these mutants affect the transport of other membrane proteins and how protein trafficking via these pathways is regulated during development.

### The PDZ Binding Domain of WTI1 Is Important for Assembly of Podocyte Cell-Cell Contacts

A. Mukherjee, J. H. Kim, A. Padiyar, S. H. Schechtmann, M. Konieczkowski, J. R. Schelling, J. R. Sedor; Medicine, Case Western Reserve University, Cleveland, OH

Podocyte differentiation is critical for glomerular filtration barrier function and regulated by WTI1, a zinc finger transcription factor. We have identified a novel, WTI1 interacting protein (WTIP) that maps to human chromosome 19q13.1, a region with familial focal segmental glomerulosclerosis genes. We hypothesized that WTIP is important for assembly of cell-cell contacts in cultured podocytes. In vivo WTIP is expressed in glomeruli in a podocyte pattern and co-localizes with synaptopodin. After density gradient ultracentrifugation fractionation using rat glomerular lysates, WTIP co-fractionates with nephrin and caveolin, suggesting association with nephrin in podocyte lipid rafts. In kinetic studies in cultured podocytes, GFP-WTIP co-localized with focal adhesion protein vinculin at the tips of actin stress fibers before cell-cell contacts are established and co-precipitated with the focal adhesion protein paxillin. In contacting cells, GFP-WTIP is targeted to the adherens-based cell-cell junctions and co-localized with ZO-1, -catenin and pan-cadherin. When cell-cell contacts are formed, GFP-WTIP co-precipitated with -catenin, -catenin, and cadherin, suggesting it is a component of the adherens junction complex. WTIP membrane targeting was calcium-dependent, consistent with cadherin association. The C-terminal, PDZ-binding domain is critical for cell-cell junction assembly. When GFP-WTIP knockdown is expressed, cell junctions are disordered; -catenin and ZO-1 fail to target to the plasma membrane, WTIP and podocyte adherens components no longer co-precipitate and cell-cell contacts fail to seal. In summary WTIP is a member of the adherens junction signaling and is important for formation and maintenance of adherens junctions in cultured cells and for normal glomerular slit diaphragm assembly in vivo.

### Helicobacter Pylori Significantly Decreases the Transepithelial Resistance of a Confluent Gastric Epithelial Monolayer

V. S. Conlin, R. I. Allan, D. Menard, E. D. Moore, B. B. Finlay, N. Ng, A. M. J. Buchan; 1Biological Chemistry, University of Michigan, Ann Arbor, MI, 2Molecular and Integrated Physiology, University of Michigan, Ann Arbor, MI, 3Internal Medicine, University of Michigan, Ann Arbor, MI

Objective To investigate the effects of *H. pylori* infection on the integrity of a gastric epithelial monolayer, with respect to transepithelial resistance, paracellular permeability and the distribution of paracellular junction proteins, occludin, ZO-1 and E-cadherin. Methods Transepithelial Resistance (RT) Measurements-The gastric epithelial cell line, HGE-17 was grown to confluence on snapwell filters. Cells were infected with wild type, G27 *H. pylori* and two isogenic mutants, Cap- [lacking cag pathogenicity island (PAI)] and VacA- [lacking vacuolating toxin A]. Resistances were monitored over 24 hours. Cells were then either fixed or processed for flux experiments (see below). Immunocytochemistry-Snapwell filters were fixed and labeled with monoclonal antibodies directed against occludin, ZO-1 and E-cadherin. Paracellular flux- 10microM 10,000KDa (HMW) dextran-conjugated to Texas Red was added to the apical chambers of control and infected monolayers. Samples from the basal chambers were removed and fluorescent levels measured. Results All *H. pylori* capPAI+ strains decreased the RT of *H. pylori* monolayers (G27 42% decrease, Cap- 8% decrease, VacA- 57% decrease p<0.001 *p=NS, n=6). Paracellular flux experiments (at 24 hours post-infection) revealed increased permeability across monolayers with a decreased RT, compared to control monolayers (control = 1 (normalized), G27 = 1.48, Cap- = 1.06*, VacA- = 1.25 p<0.05, *p=NS, n=6). ICC analysis revealed punctate labeling at tight junctions and a redistribution of proteins away from the lateral membranes into the cytoplasm. Conclusion Our research suggests that chronic *H. pylori* capPAI+ infection alters the barrier properties of an intact gastric epithelial monolayer. The presence of the capPAI results in redistribution of both tight junction and adherens junction proteins from the lateral membrane into the cytoplasm. In vivo, this has the potential to compromise the integrity of the gastric epithelial barrier.

### Low-dose Aspirin and Helicobacter Pylori Infection Significantly Decrease the Transepithelial Resistance of a Confluent Gastric Epithelial Monolayer

V. S. Conlin, R. I. Allan, D. Menard, E. D. Moore, B. B. Finlay, N. Ng, A. M. J. Buchan; 1Biological Chemistry, University of Michigan, Ann Arbor, MI, 2Molecular and Integrated Physiology, University of Michigan, Ann Arbor, MI, 3Internal Medicine, University of Michigan, Ann Arbor, MI

Objective To investigate the effects of aspirin and *H. pylori* on the integrity of a gastric epithelial monolayer, with respect to transepithelial resistance and the distribution of paracellular junction proteins, occludin, ZO-1 and E-cadherin. Methods Transepithelial Resistance (RT) Measurements-The gastric epithelial cell line, HGE-17 was grown to confluence on snapwell filters. Cells were treated with 5mM aspirin and/or wild type (G27) *H. pylori*. Resistances were monitored over 24 hours. Cells were then fixed at various time points or processed for paracellular flux experiments. Immunocytochemistry-Snapwell filters were fixed and labeled with monoclonal antibodies directed against occludin, ZO-1 and E-cadherin. Paracellular flux- 10microM 10,000KDa (HMW) dextran-conjugated to Texas Red was added to the apical chambers of monolayers. Samples from the basal chambers were removed and fluorescent levels measured. Results The addition of *H. pylori* to confluent HGE-17 monolayers resulted in a dramatic decrease within the initial 4 hours (aspirin 65%, aspirin & G27 68% p<0.001, n=6) and a gradual recovery over 24 hours; however, the presence of *H. pylori* impaired the RT recovery (aspirin 14%, aspirin and G27 49% p<0.05, n=6). Infection with G27 alone revealed no statistical difference in RT at 4 hours (G27 11% increase p=NS, n=6). After 24 hours a 55% decrease in monolayer RT was observed in G27 infected monolayers (p<0.05, n=6). Paracellular flux experiments revealed increased permeability across monolayers (control = 1 (normalized), G27 = 1.64, aspirin = 1.34, aspirin & G27 = 1.81 p<0.05, n=6). ICC revealed punctate labeling at tight junctions and a redistribution of proteins away from the lateral membranes into the cytoplasm. Conclusion Aspirin is thought to interfere with bicarbonate secretion, weakening the mucosal protection above the gastric epithelium. Here we provide evidence for aspirin-induced disruption of an intact gastric epithelium and how an existing *H. pylori* infection may exacerbate the situation.

### PALS1 Regulates Tight Junction Formation and E-Cadherin Trafficking in Mammalian Epithelial Cells

Q. Wang, X. Chen, B. Margolis; 1Biological Chemistry, University of Michigan, Ann Arbor, MI, 2Molecular and Integrated Physiology, University of Michigan, Ann Arbor, MI, 3Internal Medicine, University of Michigan, Ann Arbor, MI

PALS1 is an evolutionarily conserved scaffold protein that targets to the tight junction in mammalian epithelia. Prior work in our laboratory demonstrated that the knockdown of PALS1 in MDCK cells lead to tight junction and polarity defects. We have created new PALS1 stable knockdown cell lines with more profound reduction of PALS1 expression, and a more severe defect in tight junction formation was observed. Unexpectedly, we also observed severe adherens junction defect, and both defects were corrected when PALS1 wild type and certain PALS1 mutants were expressed in the knockdown cells. We found that the adherens junction structural component E-cadherin was not effectively delivered to the cell surface in the PALS1 knockdown cells, and E-cadherin vesicles accumulated in cell periphery. The ezocyst complex was also found to be mislocalized in PALS1 knockdown cells, potentially explaining why E-cadherin trafficking is disrupted. Our results suggest a broad and evolutionarily conserved role for the tight junction protein PALS1 in the biogenesis of adherens junction.
During spermatogenesis, inter-Sertoli tight junctions at the blood-testis-barrier must be assembled and disassembled in a timely regulated manner so that developing spermatocytes can translocate from the basal to the adluminal compartment of seminiferous epithelium for further development. Recently, a novel tight junction transmembrane protein, CLMP, was found to be expressed in mouse testis. However, the functional importance and its regulation in testis are entirely unknown. By transient transfection assay performed in a mouse Sertoli cell cell line, TM4 cells, we found that the minimal CLMP promoter was located between nucleotides -550 and -288 (relative to translation start site). By the use of site-directed mutagenesis, three motifs namely GATA, KLF4 and SRY within the minimal promoter region were found to be functionally cooperated with one another to regulate CLMP gene transcription. By EMSAs, a ternary protein complex consisting of GATA-1/GATA-6/KLF4 was found to be present in all the three identified motifs, suggesting that a looping mechanism might involve in regulating CLMP gene transcription.

Interestingly, apart from the identification of three transcription factors in ternary protein complex, a ubiquitously expressed transcription factor Sp1 was also found in this ternary complex over the KLF4 motif. Overexpression of KLF4 significantly increased the promoter activity whilst overexpression of Sp1 has an opposite effect. Co-transfection studies showed that Sp1 could significantly abolish KLF4 transactivation of the CLMP promoter, suggesting that KLF4 and Sp1 might compete for the same binding site on the CLMP promoter. Taken together, the differential interaction of transcription factors, GATA-1, GATA-6, KLF4 and Sp1, might provide a precise machinery in regulating CLMP gene expression in Sertoli cells. This work was supported by Hong Kong Research Grant Council grants (HKU7536/05M and HKU 7599/06M).

Identification of a New Protein That Interacts with the Tight Junction Protein ZO-2
S. Lechuga, J. Solano, L. Gonzalez-Marial; Physiology, Biophysics and Neuroscience, Center for Research and Advanced Studies (Cinvestav), Mexico, D.F., Mexico
With the purpose of identifying proteins that interact with the middle portion of the tight junction (TJ) protein ZO-2, we have used a yeast two-hybrid system with the 3PSG segment of ZO-2 as bait. 3PSG includes the third PDZ domain, the SH3 region and the GK module (1555-1621 m) of ZO-2 canine cDNA. The sequence of the isolated protein, named protein binding 3PSG (pb3PSG), is matched to human chromosome 7q22, has an open reading frame of 737 bp and exhibits polyadenylation sites at its 3’ end. The sequence of pb3PSG predicts a protein containing a NES, a WW domain, two SH3 binding motifs PXSP, and a PDZ binding motif located 5 residues upstream of the carboxyl terminal end. Gene specific primers for pb3PSG allowed the RT-PCR amplification of the corresponding cDNA in epithelial MDCK cells. Down pulls assays confirm the interaction of a pb3PSG-GST fusion protein with ZO-2 present in an extract of MDCK cells. When the PDZ binding motif of pb3PSG-GST is altered by a point mutation (V163A), the association to ZO-2 is lost, while the mutation of the PXXP motifs (P112Q, P113S) exerts no effect. Transfected pb3PSG, co-immunoprecipitates with ZO-2 in MDCK cells, indicating an in vivo interaction between these two proteins. In epithelial cells the transfected protein pb3PSG concentrates at the nucleus and the cellular borders. The overexpression of pb3PSG diminishes the cell border presence of ZO-2.

The Tight Junction Protein ZO-2 Has Four Functional Nuclear Export Signals
L. Alarcon, A. Ponce, B. E. Jaramillo, L. Gonzalez-Marial; Physiology, Biophysics and Neuroscience, Center for Research and Advanced Studies (Cinvestav), Mexico, D.F., Mexico
The tight junction (TJ) protein ZO-2 changes its subcellular distribution according to the state of confluency of the culture. Thus in confluent monolayers it localizes at the TJ region whereas in sparse cultures it concentrates at the nucleus. The canonical sequence of ZO-2 displays four putative nuclear export signals (NESes), two at the second PDZ domain (NES-0 and NES-1) and the rest at the GK region (NES-2 and NES-3). The functionality of NES-0 and NES-3 was unknown; hence we have explored it with a nuclear export assay, injecting into the nucleus of MDCK cells peptides corresponding to the ZO-2 NES sequences chemically coupled to ovalbumin. We show that both NES-0 and NES-3 are functional and sensitive to leptomycin B. We also demonstrate that NES-1, previously characterized as a non-functional NES, is rendered capable of nuclear export upon the acquisition of a negative charge at its Ser148 residue. Experiments performed injecting at the nuclear WT and mutated ZO-2 GST fusion proteins revealed the need of both NES-0 and NES-1, and NES-2 and NES-3 for attaining an efficient nuclear exit of the respective amino and middle segments of ZO-2. Moreover, the transfection of MDCK cells with full length ZO-2 revealed that the mutation of any of the NESes present in the molecule is sufficient to induce nuclear accumulation of the protein.

Deciliation Is Associated with Dramatic Remodeling of Polarized Epithelial Cells
C. E. Overgaard, A. Sandra, C. Yeaman; Anatomie & Cell Biology, University of Iowa, Iowa City, IA
Primary cilia mediate various chemo- and mechanosensory functions, and ciliary defects are associated with diseases affecting kidney and liver epithelia. To test the hypothesis that ciliary signaling regulates epithelial polarity, we have pharmacologically deciliated cells with chloroquine (CQ) or dibucaine. Deciliation of polarized MDCKII monolayers promotes tight junction remodeling resulting in significant, but reversible increase in trans-epithelial resistance. This reflects coordinated reduction in tight junction proteins associated with "leaky" epithelia (eg. Claudin-2) and increase in proteins associated with "tight" epithelia (eg. Claudins-4 and -7). Deciliation also affects junction remodeling in other ways. In control cells, calcium chelation inhibits cadherin-mediated adhesion, and constituents of intercellular junctions are internalized. However, deciliated cells maintain tight intercellular contacts in the absence of extracellular calcium and fail to internalize junctional complexes. Deciliation also promotes redistribution of non-cadherin-associated apical proteins. Specifically, gp114 is redistributed into a novel apical pattern and ultimately misoriented to the basolateral surface. In addition, gp80/clusterin, a protein that is normally secreted apically, is randomly secreted when cilia are removed. Dramatically, expression of gp135/podocalyxin, a protein that serves to organize apical subdomains, is significantly reduced. Deciliated cells in 3-D collagen/matrik gel cultures do not form organized cysts with well-defined apical and basolateral domains. Furthermore, polarity reversal characteristic of untreated cells upon transfer of cysts from agasone to matrigel is impaired following deciliation. Insight into mechanisms responsible for these effects is provided by analysis of clonal MDCK lines impaired in ciliogenesis, showing that cilia resorption does not, by itself, result in junction remodeling and that presence of a mature primary cilia is not required for the deciliation-triggered effects. Also, LLC-PK1 cells neither lose primary cilia nor remodel junctions following CH treatment. We conclude that CH targets a mechanism that functions to promote deciliation, tight junction remodeling, altering post-Golgi sorting and cell polarity.

Mechanism of NC-1059 Induced Increase in Paracellular Permeability of Epithelial Monolayers
S. Somasekharan, J. M. Tomich, D. Schuler; 1Biochemistry, Kansas State University, Manhattan, KS, S. Anatomy and Physiology, Kansas State University, Manhattan, KS
The goal of this study is to identify the mechanisms by which NC-1059 increases epithelial paracellular permeability. NC-1059 is a synthetic channel forming peptide that increases short circuit current (Isc) and decreases transepithelial resistance (Rte) in a variety of epithelia. Exposure of MDCK monolayers to 100 and 200 micromolar NC-1059 results in a concentration-dependent change in both Lsc and Rte. NC-1059 enhances the permeation rate of large molecular weight dextrans across monolayers, which documents a peptide induced opening of the paracellular route suggesting a reorganization of tight junction proteins. The effects on immunolabeling of occludin, ZO-1 and actin as viewed with confocal microscopy reveal substantial redistribution or loss of these proteins upon exposure to both 100 and 200 micromolar NC-1059 in MDCK monolayers. The effect of NC-1059 on the tight junctions and actin occurs in a time and concentration dependant pattern with a more rapid change occurring at 200 micromolar as compared to 100 micromolar. 100 micromolar NC-1059 causes the Rte of MDCK monolayers to drop by at least 90%. The epithelia show an average recovery in Rte of approximately 34 % at 24 hours which reaches pretreatment levels after 48 hours. The modulation of the epithelial barrier in a reversible manner has therapeutic potential to increase the efficiency of drug delivery across barrier membranes. (Supported by GM 074096 to JMT)

2456
Urinary Epithelial Growth Factor; Plausible Physiological Regulator of Tight Junction Permeability along the Nephron
D. Flores-Benitez, A. Ruiz-Cabrera, C. Flores-Maldonado, M. Cereijido, R. G. Contreras; 1Fisiologia, Biofisica y Neurociencias, CINVESTAV, D.F., Mexico, 2Laboratorio de Medicina, FES-Iztacala, UNAM, D.F., Mexico
Epithelia can adjust the permeability of their paracellular permeation route to physiological requirements, pathological conditions, and pharmacological challenges. This is reflected by a substrate dependent change in both Lsc and Rte. NC-1059 enhances the permeation rate of large molecular weight dextrans across monolayers, which documents a peptide induced opening of the paracellular route suggesting a reorganization of tight junction proteins. The effects on immunolabeling of occludin, ZO-1 and actin as viewed with confocal microscopy reveal substantial redistribution or loss of these proteins upon exposure to both 100 and 200 micromolar NC-1059 in MDCK monolayers. The effect of NC-1059 on the tight junctions and actin occurs in a time and concentration dependant pattern with a more rapid change occurring at 200 micromolar as compared to 100 micromolar. 100 micromolar NC-1059 causes the Rte of MDCK monolayers to drop by at least 90%. The epithelia show an average recovery in Rte of approximately 34 % at 24 hours which reaches pretreatment levels after 48 hours. The modulation of the epithelial barrier in a reversible manner has therapeutic potential to increase the efficiency of drug delivery across barrier membranes. (Supported by GM 074096 to JMT)
2457 IL-1β Modulation of Epithelial Tight Junction Permeability
R. Al-Sadi, 1 T. Ma 1; 1 Internal Medicine, University of New Mexico, Albuquerque, NM; 2 VA Medical Center, Albuquerque, NM

IL-1β is a prototypical pro-inflammatory cytokine that plays a central role in the regulation of epithelial barrier function. Recent studies have shown that IL-1β affects the expression of tight junction proteins in various cell types, including enterocytes, intestinal epithelial cells, and Sertoli cells. In this study, we investigated the effects of IL-1β on tight junction permeability in Caco-2 cells, a cell line that has been widely used as a model for intestinal epithelial cells.

We found that IL-1β induced a progressive time-dependent increase in transepithelial permeability in Caco-2 cells. This effect was mediated in part by the activation of NF-κB pathways but not apoptosis. Further, the IL-1β-induced increase in TJ permeability was mediated in part by the activation of NF-kappaB pathways but not apoptosis.

2458 Differential Modulation of Claudins in Skin Tumours
K. Turkson, A. Arabzadeh, T. Troy; Ottawa Health Research Institute, Ottawa, ON, Canada

It is widely recognized that the Claudin (Cldn) family of tetraspan transmembrane proteins is crucial for skin barrier function. Recent studies indicate that Cldn overexpression and Cldn deletion mutants are associated with cell permeability defects in vivo, and that the level of Cldn expression appears to be crucial in skin barrier integrity and function. Knowledge of the overall structure-function of the Cldn family of proteins is limited, however they are thought to have three distinct and characteristic functional domains: (i) four transmembrane-spanning regions, (ii) two extracellular loops responsible for barrier formation within the paracellular space and specific ion selectivity residing within the first extracellular loop; and (iii) a cytoplasmic C-terminus that functions as a transmembrane protein.

2459 Dual Transcriptional Control of Claudin-11 via an Overlapping GATA/NF-Y Motif: Positive Regulation through the Interaction of GATA, NF-Y, and CREB, and Negative Regulation through the Interaction of SMAD, HDAC1, and mSIN3A
L. Wang, W. Lee, Zoology, The University of Hong Kong, Hong Kong

The expression of claudin-11, a key tight junction protein, is tightly regulated to ensure that the integrity of the semipermeable epithelium can be maintained during the translocation of spermatozoa at the blood-testis barrier at stages VIII-IX. In this study, we elucidate how the overlapping GATA/NF-Y motif within the core promoter of claudin-11 gene is modulated by differential binding of various transcription factors, resulting in dual transcriptional control. We have found that GATA, NF-Y, and CREB form a complex in vivo and bind to the GATA/NF-Y region to promote claudin-11 gene transcription. GATA and CREB transactivation could be further modulated by the presence of Smad3 and Smad4 proteins. Binding of Smad proteins at the GATA/NF-Y motif could repress the GATA and CREB transactivation of claudin-11 gene.

2460 Occludin and Claudin-11 Participate in the Formation of Epidermal Tight Junction and the Barrier Function in Human Keratinocytes
Y. Ito, 1 M. Kasurawa, 2 S. Kuroda, 1 Y. Yamamoto, 1 H. Sasaki 1; 1 POLE Chemical Industries, Inc., Yokohama, Japan; 2 Department of Molecular Cell Biology, Institute of DNA Medicine, Jikei University School of Medicine, Tokyo, Japan

The tight junctions (TJs) of the epidermis are the most apical component of the junctional complex and play a vital role in cell-cell adhesion in epithelial and endothelial cells. TJs create a primary paracellular barrier that regulates the movement of water and solutes, and also keep cell polarity to divide the apical and the basolateral membrane domains. In the epidermis of the skin, the evidence suggests that the epidermal barrier should be contributed not only by the stratum corneum but also by TJs in the granular layer of the epidermis are accumulated. The detailed mechanism of the epidermal barrier, however, is not clearly understood. The roles of TJs and the barrier function in human skin epidermal keratinocytes, we investigated the interactions of TJ molecules using the differentiated keratinocytes induced by calcium switching (3.3 mM) and RNA interference of TJs molecules. After the calcium switching, TJs molecules that characterised claudin-11, occludin and claudin-12 were localized to cell membrane and the transepithelial electrical resistance (TER) was elevated in accordance with keratinocyte differentiation.

2461 TNFα Induces Degradation of CLMP mRNA in Sertoli Cells through a JNK-dependent Pathway
K. Sze, W. Lee, W. Lui; Zoology, The University of Hong Kong, Hong Kong

During spermatogenesis, extensive restructuring of blood-testis barrier takes place to facilitate the migration of preleptotene /leptotene spermatocytes from the basal to the adluminal compartment in the seminiferous epithelium. However, the biochemical mechanisms that regulate this event remain largely unknown. Recent studies have shown that proinflammatory cytokine tumor necrosis factor-alpha (TNFα) plays a crucial role in this event by inhibiting the expression of tight junction transmembrane proteins in Sertoli cells. In this study, we sought to examine the effect of TNFα on the expression of CLMP (cox-5a-like membrane protein), a novel identified tight junction transmembrane protein, in the testis. Addition of TNFα (10 ng/ml) to Sertoli cell culture (TM4 cells) significantly reduced the steady-state CLMP mRNA level as shown in quantitative RT-PCR. In the presence of actinomycin D, the TNFα-induced decrease in CLMP mRNA expression was not affected. On the other hand, occludin expression did not influence the localization of claudin-1, suggesting that occludin plays a more important role in the formation of epidermal barrier than claudin-1 itself, and claudin-1 is rather important for recruiting occludin to cell membrane to form epidermal permeability barrier. These data provided us the new insight into not only the TJ localization and formation during keratinocyte differentiation but also the roles of TJs on epidermal barrier function.

2462 Cldn12 and Cldn18 in different stages of mouse skin carcinogenesis. The expression of Cldns may also be involved in the initiation and progression of carcinogenesis. Here, we present data on the expression of Cldn1, Cldn6, Cldn11, Cldn12 and Cldn18 in different stages of mouse skin carcinogenesis. The comparison of Cldn expression on the keratinocyte membranes of papilloma cells clearly revealed expression and localization changes correlating with the level of tumour differentiation. This work is supported by the Canadian Institutes of Health Research.

2463 Regeneration through the Interaction of SMAD, HDAC1, and mSIN3A
W. Lui, E. Wong, W. Lee, Zoology, The University of Hong Kong, Hong Kong

The expression of claudin-11, a key tight junction protein, is tightly regulated to ensure that the integrity of the semipermeable epithelium can be maintained during the translocation of spermatozoa at the blood-testis barrier at stages VIII-IX. In this study, we elucidate how the overlapping GATA/NF-Y motif within the core promoter of claudin-11 gene is modulated by differential binding of various transcription factors, resulting in dual transcriptional control. We have found that GATA, NF-Y, and CREB form a complex in vivo and bind to the GATA/NF-Y region to promote claudin-11 gene transcription. GATA and CREB transactivation could be further modulated by the presence of Smad3 and Smad4 proteins. Binding of Smad proteins at the GATA/NF-Y motif could repress the GATA and CREB transactivation of claudin-11 gene. Such repression required the recruitment and physical interactions of histone deacetylase 1 and its co-repressor, mSin3A with Smad proteins. It is believed that cyclic changes in the ratio of positive regulators (GATA, NF-Y and CREB) to negative regulators (Smads) in the semipermeable epithelium during the spermatogenic cycle might provide a precise control in claudin-11 gene transcription. This work was supported by the Hong Kong Research Grant Council grant (HKU7536/05M), HKUCRCG Small Project Funding and HKUCRCG Seed Funding.

2464 Ocludin and Claudin-11 Participate in the Formation of Epidermal Tight Junction and the Barrier Function in Human Keratinocytes
Y. Ito, 1 M. Kasurawa, 2 S. Kuroda, 1 Y. Yamamoto, 1 H. Sasaki 1; 1 POLE Chemical Industries, Inc., Yokohama, Japan; 2 Department of Molecular Cell Biology, Institute of DNA Medicine, Jikei University School of Medicine, Tokyo, Japan

The tight junctions (TJs) are the most apical component of the junctional complex and are responsible for barrier formation within the paracellular space and specific ion selectivity residing within the first extracellular loop; and (iii) a cytoplasmic C-terminus that functions as a transmembrane protein.

2465 Dual Transcriptional Control of Claudin-11 via an Overlapping GATA/NF-Y Motif: Positive Regulation through the Interaction of GATA, NF-Y, and CREB, and Negative Regulation through the Interaction of SMAD, HDAC1, and mSIN3A
W. Lui, E. Wong, W. Lee, Zoology, The University of Hong Kong, Hong Kong

2466 Occludin and Claudin-11 Participate in the Formation of Epidermal Tight Junction and the Barrier Function in Human Keratinocytes
Y. Ito, 1 M. Kasurawa, 2 S. Kuroda, 1 Y. Yamamoto, 1 H. Sasaki 1; 1 POLE Chemical Industries, Inc., Yokohama, Japan; 2 Department of Molecular Cell Biology, Institute of DNA Medicine, Jikei University School of Medicine, Tokyo, Japan

The tight junctions (TJs) are the most apical component of the junctional complex and are responsible for barrier formation within the paracellular space and specific ion selectivity residing within the first extracellular loop; and (iii) a cytoplasmic C-terminus that functions as a transmembrane protein.
Taken together these results, we conclude that ZO-2 downregulates cyclin D1 transcription, probably by interacting with the c-Myc/E box element and recruiting HDAC1. We use ChIP and reporter gene assays employing HDACs inhibitors. Our results demonstrated that HDACs are necessary for ZO-2 repression and also that HDAC1 is recruited to the E box.

To understand how ZO-2 represses cyclin D1 promoter activity, we used deletion analyses, finding that ZO-2 negatively regulates cyclin D1 transcription via a distal E box present in cyclin D1 promoter. To establish the identity of transcription factors bound to this E box in MDCK, we employed EMSA and ChIP assays that pointed to the transcription factor c-Myc. Over-expression of c-Myc and ZO-2 resulted in a clear negative effect over transcriptional promoter activity, where c-Myc is acting as a repressor, cooperating additively with ZO-2. We also noticed that ZO-2 localizes at the E box region by ChIP assays in MDCK cells. Finally, we explored HDACs participation in cyclin D1 downregulation by the c-Myc/ZO-2 combination. To address this question, we use ChIP and reporter gene assays employing HDACs inhibitors. Our results demonstrated that HDACs are necessary for ZO-2 repression and also that HDAC1 is recruited to the E box. Taken together these results, we conclude that ZO-2 downregulates cyclin D1 transcription, probably by interacting with the c-Myc/E box element and recruiting HDAC1.

Rho-ROCK II Signaling Regulates Disassembly of Epithelial Apical Junctions
S. N. Samarin, A. I. Ivanov, C. A. Parkos, A. Nusrat; Pathology, Emory University, Atlanta, GA

The apical junctional complex (AJC) encompassing tight junction (TJ) and adherens junction (AJ) regulates epithelial barrier function. Diverse physiologic and pathologic stimuli have been observed to induce reversible disassembly of AJC associated with disruption of epithelial barrier. Nevertheless, signaling pathways that regulate A JC disassembly are poorly understood. Using a calcium depletion model of rapid junctional disassembly, we have previously shown that disintegration of the AJC is driven by myosin II-mediated contraction of the peripheral acto-myoelin ring. This study was designed to dissect signaling pathways upstream of myosin II that control A JC disassembly. Depletion of extracellular calcium in TS4 and SK-C015 model intestinal epithelial cell lines induced reorganization of the perijunctional F-actin into contractile rings, which was accompanied by disruption and internalization of apical junctions. Pharmacological inhibition and protein localization studies revealed no role for myosin light chain kinase (MLCK) in disruption of the A JC. In contrast, inhibition of Rho-associated kinase (ROCK) with Y-27632 and H-112 prevented disassembly of the AJC and loss of epithelial barrier function in calcium-depleted cells. Moreover, both isoforms of ROCK, ROCK I and ROCK II were recruited to contractile F-actin rings. However, only siRNA knock-down of ROCK II attenuated A JC disassembly. Additionally, Rho GTPase, an upstream activator of ROCK, was transiently activated and co-localized with internalized junctional proteins in calcium-depleted cells. Pharmacological inhibition of Rho with a Rho specific inhibitor DCBII completely prevented A JC disassembly. GEF-H1, a guanine nucleotide exchange factor for Rho, also accumulated in contractile F-actin rings in calcium-depleted cells. Furthermore, si-RNA-mediated down-regulation of GEF-H1 expression significantly attenuated disassembly of A JC. These results suggest that GEF-H1/Rho/ROCK II signaling pathway is a major regulatory mechanism responsible for disassembly of epithelial A JC.

Negative Curvature Contributed by Specific Lipids Is an Essential Component of Ca2+-triggered Native Membrane Fusion
M. A. Churchward, T. Rogashevskia, R. C. Taylor, J. R. Coorsen; 1Physiology and Biophysics, University of Calgary, Calgary, AB, Canada, 2Hotchkiss Brain Institute, University of Calgary, Calgary, AB, Canada

Fast Ca2+-triggered membrane merger is the defining step of regulated exocytosis. In native secretory vesicles, cholesterol (CHOL) functions in the fundamental fusion (e.g. bilayer merger) mechanism (1), and CHOL sphingomyelin - enriched microdomains define the efficiency (Ca2+ sensitivity and kinetics) of fusion (2). The contribution of cholesterol to the process of membrane fusion itself is mimicked by structurally dissimilar lipidic membrane components having spontaneous negative curvatures similar to or greater than that of CHOL. Dioleoylphosphatidylethanolamine with a single mol% of cholesterol, together triggered bilayer merger of CHOL-depleted vesicles, correlating quantitatively with the negative curvature each contributes to the membrane. Unable to substitute for CHOL in stabilizing microdomains, these lipids do not rescue fusion efficiency. Lipids of less spontaneous negative curvature than CHOL, including dioleoylphosphatic acid, are unable to effectively support fusion. This quantitative relationship between negative curvature and membrane fusion appears most consistent with the stalk-pore model (3), demonstrating that negative curvature itself is an essential component of the fundamental native fusion mechanism. The data also suggest that different fusion sites, vesicles, or secretory cell types could use other lipidic components, in addition to CHOL or similar endogenous sterols, to provide optimal local negative curvature and even to modulate the fusion process.

Hemifusion Arrest by Complex Is Relieved by Ca2+-Synaptotagmin I
B. Doneske, 1 J. R. Schaub, 2 K. Lu, 2 Y. Shin, 1 J. A. McNew; 1Department of Biochemistry and Cell Biology, Rice University, Houston, TX, 2Department of Biochemistry, Biophysics, and Molecular Biology, Iowa State University, Ames, IA

Synaptic transmission relies on an exquisitely orchestrated series of protein-protein interactions that ultimately results in neurotransmitter release into the synaptic cleft. The final step in this reaction is membrane fusion of the synaptic vesicle with the presynaptic plasma membrane catalyzed by SNARE proteins. Several extrinsic protein factors impinge on the cycle of SNARE complex assembly to regulate vesicle release in space and time. These include general regulators such as the Rab family of GTPases and the Munc18/Sec1 (SM) proteins, as well as specific regulators of synaptic transmission including complexin and synaptotagmin. The interplay of these regulatory factors and their precise mechanisms of action remain an area of intense investigation. Here we show that fusion driven by a t-SNARE complex of Syntaxin/I/SNAP25 and the v-SNARE VAMP2, but not their yeast equivalents, is inhibited by complexin. Furthermore, inner leaflet mixing is strongly impaired related to total lipid mixing indicating that inhibition by complexin arrests fusion at a hemifusion intermediate. When the calcium sensor synaptotagmin is added in the absence of calcium to the complex-inhibited reaction, the arrest persists. However, when calcium is introduced, complexin inhibition is relieved and full fusion rapidly proceeds as evidenced by restoration of inner leaflet mixing. Our results suggest that the combination of complexin and synaptotagmin provides a strong calcium-dependent clamp to inhibit full fusion at hemifusion until released by calcium influx.

Sphingosines Interfere with Antigen-stimulated, Calcium-dependent Fusion of Recycling Endosomes with the Mast Cell Plasma Membrane by Perturbing its Inner Leaflet
N. L. Smith, D. Holowka, B. Baird; Chemistry and Chemical Biology, Cornell University, Ithaca, NY

Proteins and lipids undergo trafficking to and from the plasma membrane via a spatially organized pool of intracellular membranes termed recycling endosomes. FITC-labeled cholera toxin B (FITC-CtxB) bound to the ganglioside GM1 is used to monitor IgG receptor stimulated trafficking of these endosomes to the plasma membrane in RBL mast cells (Naal et al., Traffic 4, 190, 2003). This process is refractory to most inhibitors of stimulated degranulation in these cells. We find that certain sphingosine derivatives, including D- or L-sphingosine and N,N-dimethylsphingosine (DMS), effectively inhibit this endosomal trafficking response stimulated by multivalent antigen or calcium ionophore. These amphiphiles cause a transient relief of self-quenching of FITC-CtxB at the cell surface that is restored as these compounds flip to the inner leaflet. In contrast to sphingosine and DMS, trimethyl sphingosine (TMS) stably inserts into the outer leaflet of the plasma membrane where it causes sustained relief of FITC-CtxB self-quenching and does not inhibit stimulated trafficking. Unlike their effect on recycling endosome trafficking, sphingosine and DMS only modestly inhibit ionophore-stimulated exocytosis of secretory lysosomes, suggesting different mechanisms for exocytosis of these two intracellular organelles. Our results are consistent with a model in which sphingosines alter intracellular signaling processes by physical perturbation of the cytoplasmic leaflet of cell membranes.

Thiol-Reactivity as a Route to Identifying Proteins Involved in Ca2+-Triggered Membrane Fusion
K. L. Ferber, 1 D. M. Brandman, 2 A. L. Yergey, 1 J. R. Coorsen; 1Physiology & Biophysics, Hotchkiss Brain Institute, Faculty of Medicine, University of Calgary, Calgary, AB, Canada, 2Cellular & Molecular Biophysics, NICHD, National Institutes of Health, Bethesda, MD

2006 ASCB Annual Meeting Abstracts
Ca2+-triggered membrane fusion is an essential and conserved process for the rapid release of cellular components. Despite substantial progress in identifying proteins involved in exocytosis, the mechanisms underlying regulated membrane merger remain poorly understood. Here we use isolated sea urchin egg cortical vesicles (CV), a minimal, stage-specific preparation of Ca2+-sensitive, release-ready secretory vesicles, to investigate the proteins involved in the native fusion mechanism. Thiol-reactive reagents, which alkylate free sulphydryl groups, have been consistently shown to dose-dependently inhibit the extent, Ca2+-sensitivity, and kinetics of triggered fusion. However, in this study, iodocadaverine (IA) was found to selectively enhance the Ca2+-triggered steps of membrane fusion. Treatments of 10mM-100mM IA caused an increase in Ca2+-sensitivity indicated by a maximal leftward shift in EC50 of 14.4 ± 1.5µM [Ca2+]o, with treatments in the range of 20mM-80mM IA also potentiating fusion kinetics. If Sr2+; a weak Ca2+ mimetic, was used to trigger fusion, the increase in Sr2+-sensitivity was approximately 2-fold compared to the increase in Ca2+-sensitivity. Further investigation established that IA did not increase the extent or quality of CV attachment / docking either to the plasma membrane or to other CV. Comparison of IA to other thiol-reactive reagents indicates that the differential effects of these reagents can be attributed to lipophilicity. Ongoing studies show that the same enhancement of fusion can be elicited by treatment with Lucifer yellow IA (LYIA); therefore, this fluorescent IA can be employed to simultaneously potentiate fusion and label the critical protein(s) involved. By coupling the functional assays with two-dimensional gel electrophoresis (2DE), proteins that showed a dose-dependent increase in LYIA labeling, corresponding to an increased efficiency of fusion, were isolated. These are currently being sequenced by mass spectrometric techniques. This work identifies potential candidate proteins that may act at or near the fast Ca2+-triggered steps of native membrane fusion.

Quantitative Analysis of Recycling Endosomal Trafficking in RBL Mast Cells Revealed by Real-Time Fluorescence Microscopy

S. Hammond, N. L. Smith, D. Holowka, B. Baird; Chemistry and Chemical Biology, Cornell University, Ithaca, NY

Recycling endosomes are spatially organized pools of intracellular membranes that dynamically recycle endocytosed lipids and proteins back to the plasma membrane. This membrane pool can be labeled by cholera toxin subunit B (CTxB), which binds to the ganglioside GM-1, and fluorescently tagged CTxB serves as a marker to monitor trafficking from this organelle in mast cells. Stimulation via IgE receptors, FceRI, results in a net outward trafficking response, as monitored by an increase in FITC-CTxB fluorescence (Naal et al., Traffic, 4:190, 2003). To further characterize this process, we have developed a real-time assay to monitor outward trafficking of recycling endosomes to the plasma membrane in individual cells using three-color fluorescence confocal microscopy. In this approach, surface GM1 is first blocked by unlabeled CTxB; upon stimulation, newly delivered GM1 from recycling endosomes can then bind Alexa488-CTxB, resulting in increased fluorescence at the plasma membrane. On average, stimulation by antigen or calcium ionophore increases the rate of net outward trafficking of recycling endosomes 2-3-fold. In addition, D-sphingosine inhibits the rate of calcium ionophore-stimulated outward trafficking of recycling endosomes, consistent with the results from our fluorimetric assay. Spatial proximity of newly-trafficked CTxB/GM1 to FceRI and other cell surface components can also be monitored by this method. The development of a microscopy method to study this process will be useful in characterizing the functional roles and mechanism of recycling endosomal trafficking in these and other cells.

Regulation of Syntaxin 7 Expression and Function in Macrophages by CSF-1

K. Subraamnian; Biochemistry Department, University of Osnabrueck, Osnabrueck, Germany

Protein palmitoylation is a reversible lipid modification by fatty acids, usually palmitic acid, to cysteine thiols. It stably anchors specific proteins to membranes, but may also have a direct effect on the function of a protein. The yeast protein Vac8 is required for efficient vacuole fusion, inheritance and cytosol-to-vacuole trafficking. It is anchored to vacuoles by an N-terminal myristoylation site and three palmitoylation sites, also known as the SH4 domain. Here, we address the role of Vac8 palmitoylation and show that the position and number of substrate cysteines within the SH4 domain determine the vacuole localization of Vac8: stable vacuole binding of Vac8 requires two cysteines within the N-terminus, regardless of the combination. Importantly, our data suggest that palmitoylation adds functionality to Vac8 beyond simple localization. A mutant Vac8 protein, in which the palmitoylation sites were replaced by a stretch of basic residues, still localizes to vacuole membranes and functions in cytosol-to-vacuole transport, but can only complement the function of Vac8 in morphology and inheritance if it also contains a single cysteine within the SH4 domain. Our data suggest that palmitoylation is not a mere hydrophobic anchor required solely for localization, but influences the protein function(s).

Interaction of SNAREs with ArfGAPs Precedes Recruitment of Sec18p/NSF

C. Schindler, A. Spang; Biozentrum, University of Basel, Basel, Switzerland

SNAREs are key components of the fusion machinery in vesicular transport and in homotypic membrane fusion. The ArfGAP Gsc1p accelerated v-t-SNARE complex formation in vitro, indicating that ArfGAPs may act as folding chaperones. These SNARE complexes were resolved in the presence of ATP by the yeast homologues of α-SNAP and NSF, Sec17p and Sec18p, respectively. Furthermore, the ArfGAPs Gsc1p and Glp3p, but not Age2p, induced conformational changes in v- and t-SNAREs that promoted recruitment of the small GTPase Arf1p in stoichiometric amounts. Yet, not Arf1p bound to the ‘activated’ SNAREs: Sec1p and Sec1p also recognized the SNAREs even when they were not engaged in v-t-SNARE complexes. Here again the induction of a conformational change by ArfGAPs was essential. Surprisingly, the mere recruitment of Sec1p to SNAREs did not require Sec17p or ATP hydrolysis. Moreover, Sec1p displaced prebound Arf1p from SNAREs, indicating that Sec1p may have more than one function: one to ensure that all vesicle coat proteins are removed from the SNAREs before the engagement in a trans-SNARE complex and a second one to resolve cis-SNARE complexes after fusion has occurred.

Neuronal Sec1 Binds the t-SNARE Complex and Stimulates Fusion

T. L. Rodkey, J. A. McNew; Biochemistry & Cell Biology, Rice University, Houston, TX

Neuronal Sec1 binds the t-SNARE complex and stimulates fusion driven by neuronal SNAREs in a concentration and time dependent manner. However, stimulation is specific for Syntaxin1a/SNAP25 and VAMP2 since their yeast counterparts are unaffected by the addition of n-Sec1.
Membrane fusion was blocked. Experiments are underway to determine if FusMp and Fus1p interact with each other. Blast analysis shows that fusion. Bioassays demonstrated that gametes transformed with HA-tagged FusMp showed that FusMp is localized on the male mating structure and preliminary results indicate that FusMp levels were reduced immediately after undergoing normal flagellar adhesion with female gametes, but failed to fuse. Transformation with the wild-type gene rescued fusion in cells and we have systematically studied their topology and assembly pathway. Our results suggest that both topology and assembly pathway of trans-SNARE complexes differ from the ones suggested based on earlier studies with purified proteins. These discrepancies probably reflect the control of SNARE conformation and association imposed by accessory factors in the physiological membrane.

The formation of complexes between v- and t-SNAREs is believed to be crucial for many intracellular fusion reactions. Studies with purified SNARE proteins have suggested that the t-SNARE subunits assemble on one fusion partner and that the v-SNARE is donated by the other fusion partner. We have now used a physiological membrane system, the cell-free fusion of yeast vacuoles to detect trans-SNARE complexes and we have used purified recombinant proteins, we demonstrate that yeast Sec1p binds directly and specifically to ternary SNARE complexes in vitro. Our data are consistent with models in which Sec1p binding is sensitive to the assembly state of the target membrane SNAREs. We have also initiated trials for obtaining crystals of Sec1-SNARE complexes to understand the molecular details of this interaction.

The Conserved Oligomeric Golgi (COG) complex is a widely conserved eight-subunit tethering complex required for retrograde Golgi transport, and hence for proper maintenance of Golgi protein localization. Defects in several subunits, including Cog7, have been identified as causes of congenital disorders of glycosylation in humans. The complex is thought to act upstream of SNAP Receptor (SNARE) involvement by tethering the incoming vesicle to its target membrane at a distance. Supporting this, the complex has been shown to interact with SNAREs, and several of the mammalian complex, including Cog5, have been shown to interact with Golgi-localized Rab proteins which regulate vesicle tethering. Existing partial structures of S. cerevisiae Cog2p and of subunits of the weakly homologous Exocyst complex display a common theme of bundles of α-helices, but the crystal structures of the majority of the COG subunits, and of any subunit in its context in the complex, have yet to be determined. To the end of obtaining the crystal structure of a greater number of subunits while preserving their interactions, we have purified from E. coli a recombinant subcomplex of S. cerevisiae COG consisting of the strongly interacting Cog5p and Cog7p. Proteolytic fragments of these proteins in complex, suitable for crystallographic trials, have been identified and purified, and indicate that the N-terminal 80 residues of Cog5p appear to contain its interaction domain with Cog5p.

The molecular mechanisms of gamete fusion in fertilization are unknown. The aim of this work is to study the forces that drive cell fusion from local intermediates to syncytium formation. The event of fusion is a critical step in development and in enveloped virus infection. While a lot is known about structures of some fusogenic proteins and early fusion intermediates, later fusion stages that involve the expansion of the initial fusion pore to fully merge the volumes of the fusing cells and form a new cellular entity, remain elusive. To investigate the interplay between cell fusion and rearrangements of cytoskeleton, we have used marine fibroblasts (NIH 3T3 cells) that stably express hemagglutinin, the fus fusion protein. After short-term applications of trypsin followed by acidic medium, these cells fused with each other yielding multinucleated cells in about 3 hours. Time lapse fluorescence microscopy experiments have been performed to dissect the process of syncytium formation. We found that incubation on ice blocks transition from local fusion (assayed as redistribution of fluorescent cell trackers) to syncytia formation. The actin and microtubule cytoskeleton have been labeled with phallolidin and antibodies to better understand their involvement. In addition, the rate of syncytium formation has been quantified using drugs affecting either actin cytoskeleton (latrunculin B) or microtubule cytoskeleton (taxol, nocodazole). Our data suggest that while the microtubule cytoskeleton is not significantly involved in syncytia formation, the actin cytoskeleton appears to restrain the expansion of the fusion pores. These data on syncytium formation by viral fusion protein disagree with the results published for syncytia obtained with electroporation suggesting that mechanisms of the syncytium formation may depend on numbers and/or properties of initial fusion pores. Further elucidation of the mechanisms of syncytium formation will hopefully bring important insights into the mechanisms by which living cell controls its shape and responds to its changes.

The formation of complexes between v- and t-SNAREs is believed to be crucial for many intracellular fusion reactions. Studies with purified SNARE proteins have suggested that the t-SNARE subunits assemble on one fusion partner and that the v-SNARE is donated by the other fusion partner. We have now used a physiological membrane system, the cell-free fusion of yeast vacuoles to detect trans-SNARE complexes and we have used purified recombinant proteins, we demonstrate that yeast Sec1p binds directly and specifically to ternary SNARE complexes in vitro. Our data are consistent with models in which Sec1p binding is sensitive to the assembly state of the target membrane SNAREs. We have also initiated trials for obtaining crystals of Sec1-SNARE complexes to understand the molecular details of this interaction.
Role of Cholesterol in Organization of the Neuronal Fusion Core

A. Jeremic, W. Cho, B. Jena; Physiology, School of Medicine, Wayne State University, Detroit, MI

Neurotransmitter release depends on the regulated release of neurotransmitter vesicles in the synaptic cleft and subsequent activation of post-synaptic sites. Neuronal fusion pore or poreosome, a supramolecular assembly localized at the presynaptic membrane, has been identified as the molecular structure for neurotransmitter release. To further determine the composition, organization and function of this molecular machinery at the nerve terminal, we carried out the present study. In this study we show using biochemical and high-resolution imaging approaches, that membrane cholesterol is an essential component of the neuronal presynaptic. Cholesterol, together with pre-synaptic proteins: syntaxin-1, SNAP-25 and synaptotagmin-1, co-clusters and separates out as a high-molecular weight supramolecular complex (~700 kD) estimated using gel filtration and sucrose gradient density centrifugation, respectively. Depletion of synaptic membrane cholesterol by saponin treatment abrogated binding between t-SNAREs (syntaxin-1 and SNAP-25) and N-type Ca2+-channels, leading to disassembly of the poreosome complex. In contrast to the effect of cholesterol on the organization of SNAREs in synapsosomal membrane, interactions and organization of recombinant t-SNAREs in artificial lipid membranes were not influenced by cholesterol. This study demonstrates that in the native state, cholesterol is part of the poreosome complex, and is required to maintain its integrity. It also suggests that in the native state, cholesterol regulates SNAREs in such a way that cholesterol modifies the interaction of the poreosome complex. In summary, our studies demonstrate that cholesterol controls the synaptic membrane interacts with t-SNAREs, N-type Ca2+-channels and other proteins to organize functional fusion machinery at the nerve terminal. Supported by NIH grants (BPH).

Alcohol-induced Pathological Ectopic Exocytosis in Cholinergic-stimulated Rat Pancreatic Acini

L. I. Cosen-Binker, P. Lam, M. G. Binker, H. Y. Gaisano; University of Toronto, Toronto, ON, Canada

Chronic alcoholic consumption is a major factor associated to pancreatitis. However, the susceptible mechanism of alcohol-induced pancreatitis remains unknown. Using a combination of conventional epifluorescence and confocal microscopy, electron microscopy, subcellular fractionation, immunoprecipitation and biochemical techniques, we show that acute low-dose alcohol in vitro exposure or chronic alcoholic diet reduces postprandial cholinergic-stimulated amylase secretion from rat pancreatic acinar cells by redirecting normal apical exocytosis to the less efficient basolateral plasma membrane. The molecular mechanism involves the displacement of Munc18c from the basolateral plasma membrane, which becomes receptive to pathological ectopic exocytosis, leading to interstitial pancreatitis.

Akt Regulates Insulin-mediated Recruitment/Docking of GLUT4 Vesicles to the Plasma Membrane of Adipocytes

E. Gonzalez, T. McGraw; Biochemistry, Weill Medical College of Cornell University, New York, NY

Insulin modulates glucose disposal in muscle and adipose tissue by regulating the cellular redistribution of the GLUT4 glucose transporter. Insulin promotes the translocation of GLUT4 from intracellular sites to the plasma membrane by accelerating GLUT4 exocytosis and inhibiting GLUT4 internalization. Protein kinase Akt/PKB is a central mediator of insulin-regulated translocation of GLUT4; however, the GLUT4 trafficking step(s) regulated by Akt is not known. We used acute pharmacologic: Akt inhibition and shRNA-mediated Akt knockdown to dissect the role of Akt signaling on GLUT4 trafficking in 3T3-L1 adipocytes. We observed that acute inhibition of Akt activity strongly impaired insulin-induced GLUT4 redistribution to the plasma membrane and glucose transport in adipocytes. Insulin-induced GLUT4 translocation was impaired following downregulation of Akt2 but not Akt1. Using a HA-GLUT4-GFP reporter and single cell microscopy analyses we found that activation of Akt is required for insulin-induced GLUT4 exocytosis whereas regulation of GLUT4 internalization is independent of Akt activity. To further explore the steps on GLUT4 exocytosis regulated by Akt we developed a novel total internal reflection microscopy assay and show that along the exocytotic pathway, Akt activity is specifically required for an insulin-mediated pre-fusion step involving the recruitment and/or docking of GLUT4 vesicles to within 250 nm of the plasma membrane. By contrast, the insulin-stimulated fusion of GLUT4 vesicles with the plasma membrane can occur independent of Akt activity, although based on inhibition with wortmannin, it is dependent on PI3-kinase activity. These studies propose Akt as a central regulator of insulin-induced GLUT4 vesicle recruitment/docking at the plasma membrane and show that to achieve full redistribution of GLUT4 into the plasma membrane, insulin signaling bifurcates to independently regulate both fusion and a pre-fusion step(s).

Glut4 Vesicle Mobility Is Independent of Insulin Stimulation in 3T3-L1 Adipocytes

C. A. Eyster, A. Olson; Biochemistry, University of Oklahoma Health Sciences Center, Oklahoma City, OK

GLUT4 is an integral membrane glucose transporter protein responsible for insulin-mediated glucose uptake in adipose and muscle tissue. Insulin mediated GLUT4 redistribution to the cell surface is required to maintain glucose homeostasis, and is defective in insulin resistance. It has previously been suggested the insulin treatment increases GLUT4 vesicle movement to and fusion with plasma membrane. To directly test the effect of insulin on GLUT4 vesicle movement, we carried out Fluorescence Recovery After Photobleaching (FRAP) studies of GLUT4-GFP in live 3T3-L1 adipocytes. Surprisingly, we found that GLUT4 has highly mobile in the basal state at the cell surface, in the cytosol, and in the perinuclear compartment. In addition, we determined that insulin stimulation does not alter GLUT4 mobility in any of the three compartments tested. It had also been hypothesized that insulin signals to the microtubule network in order to increase the rate of GLUT4 vesicle mobility. Indeed, pharmacological inhibition of the microtubule network has been shown to block insulin mediated GLUT4 redistribution. However, recent work from our lab suggests that the microtubule requirement lies upstream of Akt activation in formation of the insulin signaling complex. Using a constitutively active Akt (myr-Akt), we tested if the requirement for the microtubule network was bypassed. As previously reported, insulin-dependent GLUT4 redistribution was blocked by Nocodazole, a microtubule inhibitor. However, Nocodazole did not inhibit GLUT4 redistribution signaled by expression of myr-Akt. This suggests that the microtubule network functions upstream of Akt activation. Indeed, in Nocodazole treated adipocytes, insulin-dependent Akt activation is blocked. These data suggest that insulin does not alter GLUT4 vesicle mobility. GLUT4 vesicles are not tethered in the basal state, and the microtubule requirement lies upstream of Akt activation.

Insulin Modulates Perinuclear GLUT4 Redistribution Independently of Toxin-sensitive VAMP2

V. K. Randhawa,1 A. W. P. Cheng,2 A. Klip 1; Programme in Cell Biology, Hospital for Sick Children, Toronto, ON, Canada; 1Department of Biochemistry, University of Toronto, Toronto, ON, Canada

Skeletal muscle and adipose are the main insulin-responsive tissues with regards to glucose uptake via the GLUT4 glucose transporter. GLUT4 resides intracellularly in compartments sequestered about the perinucleus and dispersed within the cytosol. Insulin increases surface GLUT4 levels by reducing its total internal complement. However, little is known of the nature of insulin-sensitive pools that furnish surface GLUT4. To this end, we made use of an L6 skeletal muscle cell line stably expressing exocytosis myr-tagged GLUT4 that allows high spatial resolution of these internal domains. Confocal microscopy revealed a predominantly conical perinuclear distribution of fluorescent-tagged GLUT4mGFP in the basal steady state. Insulin elicited a redistribution of perinuclear GLUT4 into a concentric morphology. As well, insulin increased the GLUT4 found with VAMP2 but not VAMP3 in both punctate cytoplasmic elements and the insulin-induced actin mesh. Insulin also increased GLUT4 recycling as measured by uptake of Cy3-anti-HA antibody by HA-tagged VAMP2. While insulin signals may directly modulate these intracellular sites, it was recently proposed that insulin regulation lies nearer to the plasma membrane. To determine if the insulin-induced perinuclear remodeling could arise from queuing of GLUT4 when vesicle fusion is prevented, we examined perinuclear GLUT4 distribution in cells transfected with tetanus toxin (TeTx). While TeTx abolishes insulin-dependent GLUT4 externalization in L6 myoblasts due to cleavage of VAMP2 (Randhawa et al, Mol Biol Cell 11:2403, 2000), we show here that TeTx does not alter the remodeling of perinuclear GLUT4 by insulin. Taken altogether, these results suggest that this remodeling is independent of GLUT4 fusion with the plasma membrane. Rather, we propose a model whereby GLUT4-containing compartments are in dynamic equilibrium and insulin may regulate the acquisition of VAMP2-positive GLUT4 vesicles en route to furnishing transporters the cell surface.

α-Actinin-4 Binds to Glut4 and Participates in Insulin-dependent GLUT4 Mobilization Towards the Plasma Membrane

I. Talon,1 V. K. Randhawa,1,2 A. Klip 1; Cell Biology, Hospital for Sick Children, Toronto, ON, Canada; 1Biochemistry Department, University of Toronto, Toronto, ON, Canada

Glucose transporter-4 (GLUT4) translocates from intracellular pools to the plasma membrane in response to insulin acidic secretion from rat pancreatic acinar cells by redirecting normal apical exocytosis to the less efficient basolateral plasma membrane. The molecular mechanism involves the displacement of Munc18c from the basolateral plasma membrane, which becomes receptive to pathological ectopic exocytosis, leading to interstitial pancreatitis. In contrast to the effect of cholesterol on the organization of SNAREs in synapsosomal membrane, interactions and organization of recombinant t-SNAREs in artificial lipid membranes were not influenced by cholesterol. This study demonstrates that in the native state, cholesterol is part of the poreosome complex, and is required to maintain its integrity. It also suggests that in the native state, cholesterol regulates SNAREs in such a way that cholesterol modifies the interaction of the poreosome complex. In summary, our studies demonstrate that cholesterol controls the synaptic membrane interacts with t-SNAREs, N-type Ca2+-channels and other proteins to organize functional fusion machinery at the nerve terminal. Supported by NIH grants (BPH).
domestic actin remodelling is essential for insulin-induced GLUT4 translocation, we hypothesized that α-actinin-4 may link GLUT4 to actin filaments in the course of its mobilization to the cell surface. Here we report increased co-precipitation of α-actinin-4 with GLUT4myc (but not GLUT1) from L6 muscle cells in response to insulin (but not PDGF), by immunoblotting with isoform-specific α-actinin-4 antibodies. Co-precipitation was significantly decreased by Latrunculin B, an inhibitor of actin filament reassembly. Interestingly, GLUT4myc co-localized with α-actinin-4 in regions within the insulin-remodelled actin mesh in L6 myotubes. Knockdown of α-actinin-4 (60%) via specific siRNA reduced the insulin-stimulated glucose uptake and gain in surface GLUT4myc, compared to unrelated siRNA. Notably, α-actinin-4 knockdown prevented GLUT4myc arrival at the membrane, scored by the lack of a submembrane perinuclear rim of myc immunofluorescence in permeabilized, rounded-up myotoblasts. Consequently, there was also no exocytotic myc rim in intact cells. Conversely, blocking PDK or AS160 allowed significant GLUT4myc arrival but prevented fusion with the membrane. α-actinin-4 siRNA did not perturb GLUT4 or α-actinin-1 expression, perinuclear GLUT4 distribution, insulin-stimulated actin remodelling or Akt activation. Collectively, this work suggests that the interaction of α-actinin-4 with GLUT4myc contributes to GLUT4 mobilization to the cell surface through its association with the actin cytoskeleton, and that GLUT4 mobilization is likely an insulin-regulated step. Supported by CIHR, BBDC and Sickkids.

Dominant Negative Rab11-FIP2 Trafficking Mutants Reveal Novel Protein Interactions Regulating Recycling
N. A. Ducharme,1 J. R. Goldenring2; 1Cell and Developmental Biology, Vanderbilt University, Nashville, TN, 2Surgery, Vanderbilt University, Nashville, TN
Rab11-FIP2 binds Rab11a and myosin Vb and regulates trafficking through the apical recycling system in polarized cells. We isolated a mutant EGFPRab11-FIP2 construct, Rab11-FIP2(S229A/R413G), which demonstrated a dominant negative phenotype for the Rab11a-containing recycling system. We assessed the effects of each single mutant and the double mutant in stable MDCK cell lines. EGFPRab11-FIP2(S229A) has no discernable effect on the morphology of the recycling system. EGFPRab11-FIP2(R413G) was a less severe dominant negative than EGFPRab11-FIP2(S229A/R413G), which caused a marked collapse and tubulation of the recycling system. The collapsed EGFPRab11-FIP2(S229A/R413G) tubular cisternae were often located eccentrically towards one corner of the cell. This was in marked contrast to our previously characterized dominant negative Rab11-FIP2 mutant, EGFPRab11-FIP2(129-512), a Rab11-FIP2 construct lacking the C2 domain which elicited generally a round, more regular shaped cisternal structure. Like EGFPRab11-FIP2(129-512), Rab11-FIP2(S229A/R413G) caused an inhibition in plgA trafficking in MDCKs cells. Rab11-FIP2(R413G) mutant effects on the recycling system that are distinctly separate from the EGFPRab11-FIP2(129-512) mutant-induced collapse of early endosomal system towards the centrosome. However, this alteration is not seen in Rab11-FIP2(S229A/R413G) cells. In contrast, Rab11-FIP2(S229A/R413G) expressing cells showed a partial collapse of GP135 to the tubular cisternae that is not seen in Rab11-FIP2(129-512) cells. The availability of multiple mutants in the Rab11a pathway will allow a more rigorous analysis of the regulation of plasma membrane recycling.

From Sorting Endosome to Exocytosis: Imaging the Recycling Pathway Using Novel Multifocal Plane Microscopy
P. Prabhath,1 Z. Gao,1 J. Chao,2 S. Ram,1 C. Vaccaro,1 S. Gibbons,1 R. J. Ober,2 E. S. Ward1; 1Center for Immunology, University of Texas Southwestern Medical Center, Dallas, TX, 2Department of Electrical Engineering, University of Texas at Dallas, Richardson, TX, Joint Biomedical Engineering Graduate Program, University of Texas at Arlington/University of Texas Southwestern Medical Center, Arlington/Dallas, TX
Elucidation of intracellular events on the recycling pathway from sorting endosomes to exocytosis on the plasma membrane is of fundamental importance. Epifluorescence microscopy is typically used to study recycling events inside the cell, whilst Total Internal Reflection Fluorescence (TIRF) microscopy provides valuable insight into the nature of exocytic events on the plasma membrane. However, events on the recycling pathway preceding exocytosis are poorly characterized. This is primarily due to the fact that the imaging of fast moving transport containers (TCs) on the recycling pathway poses significant technical challenges. To overcome this limitation, we recently developed a microscopy technique [1] that enables the simultaneous imaging of distinct focal planes in a specimen. Using this technique, events on the plasma membrane of a cell can be imaged with TIRF excitation whilst simultaneously imaging additional focal planes inside the cell using widefield excitation. This has enabled us to track events preceding exocytosis on the recycling pathway of the MHC Class I related receptor, FcRn, in human endothelial cells. We observe both direct and indirect delivery of TCs from sorting endosomes to exocytic sites at the plasma membrane. In the direct delivery pathway, vesicular and tubular TCs that are in close proximity to sorting endosomes undergo fusion. In some cases, TCs that extend from sorting endosomes to the plasma membrane as tubular extensions can be seen. In contrast, for the indirect pathway, exocytosis involving TCs which are not in close proximity to sorting endosomes is observed. These TCs can move large distances within the cell prior to arresting in ‘holding zones’ above the plasma membrane. TCs can also interact with multiple sorting endosomes prior to exocytosis. 1. Prashant Prabhath, et. al., IEEE Transaction on Nanobioscience, 3(4), 257-242, (2004) Supported by grants from the NIH (R01 AI39167, GM071048).

Interaction between SCAMPs and Complexins
S. A. Shestopal, D. Castle, Cell Biology, University of Virginia, Charlottesville, VA
Secretory carrier membrane proteins (SCAMPs) comprise a family of tetraspan transmembrane proteins, implicated in membrane trafficking. Complexins are proteins that are able to bind assembled SNARE complexes. Mammalian complexins 1 and 2 are soluble and expressed in neuronal and neuroendocrine cells where they are involved in regulation of exocytosis, but their exact role is not yet established. Using a pull-down assay, we have demonstrated interaction between recombinant complexins 1 and 2 and SCAMPs 1, 2, 3 and 5 from brain and PC12 cell lysates. We made a deletion mutant of complexin 2 (residues 456-497) which eliminates the interaction with complexin and map within a localized groove of the primary sequence, all map in a localized groove of the high resolution nsec1 structure. Thus, phylogenetic analysis provides a powerful tool for probing the precise function of Sec1p in membrane trafficking.

A Sec8/Sec6/Sec5 Sub-complex of the Mammalian Exocyst Mediates Polarized Endocytic Recycling via Rab GTPase during Myoblast Migration
X. Chen,1 Q. Wang,1 S. C. Hsu,2 A. R. Saitiel,3 University of Michigan, Ann Arbor, MI, 3Rutgers University, Piscataway, NJ
Spatial regulation of endocytic recycling during polarized cellular processes remains a central question to be understood. The protein complex exocyst has been suggested to provide spatial control of endocytic recycling. Here we report that the mammalian exocyst subunits Sec8, Sec6, and Sec5 form a stable sub-complex. Although the assembly of this subcomplex is independent of RabA; RaA activity is important for recruiting these exocyst proteins to the exocytic vesicles. Sec8 regulates the stability of Sec6 and Sec5, which in turn bridges RabA-localized Rab GTPase to the plasma membrane. Unlike Sec6 and Sec5 accumulate to the membrane ruffle region of myoblast in response to HGF signaling, while knockdown of RaA or Sec5 inhibits HGF-induced myoblast migration. Our data provided insights into the molecular architecture of the mammalian exocyst and suggested that RaA specifies the targeting of RE vesicles via recruitment of the Sec6/Sec8/Sec5 sub-complex.

Exploiting Phylogenetic Analyses to Explore the Function of Sec1p in Saccharomyces cerevisiae
J. L. Hutton,1 C. Chiu,1 C. M. Carroll1; 1Pathology, UMDNJ-RWJMS, Piscataway, NJ, 2Life Sciences, Rutgers, Piscataway, NJ
Sec1p/Munc 18 (SM) proteins are essential for SNARE-mediated vesicular trafficking and fusion in eukaryotes and, in S. cerevisiae, loss of function mutations can result in a lethal phenotype. However, despite extensive work in various eukaryotic species, the precise role of SM proteins is unclear. Here, aligning over 150 SM proteins from 30 diverse organisms including S. cerevisiae, C. elegans and H. sapiens followed by phylogenetic analyses, yields insights into their evolution and functionally important residues. Our findings confirm that SM proteins represent a superfamily comprised of four paralogous families (Sec1, Sty1, Vps33 and Vps45) that function at different points of protein trafficking/ secretary pathways. These subfamilies arose from ancient gene duplication events, since all eukaryotic organisms examined contained orthologous proteins. Interestingly, we have been able to place previously un-annotated genes into SM subfamilies. Furthermore, our data suggests that the Vps33 subfamily was the last to appear and this subfamily of proteins contains the largest amount of diversity between orthologues in different species and between paralogues within the same species. Finally, several highly conserved amino acids, spread throughout the primary sequence, all map in a localized groove of the high resolution nsec1 structure. Thus, phylogenetic analysis provides a powerful tool for probing the precise function of Sec1p in membrane trafficking.

Specifity of Yeast Sec1p for the Exocytic SNARE Complex Defines a New Binding Mode for Sec1/Munc-18 Proteins

J. Togneri; UMDNJ, Piscataway, NJ

The Sec1/Munc-18 (SM) family of proteins is required for vesicle fusion in eukaryotic cells and has been linked to the membrane-fusion proteins known as SNAREs. SM proteins may activate the target-membrane SNARE, syntaxin, in support of the fusion event, and SM proteins bind directly to their cognate syntaxins. An exception is the yeast Sec1p, which does not bind the yeast plasma-membrane syntaxin, Sso1p. This exception could be explained if the SM interaction motif was blocked by the highly stable conformation of Sso1p. We tested the possibility of a latent binding motif using Sso1p mutants in yeast and reconstituted the Sec1p binding specificity observed in vivo with purified proteins in vitro. Our results indicate that there is no latent binding motif in Sec1p. Instead, Sec1p binds specifically to the ternary SNARE complex, with no detectable binding to the binary S-N/P complex or any of the three individual SNAREs in their uncomplexed forms. We propose that vesicle fusion requires a specific interaction between the SM protein and the ternary SNARE complex.

Overexpression of Synaptotagmin 1 in the Brain of Down Syndrome Mouse Models Causes Defects in PtdIns(4,5)P2 Metabolism and Learning Deficits

S. V. Voronov1, S. G. Fere1, S. Giovedi1, E. A. Pollina1, C. Schmidt1, L. Cimasoni1, C. Borel1, D. M. Wenk2, E. S. Antonarikas1, K. Gardner3, M. T. Davison4, O. Arancio5, P. De Camilli1, G. D. Paoli1, 1Pathology, Columbia University, New York, NY, 2Cell Biology, Yale University, New Haven, CT, 3The Jackson Laboratory, Bar Harbor, ME, 4Genetic Medicine and Development, University of Geneva, Geneva, Switzerland, 5Biochemistry, National University of Singapore, Singapore, 1Eleanor Roosevelt Institute at the University of Denver, Denver, CO

Down syndrome (DS) is the most common cause of mental retardation. In DS, integrated gene expression is altered due to the presence of a third copy of human chromosome 21 (H21C). Although mental retardation has been linked to non-overlapping regions of H21C, indicating the multicogenicity of its etiology, the relative contribution of single genes to this phenotype is unknown. Among all the HC21 genes, SYNJ1 is a strong candidate for contributions to mental retardation in DS. SYNJ1 encodes synaptotagmin 1, a brain-enriched lipid phosphatase that dephosphorylates phosphatidylinositol-4,5-bisphosphate [PtdIns(4,5)P2]. This lipid regulates multiple biological functions, including signal transduction and membrane trafficking. Our previous work has shown that PtdIns(4,5)P2 regulates synaptic vesicle trafficking and thereby, neurotransmission. This property is largely due to its ability to recruit to the plasma membrane key components of the endocytic machinery, which mediates the recycling of synaptic vesicles via a clathrin-dependent pathway. Here we show that SYNJ1 is overexpressed in the brain of a mouse model for segmental trisomy 21 (Ts65Dn). Furthermore, gene dosage imbalance for SYNJ1 in Ts65Dn brains correlates with an increase in PtdIns(4,5)P2 phosphorylation and a corresponding reduction in the mass of PtdIns(4,5)P2. These phenotypes are recapitulated by transgenic mice overexpressing SYNJ1 [Ts(Synj1)] at levels comparable to those found in Ts65Dn mice and rescued by genetically restoring a normal Synj1 copy number in the segmentally trisomic mice. Finally, Ts(Synj1) mice exhibit learning deficits in the Morris water maze paradigm, suggesting that normal PtdIns(4,5)P2 balance is critical for proper cognitive functions. Altogether, our study indicates that the mild overexpression of a single gene, SYNJ1, causes PtdIns(4,5)P2 dyshomeostasis in the brain of DS mouse model and that this biochemical defect results in discernable behavioral deficits, likely as a result of altered synaptic vesicle trafficking and suboptimal neurotransmission.

Temporal Analysis of Synaptojanin 1 Recruitment at Clathrin Coated Pits

R. M. Perera1, R. Zoucs1, L. Lucast1, P. De Camilli1, D. Toomre1, 1Cell Biology, Yale University School of Medicine, New Haven, CT, 2Cell Biology/HHMI, Yale University School of Medicine, New Haven, CT, 3Department of Cellular and Molecular Medicine, University of California, San Diego School of Medicine, Howard Hughes Medical Institute, La Jolla, CA, 4 Ludwig Cancer Research Institute, La Jolla, CA

Synaptojanin (SYNJ1) is a non-synaptic polyphosphoinositide phosphatase that dephosphorylates phosphatidylinositol-4,5-bisphosphate (PtdIns(4,5)P2) with endocytic clathrin adaptors, while functional studies using cell-free systems or intact cells have demonstrated the importance of PtdIns(4,5)P2 synthesis and dephosphorylation in clathrin coating and uncoating, respectively. Furthermore, genetic manipulations of kinases and phosphatases involved in PtdIns(4,5)P2 metabolism result in major defects in synaptic vesicle recycling and other forms of exo-endocytosis. However, a dynamic visualization of these enzymes at clathrin coated pits has yet to be conducted. We have used live TIRF imaging of cells transfected with fluorescently tagged proteins to determine the spatial and temporal recruitment of the polyphosphoinositide phosphatase synaptojanin 1 at endocytic clathrin coated pits. The 145 KDa isoform of synaptotagmin 1 (i.e. the isoform that by far predominates at synapses), was recruited together with endophilin at a late stage and closely correlated with a burst of dynamin recruitment. This is consistent with a role of synaptotagmin 145 during late stages of vesicle formation and uncoating. In contrast, the 70 KDa isoform of synaptotagmin, which has a ubiquitously tissue distribution and predominates in brain before synaptogenesis, was recruited to clathrin-coated pits at an early stage and persisted on the coat throughout its lifetime. Recruitment of synaptotagmin-170 was dependent on the presence of clathrin and AP2 binding sites contained in this isoform. These results suggest that normal PtdIns(4,5)P2 balance is critical for proper cognitive functions. Altogether, our study indicates that the mild overexpression of a single gene, SYNJ1, causes PtdIns(4,5)P2 dyshomeostasis in the brain of DS mouse model and that this biochemical defect results in discernable behavioral deficits, likely as a result of altered synaptic vesicle trafficking and suboptimal neurotransmission.

Regulation of Phosphoinositide Kinase Signaling at the Plasma Membrane

C. Stefan1, D. Baird1, Y. Ling1, A. Audhya1, S. Emr1, 1Department of Cellular and Molecular Medicine, University of California, San Diego School of Medicine, Howard Hughes Medical Institute, La Jolla, CA

Phosphoinositides (PIs) are thought to play an important role in clathrin coated pit dynamics. Biochemical and structural studies have shown that a direct interaction of phosphatidylinositol-4,5-bisphosphate (PI(4,5)P2) with endocytic clathrin adaptors, while functional studies using cell-free systems or intact cells have demonstrated the importance of PI(4,5)P2 synthesis and dephosphorylation in clathrin coating and uncoating, respectively. Furthermore, genetic manipulations of kinases and phosphatases involved in PI(4,5)P2 metabolism result in major defects in synaptic vesicle recycling and other forms of exo-endocytosis. However, a dynamic visualization of these enzymes at clathrin coated pits has yet to be conducted. We have used live TIRF imaging of cells transfected with fluorescently tagged proteins to determine the spatial and temporal recruitment of the polyphosphoinositide phosphatase synaptojanin 1 at endocytic clathrin coated pits. The 145 KDa isoform of synaptotagmin 1 (i.e. the isoform that by far predominates at synapses), was recruited together with endophilin at a late stage and closely correlated with a burst of dynamin recruitment. This is consistent with a role of synaptotagmin 145 during late stages of vesicle formation and uncoating. In contrast, the 70 KDa isoform of synaptotagmin, which has a ubiquitously tissue distribution and predominates in brain before synaptogenesis, was recruited to clathrin-coated pits at an early stage and persisted on the coat throughout its lifetime. Recruitment of synaptotagmin-170 was dependent on the presence of clathrin and AP2 binding sites contained in this isoform. These results suggest that normal PtdIns(4,5)P2 balance is critical for proper cognitive functions. Altogether, our study indicates that the mild overexpression of a single gene, SYNJ1, causes PtdIns(4,5)P2 dyshomeostasis in the brain of DS mouse model and that this biochemical defect results in discernable behavioral deficits, likely as a result of altered synaptic vesicle trafficking and suboptimal neurotransmission.

Essential and Unique Roles of PIP5K1a and γ in FcγR-mediated Phagocytosis

M. Yamagua1, Y. S. Mats1, H. Q. Sun1, M. Yun2, P. De Camilli1, M. Muller3, C. Y. Lu1, H. L. Yin1, 1Physiology, University of Texas Southwestern Medical Center, Dallas, TX, 2Cell Biology, Yale University Medical School, New Haven, CT, 3Internal Medicine, University of Texas Southwestern Medical Center, Dallas, TX

Fc receptor (FcγR)-mediated phagocytosis is a spatially and temporally regulated process that includes three morphologically defined phases: the attachment of the IgG-opsonized particle, the extension of pseudopodia to form a phagocytic cup, and the engulfment of the particle to form a phagosome. The actin cytoskeleton is extensively restructured during these steps; actin assembles at the nascent phagocytic cup and at pseudopodia during the ingestion phase, and actin disassembles during the completion phase. Previous studies have shown that actin remodeling during phagocytosis is regulated by localizations of phosphatidylinositol-4,5-bisphosphate, and a type 4 phosphatidylinositol 5 kinase (PIP5K4) that generates PIP2 is recruited to the phagocytic cup. Here we investigated the roles of the PIP5KIs on phagocytosis by depleting PIP5K1a isoforms individually by RNA interference in FcγRI receptor overexpressing CHO cells (CHO-IA) and, in one case, by gene knockout in mice. We found that PIP5K1a (human nomenclature) or γ depletion inhibited different steps in phagocytosis by CHO-IA cells. PIP5K1a depletion prevented particle binding and decreased the macroscopic clustering of FcγR by IgG immune complexes. Unlike control cells, the PIP5K1a-depleted CHO-IA cells did not dismantle their actin stress fibers on exposure to the IgG-opsonized particles, suggesting that the primary defect may be due to an inability to initiate the actin disassembly process that is required for stable particle attachment and FcγR clustering. Likewise, bone marrow-derived macrophages isolated from PIP5K1a knockout mice also did not bind the IgG-opsonized particles normally. In contrast, the PIP5K4-depleted CHO-IA cells bound the particles, but were unable to engulf them. Actin assembly under the phagocytic cup was decreased, suggesting that the defect is due to an inability to polymerize actin at the site of particle contact. Our results establish that PIP5K1a and γ have essential and unique roles in the different stages of FcγR-mediated phagocytosis.

Differential Regulation of PIP5Ks by the Syk Protein Tyrosine Kinase during Fc Receptor-mediated Phagocytosis

Y. J. Wei, B. Liu, M. Yamaga, H. Q. Sun, H. L. Yin, Physiology, UT Southwestern Medical Center, Dallas, TX

During FcR-mediated phagocytosis, type I phosphatidylinositol 5-kinases (PIP5Ks) are recruited to the nascent phagocytic cup to increase phosphatidylinositol 4,5-bisphosphate (PIP2) generation in situ. We now report that PIP5Kγ (human nomenclature) and PIP5Kβ, but not PIP5Kα, are also tyrosine phosphorylated during phagocytosis. PIP5Kγ and β tyrosine phosphorylation increases with a time course that parallels the activation the Syk tyrosine kinase, which has an essential apical role in the FcγR signaling cascade. PIP5K phosphorylation is decreased by the Syk inhibitor, piceatannol, and Syk overexpression promotes PIP5K phosphorylation in CHO-IA cells, which has much less Syk than the professional phagocytes, during phagocytosis. Using an in vitro protein kinase assay, we found that Syk phosphorylates the two differentially spliced PIP5Kγ variants (90 and 87 kDa), as well as PIP5Kβ. Furthermore, Syk immunoprecipitation pulls down endogenous PIP5Kγ in the RAW macrophage-like cells, and also overexpressed PIP5Kγ/87 and 90 in non-phagocytic COS cells. Taken together, our results establish that these PIP5Ks are bona fide Syk substrates, and suggest that they are likely to bind Syk directly. In vitro lipid kinase assay shows that tyrosine phosphorylation increases the activity of PIP5Kγ/87 and 980, but not of PIP5Kα.

We conclude the PIP5K isoforms are differentially regulated by Syk during phagocytosis, and that PIP2 is increased at the phagocytic cup by recruiting PIP5Ks into the membranes. The recruitment of select PIP5Ks by tyrosine phosphorylation for functional roles in phagocytosis is regulated by Syk has broader significance beyond PIP2 regulation of phagocytosis, because Syk has crucial roles in multiple leukocyte signaling pathways, and Syk has been implicated in cytokinesis and tumorigenesis in non-hematopoietic cells as well.

Effects of SHIP1 on the Dynamics of 3' Phosphoinositides during Fc Receptor-mediated Phagocytosis

L. A. Kamen, J. Levinsohn, J. A. Swanson, Microbiology and Immunology, University of Michigan Medical School, Ann Arbor, MI

Lipid kinases and phosphatases regulate receptor-mediated phagocytosis in macrophages. PI 3-kinase, which generates PI(3,4,5)P3 from PI(4,5)P2, is necessary for later stages of the phagocytosis of particles larger than 3 µm in diameter. Overexpression of the phosphatase PTEN, which catalyzes the reverse reaction, inhibits phagocytosis after formation of phagocytic cups, much like inhibitors of PI 3-kinase. SHIP1, a lipid phosphatase that hydrolyses PI(3,4,5)P3, to PI(3,4)P2 also inhibits phagocytosis when overexpressed in macrophages. We hypothesize that the inhibitory activities of SHIP1 contribute to phagosome formation by modifying the distribution or PI(3,4,5)P3,5-PIP2 in the phagocytic cup. To test this, we quantitatively analyzed the distributions of SHIP1, PTEN, YFP, or phosphatase PLT (the regulatory subunit of PI3K), and YFP chimeras of phosphoinositide-binding domains that recognize PI(3,4,5)P3 (BikPH), PI(3,4,5)P2/PI(3,4)P2 (PiclPH), PI(3,4)P2 (Tapp1PH), and PI3P (2xFYVE) during phagocytosis. PTEN-YFP never localized to phagosomes, but SHIP1-YFP and PI(3,4)P2-YFP localized to the phagosomes with similar rates of association. Coexpression of SHIP1-YFP and PI(3,4)P2-CFP revealed that SHIP1-YFP associated from phagocytic cups earlier than did PI(3,4)P2-CFP, indicating that SHIP1 inhibitory activity may be relieved before phagocytosis is completed. Although the phospholipid profile of the phagocytic cups was distinct from that of the plasma membrane, no significant gradients of phosphatidylserine were detected within the membranes of the cup. Rather, PI(3,4,5)P3 and PI(3,4)P2 increased and decreased similarly over the forming cup. Using an IRES vector system, we examined the effects on 3' phosphoinositide dynamics of overexpressing SHIP1 or inhibitory SHIP1-ΔSH2 domains. All IRES-based manipulations of SHIP1 function decreased levels of PI(3,4,5)P3 and PI(3,4)P2 on the phagosome. These results support a model in which transient recruitment of SHIP1 to forming phagosomes permits early PI 3-kinase-independent activities and delays the later PI 3-kinase-dependent activities necessary for completion of phagocytosis.

Cooperation of Phosphoinositides and Bar Domain Proteins in Endosomal Tubulation

N. Shinozaki-Narikawa,1,2 T. Kodama,1 Y. Shibasaki1; 1Laboratory for Systems Biology and Medicine, RCAST, University of Tokyo, Tokyo, Japan, 2Yokogawa Electric Corporation (NEDO fellow), Tokyo, Japan

Phosphorylated derivatives of phosphatidylinositol (PtdIns) regulate many intracellular events, including vesicular trafficking and actin remodeling, by recruiting proteins to their sites of function. PtdIns(4,5)P2 (PIP2) is recruited to the nascent endocytic tubules in COX-7 cells. ADP-ribosylation factor (Arf) has been shown to act upstream of PIP5K and regulate endocytic transport and tubulation. ACAP1 has GTPase activating protein (GAP) activity for Arf6. While there were few tubules induced by the expression of ACAP1 alone, numerous endosomal tubules were induced by coexpression of PIP5K and ACAP1. ACAP1 has a pleckstrin homology (PH) domain known to bind phosphoinositide, and a Bin/amphiphysin/Rvs (BAR) domain that has been reported to detect membrane curvature. All of these three sub-domains, the hydrophobic ridge, the helix 0 and the rigid crescent main body, are necessary to induce plasma membrane tubulation in cells over-expressing the endophilin-A1 BAR domain. Our results support the putative liposome binding activity. These results suggest that the rigid crescent dimer shape of the BAR domain is crucial for the tubulation. All of these three sub-domains, the hydrophobic ridge, the helix 0 and the rigid crescent main body, are necessary to induce plasma membrane tubulation in cells over-expressing the endophilin-A1 BAR domain. Our results support the putative mechanism that the BAR domain dimer imparts its intrinsic curvature on membrane to tubulate it. We have propose that the BAR domain drives membrane curvature by coordinate action of the crescent’s scaffold mechanism and the ridge’s membrane insertion in addition to membrane binding via the helix 0.

Endophilin-A1 BAR Domain Uses Two Mechanisms to Drive Membrane Curvature

M. Masuda,1 S. Takeda,2 M. Sone,3 T. Ohki,4 H. Mori,2 Y. Kamioka,1 N. Mochizuki1; 1Structural Analysis, National Cardiovascular Center Research Institute, Suita, Japan, 2Cardiac Physiology, National Cardiovascular Center Research Institute, Suita, Japan, 3Laboratory of Structural Biochemistry, RIKEN Harima Institute at SPring-8, Mikazuki-cho, Sayo, Japan

Membrane dynamics in a cell, such as membrane budding, tubulation, fission and fusion, is associated with vigorous changes in membrane curvature. The crescent-shaped BAR domain of human endophilin-A1 consists of a pair of helix-loop appendages sprouting out from the crescent-shaped main body. The short helices of the appendages form a hydrophobic ridge, which runs across the concave surface of the main body at its centre. Liposome binding and tubulation assays of the recombinant BAR domain and its mutants indicate that the ridge penetrates into the membrane bilayer and enhances liposome tubulation. The N-terminal amphipathic helix preceding the BAR domain (helix 0) is crucial for liposome binding. The crystal structure of a designed mutant solved at 2.4 Å shows flexibility in the helix kinks that make the curved molecular shape. This flexible-arm mutant loses liposome tubulation activity yet retaining intact liposome binding activity. These results suggest that the rigid crescent dimer shape of the BAR domain is crucial for the tubulation. All of these three sub-domains, the hydrophobic ridge, the helix 0 and the rigid crescent main body, are necessary to induce plasma membrane tubulation in cells over-expressing the endophilin-A1 BAR domain. Our results support the putative mechanism that the BAR domain dimer imparts its intrinsic curvature on membrane to tubulate it. We have propose that the BAR domain drives membrane curvature by coordinate action of the crescent’s scaffold mechanism and the ridge’s membrane insertion in addition to membrane binding via the helix 0.

Core Protein Machinery for PtdIns 3,5-P2 Synthesis and Turnover Controls Mammalian Endosome Carrier Vesicle Formation/Detachment: Novel Sac3 Phosphatase Joins the ArPKfyve-Pikfyve Complex

D. Shroira, G. Demel, T. Iain, T. Takenawa, A. Shisheva; Physiology, Wayne State University, Detroit, MI

PtdIns 3,5-P2, plays an essential role in regulating diverse endosome-related events. This role is conserved in evolution as evidenced by the similar aberrant morphology of endocytic organelles, associated with inactivation of structurally related PtdIns 3,5-P2-producing enzymes, Fab1, in yeast, and PIKfyve, in mammalian cells. The conservation of the PtdIns 3,5-P2 pathway is reinforced by the structural and functional homology between yeast Vac14 and mammalian ArPKfyve, which activate Fab1 and PIKfyve, respectively. Regulation of PtdIns 3,5-P2 levels occurs by ArPKfyve and ArPKfyve turnover, and a Sac3, 35-kDa, PtdIns 3,5-P2-specific phosphatase. Fig. 8, in interaction with Vac14, turns over PtdIns 3,5-P2, in yeast. Whether such mechanism operates in mammalian cells is unknown. We identified and partially characterized mammalian Sac3, a 90 kDa Sac domain phosphatase and putative ortholog of Sac3, Sac3, ArPKfyve or ArPKfyve antibodies coinmunoprecipitated the other two proteins in several mammalian cell types, consistent with the presence of endogenous PIKfyve/Sac3 ternary complexes. In this heterologous system, Sac3 and ArPKfyve, but not PIKfyve, could self-assemble as revealed by coimmunoprecipitation in COS7 cells coexpressing HA- and Myc-tagged forms of either protein. Individual siRNA-mediated depletion of Sac3 or ArPKfyve in 3T3-L1 fibroblasts resulted in their coincidental loss, consistent with a mutual dependence of the two proteins for stability. Sac3 cofractionated with PIKfyve by density gradient sedimentation in HEK293 cells. Fluorescence microscopy in cotransfected COS7 cells visualized Myc-Sac3 diffuse or on vesicles colocalizing in part with PIKfyve- or ArPKfyve-positive signals. Depletion of either protein altered the in vitro formation of endosome carrier vesicle intermediates, consistent with the role of PtdIns 3,5-P2 in this process. Physical assembly of core protein machinery for regulated PtdIns 3,5-P2 synthesis and turnover ensures a tight coupling between these two processes and fulfills the crucial need for a firm spatial and temporal control of PtdIns 3,5-P2 on endosome membranes.
Phosphatidylinositol 3-kinase C2α Links Clathrin to Microtubule-dependent Movement

Y. Zhao, I. Gaidarov, J. H. Keen; Dept. of Biochemistry and Molecular Biology, Kimmel Cancer Center, Thomas Jefferson University, Philadelphia, PA

Phosphatidylinositol 3-kinase C2α (PI3K-C2α) has been implicated in several important membrane transport and signaling processes. We previously showed that overexpression of PI3K-C2α inhibits clathrin-mediated membrane trafficking and induces proliferation of clathrin coated structures within the cytoplasm. Using fluorescently tagged fusions of PI3K-C2α and clathrin, we find that these structures contain both proteins. Further, they exhibit localized, extremely rapid mobility such that they can be reliably tracked for only several frames captured at video rate. The movement is microtubule-based as revealed by use of inhibitors, and PI3K-C2α rapidly and reversibly accumulates on microtubules upon cytoplasmic acidification, which also blocks movement. The microtubule-based movement is mediated by dynamin, as its p50 subunit both immunoprecipitates with PI3K-C2α and, upon overexpression, inhibits movement. Based on these findings, we have more closely evaluated the dynamics of GFP-clathrin coated structures in the absence of exogenous PI3K-C2α expression. In addition to the relatively stationary distribution of cell surface coated pits and established vectorial movement of putative coated endosomes/vesicles, a proportion of transient GFP-clathrin spots exhibited localized and rapid movements similar to those widespread in PI3K-C2α-expressing cells. Importantly, these hyper-motile clathrin coated structures repeatedly interact with microtubules. Collectively, these results reveal a novel population of intracellular clathrin coated structures characterized by localized fast mobility and suggest that PI3K-C2α is a functional linker of these and potentially other clathrin coated membranes to the microtubule motor machinery.

Domain-mediated Oligomerization, Phosphoinositide Binding, and Membrane Targeting by Human DIP13/APPL Rab5 Effector Proteins

H. J. Chiai,1 P. Lenart,2 R. Wu,3 L. C. McPhail,4 Y. Q. Chen;1 Dept. of Neurology and Neurological Sciences and the Neuroscience Institute at Stanford, Stanford University School of Medicine, Stanford, CA,4 Stanford Research Institute of Molecular Pathology (IMP), Vienna, Austria,5 Dept. of Cancer Biology, Wake Forest University School of Medicine, Winston-Salem, NC,6 Dept. of Biochemistry, Wake Forest University School of Medicine, Winston-Salem, NC

α-DIP13 and α-DIP13β are a pair of highly homologous proteins that contain three predicted domains: a N-terminal Bin/Amphiphysin/Rvs (BAR) domain, a central pleckstrin homology (PH) domain, and a C-terminal phosphorysytline binding (PTB) domain. DIP13α interacts with a diverse set of receptors and signaling proteins, including DCC (Liu et al., 2002), FSHR (Nechamen et al., 2004), AdipoR1 and AdipoR2 (Mao et al., 2006), AKT proteins, and PI3K subunits (Mitsuuchi et al., 1999). DIP13α and DIP13β also interact with GTP-bound Rab5, and are proposed to function in an endosome-mediated signaling pathway linking the cell surface to the nucleus (Miaczynska et al., 2004). Here, we investigated the function of DIP13 BAR, PH, and PTB domains. BAR domains form crescent-shaped dimers capable of sensing and inducing membrane curvature, whereas PH and PTB domains are similar in structure and interact with both phosphoinositides and protein targets. Our co-immunoprecipitation and yeast two-hybrid studies demonstrate that full-length DIP13 proteins form homo-oligomers (DIP13α-DIP13α and DIP13β-DIP13β) and hetero-oligomers (DIP13α-DIP13β), and that DIP13 BAR domains are necessary and sufficient for mediating these interactions. We also found that DIP13 isolated BAR domains are targeted to novel cell membrane structures that overlap with regions of altered cellular morphology. We developed a dual-mode confocal microscopy-based approach for fluorescence resonance energy transfer (FRET) studies in which a single cell is analyzed using four independent FRET methods, and observed strong FRET signal for DIP13α-DIP13α, DIP13α-DIP13β, and DIP13β-DIP13β isolated BAR domain FRET pairs. Finally, we found that full-length DIP13 proteins bind membrane-immobilized phosphoinositides, and that DIP13 isolated PH or PTB domains are sufficient for phosphoinositide binding in vitro and membrane targeting in vivo. Taken together, these findings suggest that DIP13 proteins may function as protein scaffolds that organize Rab5 subdomains on signaling endosomes via their underg00 do segment-mediated oligomerization, phosphoinositide binding, and membrane targeting.

PI4P Promotes the Recruitment of GGA Adaptor Proteins to the trans-Golgi Network and Regulates Their Recognition of the Ubiquitin Sorting Signal

J. Wang, H. Yin, H. Sun; Physiology, University of Texas Southwestern Medical Center at Dallas, Dallas, TX

Phosphatidylinositol 4-phosphate (PI4P) is highly enriched in the trans-Golgi network (TGN). Here we establish that PI4P is a key regulator of the recruitment of the GGA clathrin adaptor proteins (GGAs) to the TGN and show that PI4P has a novel role in promoting their recognition of the ubiquitin (Ub) sorting signal. Knockdown of PI4KIIe by RNA interference (RNAi), which depletes the TGN’s PI4P, impaired the recruitment of the GGAs to the TGN. The GGAs bind PI4P through their GAT domain, in a region called C-GAT which also binds Ub but not Arf. We identified two basic residues that are essential for PI4P binding in vitro and for the recruitment of the full-length GGAs to the TGN. These GGA mutants failed to rescue the normal TGN phenotype of the GGA RNAi-depleted cells. These residues partially overlap with those that bind Ub, and PI4P increased the binding affinity of the GAT domain for Ub. Since the recruitment of clathrin adaptors and their cargoes to the TGN is mediated through a web of low affinity interactions, our results show that the dual roles of PI4P can promote specific GGA targeting and cargo recognition.

Membrane Targeting of Phosphatidylinositol 4 Kinase Type II beta

G. Jung, B. Barylo, J. Abanesi; Department of Pharmacology, UT Southwestern Medical Center, Dallas, TX

Phosphorylation of phosphatidylinositol (PI) at the D-4 hydroxyl yields PI(4,5)P2, the principal precursor in the synthesis of two signaling lipids, P(4,5)IP2 and P(3,4,5)IP3. Mammalian cells express four enzymes that catalyze this reaction, the PI4-kinases known as PI4KIIα, PI4KIIβ, PI4KIIIα, and PI4KIIIβ. This study is concerned specifically with PI4KIIα, a 55kDa protein that is almost evenly distributed between cytosol and membrane. The cytosolic pool is unmodified and catalytically inactive, whereas the membrane-associat ed pool is both phosphorylated and palmitoylated and expresses a catalytic activity of about 100 min⁻¹. Palmitoylation, but not phosphorylation, is essential for activity. A portion of cytosolic PI4KIIα redistributes to the plasma membrane particularly to cell-cell junctions, in response to Rac activation. The N-terminal 90 amino acids are required for this rec localization but are not involved in overall binding of the kinase to membranes. Instead, its relative distribution between membranes and cytosol is determined by the C-terminal catalytic domain (residues 91-481). A candidate binding partner for this catalytic domain is Hsp90, which protects PI4KIIα from proteolytic degradation, but also appears to sequester it to the cytoplasm.

Phosphoinositide-mediated ACAP4 Recruitment to the Plasma Membranes of Endothelial Cells Stimulated by EGF

F. Wang,1,2 Z. Fang,3 F. Wu,4 L. Ge,5 X. Cao,2 Y. Liu,2 X. Ding,2 X. Yao,1,6 M. Powell1; 1Cellular Proteomics, Morehouse School of Medicine, Atlanta, GA, 2Univ. of Sci. & Tech. of China, Hefei, China, 3Cellular Dynamics, Univ. of Sci. & Tech. of China, Hefei, China, 4Physiology, Morehouse School of Medicine, Atlanta, GA, 5Medicine, Beijing Univ. of Chinese Med., Beijing, China, 6Hefei National Laboratory, Hefei, China

ARF6 is a conserved regulator of membrane trafficking and actin cytoskeleton dynamics at the leading edge of migrating cells. A key determinant of ARF6 function is the lifetime of the GTP-bound active state, which is orchestrated by GTPase-activating protein and GTP-GDP exchange factor. However, very little is known about the mechanisms underlying ARF6-mediated cell migration. To systematically analyze proteins that regulate ARF6 activity, we performed a proteomic discovery of proteins selectively bound to active ARF6 using mass spectrometry and identified a novel ARF6-specific GTPase-activating protein ACAP4 (Mol. & Cell Proteomics. 2006. 5, 1437-1449). ACAP4 co-distributes with ARF6 in the cytoplasm but relocates the plasma membrane particularly to cell-cell junctions, in response to Rac activation. The N-terminal 90 amino acids are required for this relocalization but are not involved in overall binding of the kinase to membranes. Instead, its relative distribution between membranes and cytosol is determined by the C-terminal catalytic domain (residues 91-481). A candidate binding partner for this catalytic domain is Hsp90, which protects PI4KIIα from proteolytic degradation, but also appears to sequester it to the cytoplasm.

Phosphoinositide-mediated ACAP4 Recruitment to the Plasma Membranes of Endothelial Cells Stimulated by EGF

F. Wang,1,2 Z. Fang,1 F. Wu,4 L. Ge,5 X. Cao,2 Y. Liu,2 X. Ding,2 X. Yao,1,6 M. Powell1; 1Cellular Proteomics, Morehouse School of Medicine, Atlanta, GA, 2Univ. of Sci. & Tech. of China, Hefei, China, 3Cellular Dynamics, Univ. of Sci. & Tech. of China, Hefei, China, 4Physiology, Morehouse School of Medicine, Atlanta, GA, 5Medicine, Beijing Univ. of Chinese Med., Beijing, China, 6Hefei National Laboratory, Hefei, China

2006 ASCB Annual Meeting Abstracts
ARF6 is a conserved regulator of membrane trafficking and actin cytokinesis dynamics at the leading edge of migrating cells. A key determinant of ARF6 function is the lifetime of the GTP-bound active state, which is orchestrated by GTPase-activating protein and GDP-GTP exchanging factor. However, very little is known about the mechanisms underlying ARF6-mediated cell migration. To systematically analyze proteins that regulate ARF6 activity, we performed a proteomic discovery of proteins selectively bound to active ARF6 using mass spectrometry and identified a novel ARF6-specific GTPase-activating protein (ACAP4; Mol. Cell Proteomics, 2006; 5, 1437-1449). ACAP4 co-localizes with ARF6 in the cytoplasm but relocates the plasma membrane ruffles upon the EGF stimulation. Our computational analysis reveals that ACAP4 contains one PH domain, one GAP motif, and two ankyrin repeats. Within the PH domain, ACAP4 contains four PI(2)P-binding sites. To illustrate the functional relevance of the PI(2)P-binding sites in the recruitment of ACAP4 to the plasma membrane, we carried out systematic mutational analyses to change lysine residue individually or jointly and assessed the ability of mutant proteins to locate to the plasma membrane in response to EGF stimulation. Our analyses revealed that the four PI(2)P-binding sites cooperate to provide an adaptor for the recruitment of ACAP4 to the plasma membrane. Significantly, overexpression of the PI(2)P-binding deficient mutant abolished the recruitment of ACAP4 to the plasma membrane, which results in accumulations of ACAP4 and ARF6 in the cytoplasm and an inhibition in membrane ruffling. In addition, overexpression of the PI(2)P-binding deficient ACAP4 mutant suppresses ARF6-dependent cell migration in wound-healing. These results suggest that phosphoinositide-mediated recruitment of ACAP4 is essential for EGF-stimulated membrane dynamics underlying cell migration. Using fluorescence resonance energy transfer measurements in living cells, we are evaluating how PI2P determines the segregation of proteins in the membrane ruffle induced by EGF.

Actin Comet Tails Rocketing EGF-containing Endosomes Are Induced by Phosphatidic Acid
A. Norambuena, E. Pardo, A. González; Reumatología, Fac. Medicina, and Centro de Regulación Celular y Patología, Fac. Ciencias Biológicas, Pontificia Universidad Católica de Chile, and MIFAB, Santiago, Chile
Endocytosis of EGF can be induced in the absence of ligand and independently of tyrosine phosphorylation and ubiquitilation of the receptor by inhibiting basic PKA activity (Salazar and González, Mol Cell Biol 13; 1677-1693. 2002). This indicates that the permeability of inactive EGF at the cell surface can be transmodulated. Here, we explored the role of phosphatidic acid (PA) as a signaling lipid involved in the regulation of clathrin-mediated endocytosis, actin cytoskeletal function and phosphodiesterase(PDE)-dependent cAMP levels. In several cell lines, inhibition of phosphatidic acid phosphohydrolase by propranolol treatment increased the membrane levels of PA, leading to induction of clathrin-mediated endocytosis of inactive EGF. This PA-induced endocytosis negative regulation of PKA, through activation of rolipram-sensitive cAMP-PDEs, as well as activation of RhoA and Rac-1. Strikingly, in NIH3T3 cells permanently transfected with human EGF, propranolol treatment both in the absence or presence of EGF, induced actin tails emerging from EGF-containing endosomes in a process involving Cdc42 and N-WASP activity. Generation of these actin tails requires the expression of the EGFFR. Although actin comets have been widely described as propelling forces for certain bacterial and viral pathogens as well as for endocytic vesicles and other membranous organelles, to our knowledge, this is the first time that detection of actin tails associated with endosomes containing a signaling receptor. We also showed a novel function for a await known mechanism in this paper and PA pathways, namely, control of the endocytic trafficking of EGF. The mechanism involves an actin role at different steps. Because PA levels is regulated by a variety of stimulus, such a control system provides wide possibilities of transmodulating both the accessibility of empty EGF to extracellular stimuli and the spatial determinants of receptor signaling (Financed in part by FONDAP grant# 1398001 and Millennium project from Ministerio de Planificación).

Sorting Nexin 9 Links Assembly Dynamics to Membrane Remodeling
D. Yarar, C. Waterman-Storer, S. L. Schmid; The Scripps Research Institute, La Jolla, CA
Remodeling of the plasma membrane is essential for multiple types of endocytosis. However, the factors that contribute to these distinct pathways are not clearly understood. We previously demonstrated that Sorting Nexin 9 (SNX9) interacts with dynamin and functions in clathrin-mediated endocytosis. Here, we demonstrate by siRNA-mediated knockdown that SNX9 is also critical for other clathrin-independent, but nonetheless actin-dependent, fluid phase internalization pathways. Moreover, we report that SNX9 localizes to circular dorsal ruffles and peripheral ruffles, actin-rich structures implicated in fluid-phase uptake. To identify the mechanism by which SNX9 functions at these sites, we investigated the connection of SNX9 with established components of the actin cytoskeleton. We find that SNX9 binds directly to the N-WASP, an Arp2/3 complex nucleation promoting factor, and stimulates N-WASP/Arp2/3-mediated actin nucleation. At low, physiological concentrations, the ability of SNX9 to stimulate WASP/Arp2/3-mediated actin polymerization is greatly enhanced by the presence of PI(2)P-containing liposomes, which is in part due to PI2P-induced SNX9 oligomerization. Isolated SNX9 oligomers have significantly higher N-WASP stimulatory activity than unassembled forms of SNX9. These results define a novel mechanism for the regulation of N-WASP-dependent actin assembly and implicate SNX9 in the coupling of actin dynamics to membrane remodeling.

Dynamic Actin Facilitates Endosomal Traffic
D. A. Schafer; Biology, University of Virginia, Charlottesville, VA
Actin filaments participate in several steps of endocytosis and trafficking: to internalize ligands at the plasma membrane, to propel endosomes about the cytoplasm and to promote vesicle fusion. To investigate how actin filaments function during intracellular endosomal trafficking, we observed dynamic actin and endocytic tracers in live cells. Several pools of dynamic actin were visualized in Ptk1 fibroblasts stably expressing GFP-capping protein (GFP-CP), a convenient marker for actin filaments undergoing rapid turnover. One pool of dynamic actin exists as small foci that move in a salutatory manner about the periphery of perinuclear vesicular compartments but do not power movement of the compartments. Arp2/3 complex, cortactin, capping protein, and N-WASP contribute to this dynamic actin pool. The vesicular compartments containing actin foci loaded with TexasRed-transferrin (TR-Tf) within 5-10 minutes. In fixed cells, the vesicular compartments labeled with antibodies to the early endosome marker, EEA-1, however, its distribution and that GFP-CP at the periphery of these compartments was not controlled. In contrast, the distribution of one of the ubiquitously expressed secretory carrier membrane proteins, SCAMP3, was coincident with actin foci. Thus, early endosomes assemble actin foci within discrete domains on their surfaces. Inhibition of actin dynamics with Latrunculin B stopped the movement of endosome-associated actin foci and blocked the trafficking of TR-Tf. Two observations point to a connection between actin dynamics and the formation of tubules that might sequester sorted proteins during trafficking. First, endosomes in LatB-treated cells became enlarged and more "tubular" compared to those in untreated cells. Second, a phospholipaseA2 antagonist that inhibits tubule formation on endosomes and blocks recycling traffic also blocks actin dynamics on endosomes. These findings are consistent with a role for dynamic actin filaments in selective sorting via tubulovesicular compartments early in the endocytic pathway.

Transmembrane Ser/Thr Kinase KPI-2 Is a Myosin VI-Binding Protein Involved in Endocytic Membrane Trafficking
T. Inoue,1 T. Kon,1 R. Okaura,2 H. Yamakawa,2 O. Ohara,1 J. Yokota,1 K. Sutoh1; 1Department of Life Sciences, Graduate School of Arts and Sciences, University of Tokyo, Tokyo, Japan, 2Kazusa DNA Research Institute, Chiba, Japan, 3Biology Division, National Cancer Center Research Institute, Tokyo, Japan
Endocytic membrane traffic in eukaryotic cells is a fundamental process in sorting and delivering membrane components to various intracellular compartments. Interactions of endocytic components with the cytoskeleton and associated motor proteins have important roles in this pathway. Several studies have shown that the cellular functions of myosin VI are involved in clathrin-mediated endocytosis, in intracellular transport of clathrin-coated and uncoated vesicles, in the maintenance of Golgi-distributed morphology and in secretion in mammals. The diverse functions and cellular localizations of myosin VI are considered to be mediated by interacting with distinct cargos proteins. In this study, using a yeast two-hybrid screen, we have identified and characterized a novel myosin VI-binding partner, KPI-2 (Kinesin/Phosphatase/Inhibitor-2), a transmembrane Ser/Thr kinase. Several binding experiments confirmed the interaction of KPI-2 with myosin VI in vivo in vitro. Immunocytochemical analyses showed that KPI-2 localizes to perinuclear recycling endosomes (REs), where transferrin receptor or transfected GFP-Rab11 resides. Overexpression, the cells whose KPI-2 was depleted by siRNA were still able to internalize transferrin molecules and transport them to early endosomes (EE), but could not further transport them to perinuclear REs. EAE-based analysis also revealed that the rate of transferrin uptake was reduced in KPI-2-depleted cells. These results support the notion that KPI-2 is essential for transition of endocytosed vesicles from EEs to perinuclear REs, also suggesting a possible involvement of myosin VI in this pathway.

Role of the Rho Family GTP-binding Protein Rac1 and Its Guanine Nucleotide Exchange Factor Ost in Negative Regulation of Receptor Endocytosis
K. Ieguchi, S. Ueda, T. Katoaka, T. Satoh; Division of Molecular Biology, Department of Molecular and Cellular Biology, Kobe University Graduate School of Medicine, Kobe, Japan
Clathrin-mediated endocytosis is the main pathway for internalization of cell surface receptors. In this study, we examined the involvement of the Rho family GTP-binding protein Rac1 and the Dbl family guanine nucleotide exchange factor Ost in receptor endocytosis. The GTP-bound active form of Rac1, but not other Rho family members including RhoA and Cdc42, negatively inhibits internalization of epidermal growth factor receptor (EGFR) by re-localizing it to the plasma membrane and promoting ligand-induced receptor tyrosine phosphorylation.
regulated endocytosis of the transferrin receptor (TfR) in HeLa cells. Downregulation of Rac1 expression by siRNA treatment significantly increased TfR endocytosis. The Ost splice variant Ost-III, which contains a unique C-terminal region including an SH3 domain, potently inhibited TfR endocytosis like activated Rac1, whereas expression of other splice variants Ost-I and Ost-II had virtually no effect. Downregulation of Rac1 expression by siRNA treatment, in fact, canceled the inhibitory effect of Ost-III. Furthermore, we identified γ-amino butyric acid type A receptor-associated protein (GABARAP) as a protein that binds to the C-terminal region of Ost-III. When ectopically co-expressed, GABARAP potently suppressed Ost-III inhibition of TfR endocytosis, suggesting that GABARAP modulates Rac1 activity by binding to Ost-III. Indeed, Ost-III-dependent Rac1-GTP formation in transfected cells as assessed by pull-down assays was significantly reduced upon co-expression of GABARAP. Ost-III inhibited epidermal growth factor receptor endocytosis as well, implicating Ost-III/Rac1-dependent inhibition as a general regulatory mechanism for clathrin-mediated receptor endocytosis.

A Rhoa Guanine Exchange Factor Associates with the Early Endosome and Regulates Clathrin-dependent Uptake

M. Liu, A. Horowitz; Medicine, Angiogenesis Research Center, Dartmouth Medical School, Lebanon, NH

We have recently reported (MBC, 17:1880-7, 2006) that the targeting and activity of the novel Rhоa guanine exchange factor (GEF) Syx depends on its interaction with the PDZ adaptor protein synectin, a member of the immunoglobulin superfamily. Syx accounted for a major portion of the total RhoA activity in rat microvascular endothelial cells and was essential for the maintenance of cell migration. Synectin is involved in vesicle traffic and in the recruitment of the molecular motor myosin VI to uncoated vesicles (MBC, 14: 2728-43, 2003; PNAS, in press, 2006). We asked, therefore, if the activity of Syx, the ensuing activation of Rhoa, and the remodeling of the actin cytoskeleton are involved in the clathrin-dependent uptake of transferrin. We found that Syx colocalized with the early endosome markers Rab5 and EEA1. These findings are in agreement with the known participation of synectin in the traffic of uncoated vesicles between the plasma membrane and the early endosome and with its colocalization with Rab5. Furthermore, Syx co-immunoprecipitated with both EEA1 and Rab5, suggesting these proteins participate in the same complex. In order to examine the possible involvement of Syx in vesicle traffic we tracked the uptake of fluorescently-labeled EGF, a known clathrin-dependent process. We compared the rate of EGF uptake in endothelial cells transfected with Syx-specific siRNA to that of control cells. In pulse-chase experiments EGF reached perinuclear late endosomes in 15 min in close to a 100% of control siRNA-transfected cells. In the same time interval EGF reached perinuclear late endosomes in less than 20% of the Syx-specific siRNA-treated cells. These results suggest that the Rhоa GEF Syx modulates vesicle traffic, most likely that of uncoated vesicles up to their fusion with early endosomes. Consequently, Syx is an attractive target to probe actin dynamics accompanying vesicle movement in the cytoplasm.

Rac1 Regulates the Endosomal Localization and Function of the Rab5 Guanine Nucleotide Exchange Factor ALS2/asin via Rac1-activated Macropinocytosis

R. Kunita,1,2 A. Otomo,1 H. Mizumura,7 K. Suzuki-Utsunomiya,7 S. Hadano,1,2 J. Keddi1,2; 1Department of Molecular Life Sciences, Tokai University School of Medicine, Isehara, Kanagawa, Japan, 2Solution Oriented Research for Science, Japan Science and Technology Agency, Kagawuchi, Saitama, Japan

ALS2/asin is a member of guanine nucleotide exchange factors for Rab5 (Rab5GGEF) and a modulator in endosome dynamics. It has been demonstrated that, in cultured cells, ALS2 is mostly sequestered in cytoplasm with a rare distribution onto early endosome autoantigen 1 (EEA1)-positive endosomes, while a constitutively active form of ALS2 lacking the N-terminal RCC1-like domain is exclusively recruited to endosomes, promoting their enlargement. Thus, the intracellular localization and function of ALS2 can be regulated by certain upstream molecular signalings as well as its own domain structures. However, such regulatory mechanisms remain unknown. Here, we show that the subcellular localization of ALS2 is controlled by Rac1 signaling. ALS2 preferentially interacts with activated Rac1 in the cells and in vitro. Further, cytoplasmic ALS2 was exclusively recruited to membrane ruffles by activated Rac1 and then relocated to nascent macropinosomes via Rac1-activated macropinocytosis. At later endocytic stages, macropinosomal ALS2 enhanced fusion of the ALS2-associated macropinosomes with the transferrin-positive endosomes, depending on the ALS2-associated Rab5GGEF activity. These results suggest that ALS2 mediates fusion between distinct endosomal compartments under the control of Rac1 signaling. To our knowledge, ALS2 is the first Rab5GGEF that acts as a Rac1 effector and is involved in Rac1-activated macropinocytosis. ALS2 is a novel clue to delineate a molecular basis of the Rac1-Rab5 signaling.

Interaction of the μ Subunit of the Adaptor Protein Complex AP-4 with the Small GTPase RhoB

C. Rondanino, L. Leiva-Vega, J. Kunikle, G. Apodaca; Medicine/Cell Biology, University of Pittsburgh, Pittsburgh, PA

RhoB, a member of the Rho family of GTPases that localizes in part to endosomes, was recently shown to modulate basolateral traffic in polarized Madin-Darby Canine Kidney (MDCK) cells. However, the mechanism by which RhoB mediates this process is unknown. We hypothesize that RhoB acts through downstream effectors. To identify novel RhoB binding partners, we performed a yeast-two hybrid screen of a human kidney library. Both dominant active RhoB (RhoBV14) and dominant negative RhoB (RhoBN19) were found to interact with the μ subunit of the adaptor protein complex AP-4 (μ4). AP-4 is a heterotetrameric complex shown to be also present on endosomes and to regulate basolateral sorting in MDCK cells. We mapped the RhoB interaction site to the C-terminal domain of μ4. Among the small GTPases, the switch I and switch II regions have been shown to be the sites of interaction with effector molecules. The T37Y mutation in the switch I domain of RhoB, known to impair the binding to both GDP and GTP, abolishes the interaction with μ4. However, other mutations in the switch II domain, such as F39A, F170L, F197L, and C42Y, were found to be inactive. RhoA, which is 92% homologous to RhoB, also bound the C-terminus of μ4 whereas other GTPases such as Cdc42 and Rac1 did not. Myc-tagged RhoBV14 and RhoBN19 were overexpressed in MDCK cells together with full length μ4 bearing an internal HA tag. Both proteins were found to co-localize in vesicular structures. Moreover, full length μ4 co-immunoprecipitated with RhoBV14. Taken together, these data show that μ4 is a novel RhoB binding protein. RhoB may modulate endocytic traffic through its interaction with μ4.

Gus Regulates Endosome Maturation

A. Beas, C. Lavoie, I. R. Niesman, M. G. Farquhar; Cellular and Molecular Biology, University of California San Diego, La Jolla, CA

 Trafficking from early endocytic vesicles to lysosomes involves endosomal growth by fusion, multivesicular body (MVB) sorting, and endosome-lysosome fusion. This pathway is utilized to downregulate many cell surface receptors including the EGFR receptor (EGFR). Previously, we found that the heterotrimeric G-protein stimulatory n-subunit (Gαs) and its GAP, RGS-PX1, may regulate EGFR sorting (Zheng, B. et al., 2001, Science 294: 1939; Zheng, et al., 2004, MBC 15:5538). In the current study, we report a possible role for Gus in regulating endosome size. HeLa cells overexpressing GusGFP contain smaller EEA1-labeled endosomes compared to control cells; conversely, Gus depleted cells have larger endosomes. EM analysis demonstrates that Gus depleted cells accumulate larger multivesicular endosomes (MVB) than control cells. Also, Gus depletion shifts EEA1 to membrane fractions, while Gus overexpression shifts EEA1 to cytosolic fractions. Overall, our data suggests Gus regulates endosome size and/or maturation and in turn, affects trafficking from endosomes to lysosomes.

The Role of Newly Identified Protein, Melanoregulin in Phagocytic Processes

D. Mamek-Poprawa, K. Boese-Battaglia; Biochemistry, University of Pennsylvania, School of Dental Medicine, Philadelphia, PA

Introduction: Deletion mutation of melanoregulin (Mreg) (a.k.a. dilute suppressor protein dsu), a recently identified 26 kDa product of the Wnd2 gene (a.k.a. dou, Gm074, MGC32980), affects phagocytosis, but not the inhibition by activated Rac1, suggesting that melanoregulin functions downstream of Rac1. Melanoregulin containing protein-complexes were analyzed using co-immunoprecipitation with mAb 165 and anti-Merk antibodies. Results: Human retinal pigment epithelium (ARPE-19) cells express high level of melanoregulin mRNA comparing to lymphocytes and Jurkat cells. Confocal analysis was performed by confocal microscopy using fluorescent probes to detect Mreg and a membrane raft associated marker GM1. Dark- and light-adapted cells were analyzed in order to take into account membrane rearrangement during the rhytmic phagocytic activity. Melanoregulin co-precipitated with phagocytic receptor c-mer tyrosine kinase (Merk) from ARPE-19 cell lysate. Mreg level was further validated and confirmed in vitro on primary photoreceptor cells by temporary transfection and phagocytosis processes, including phagocytosis. Our results suggest that melanoregulin is localized to lipid rafts in response to light. Moreover, melanoregulin interacts with phagocytic receptor Merk. Therefore, we propose that the light-dependent dynamic association of melanoregulin with rafts is necessary for normal phagocytosis in RPE cells and consequently for continuing photoreceptor renewal process.
Rab5, a member of the Rab-family GTPases, plays important roles in the endocytosis and homotypic early endosome fusion. However, the function of Rab5 has been examined mainly by cell biological experiments using constitutively-active (CA) and dominant-negative (DN) mutants, or in vitro biochemical analyses. Thus, it is largely unknown when and where Rab5 is activated and inactivated during endocytosis. In order to address this issue, we developed a fluorescence resonance energy transfer (FRET)-based probe, designated Raichu-Rab5, for visualizing Rab5 activity in living cells. Raichu-Rab5 consists of YFP, the Rab5 binding domain of EEA1, CFP, and Rab5a. Raichu probes for wild-type, CA, and DN mutants of Rab5 were expressed in 293F cells and their emission profiles were examined. Compared with the wild-type Rab5 probe, Raichu-Rab5-CA had a markedly increased FRET efficiency, while Raichu-Rab5-DN had a decreased FRET efficiency. The dynamic range of Raichu-Rab5 was over 90%, proving that Raichu-Rab5 was a useful tool for monitoring the change of Rab5 activity. The GTP loading of the Rab5 probes correlated well with that of the authentic Rab5 proteins. Next, we confirmed the increased and decrease in the FRET level of Raichu-Rab5 by the expression of GEFs and GAPs acting on Rab5, respectively. The subcellular distribution of Raichu-Rab5 was similar to that of mRFP-Rab5 and the localization of the probe to early endosomes was ascertained using markers for PI(3)P. We also confirmed that Raichu-Rab5 bound to RabGDI, which controls the shuttling of Rab5. In Swiss3T3 cells, we observed a higher activity of Rab5 in the endosomal structures than in the cytosol. In order to elucidate the precise role of Rab5 in endocytic processes, we are currently trying to obtain informative images of Rab5 activation during endocytosis.

Interaction of Drosophila Rab GDI with Gint3, a UBX-domain Containing Protein

P. Amin, M. Lawson, A. Chen, B. Richardson, K. Ayres, A. Moore, N. Sangi, M. Keese, C. M. Cheney; Biology, Pomona College, Claremont, CA
Rab GTPases play multiple roles in vesicle transport. Rab GDP dissociation inhibitor (GDI) regulates Rab polymerization by retrieving Rab proteins from the cytoplasm to donor membranes. GDP plays a critical role in ensuring that the correct Rab is placed in the correct membrane. To identify proteins that interact with GDI, we have carried out screens for GDI interactors, using Drosophila as the model system, since the fly genome has a single GDI, but multiple Rab5a. In a yeast two-hybrid (Y2H) screen, a protein with a ubiquitin-like UBX domain was identified as a GDI inhibitor. This protein was named Gint3, for GDI interacting protein 3. Gint3 has a PUG-N-glycanase-associated domain and a UBX ubiquitin-like domain, but no obvious transmembrane domain. Gint3 did not interact with L319 mutant GDI, which has a mutation that alters the lipid-binding pocket of Domain II of GDI (Ricard et al, 2001, Genesis 31:17). Gint3 also did not interact with AK037 GDI, which has E349K mutation. Phosphoryl analysis of Gint3 and UBX domain proteins shows that Gint3 forms a distinct subfamily of UBX domain proteins with the highest bootstrap value. The region between the PUG and UBX domains also shows a high degree of conservation. Supported by NSF-RUI grant 0212730 to CMG.
mediated by different vSNAREs (VAMP3, VAMP4, VAMP7 and VAMP8). VAMP3 and VAMP8 are v-SNAREs of the early and late endosomes respectively. TI-VAMP has been proposed to mediate vesicular transport from endosomes to lysosomes. Here we have investigated the role of these different v-SNAREs in the trafficking of the EGF/EGFR complex by silencing their expression level by RNA interference. Our results indicate that silencing TI-VAMP expression results in increased EGF compared with control and VAMP3, VAMP4 or VAMP8 silenced cells. The precise membrane trafficking steps involving TI-VAMP in EGF degradation are under investigation.

Regulation of EGF Receptor Degradation by SCAMP3

Q. Aoh, D. Castle; Cell Biology, University of Virginia, Charlottesville, VA

Downregulation of cell surface receptors by endocytosis and degradation in the lysosome is vital to regulating cell signaling events and maintaining homeostasis. Ubiquitylation plays a key role in recognition of downregulated receptors such as the epidermal growth factor receptor (EGFR) and in regulating and mediating interactions with accessory and adapter proteins, e.g. epsins, Hrs and ESCRT complexes, that act along this pathway. Here we report that SCAMP3, a member of the Secretory Carrier Membrane Protein (SCAMP) family is multi-monoubiquitylated and interacts with both Hrs and Nedd4 family ubiquitin ligases. A portion of SCAMP3 localizes to compartments that traffic EGF. Additionally, SCAMP3 associates with endocytic cargos through a carboxy-terminal proline-rich (PR) motif. Our results demonstrate that SCAMP3 plays an important role in ubiquitinating EGFR and regulate the sorting efficiency of ubiquitinated EGFR degradation. These results suggest SCAMP3 has important roles in organizing the early endosomal compartment and in regulating sorting between degradative and recycling pathways.

The Role of Oligo-ubiquitin and Endocytic Adaptors in Misfolded CFTR Degradation from the Cell Surface

H. Barriere, C. Nemes, G. L. Lukacs; Cell Biology, Hospital for Sick Children, Toronto, ON, Canada

Recently we have demonstrated that ubiquitination plays a pivotal role in the rapid elimination of non-native CFTRs from the plasma membrane by rerouting the mutant channel from constitutive recycling towards lysosomal degradation. This process is conceivably mediated by the ubiquitin-dependent endosomal sorting machinery, including components of ESCRT-I, II and III (J. Cell. Biol. 2004, 164-923-933). To gain insight into the molecular basis of ubiquitinated transmembrane protein, including CFTR, internalization and endosomal sorting, we used type-I and type-II membrane proteins harbouring ubiquitin (Ub) as their exclusive sorting signal. Relying on CD4 and invariant-chain Ub-chimeras in combination with functional, biochemical and genetic techniques, we obtained evidences indicating that poly- and monoubiquitin, but not monomeric Ub can be recognized as an endocytic sorting signal by a subset of UIM containing clathrin adaptors (eps15/15R and epsin) in higher eukaryotes. The preferential binding of poly-Ub by eps15 was also verified in vitro. Combination of morphological and genetic techniques also showed that Ub chimeras were targeted for clathrin-dependent and caveolin-independent internalisation. Similar internalisation route and adaptor requirement were identified for CD4 ubiquitinated by MARCKS, a highly cationic receptor as well as ubiquitinated mutant CFTR. Measuring CFTR internalization rates in clathrin-adaptor-depleted cells demonstrated that CFTR ubiquitination provoked the switch from an AP-2-dependent internalization, driven by Tyr- and di-Leu based endocytic motifs of native channel to eps15/epsin-dependent endocytosis of misfolded CFTR. Ongoing experiments aim at identifying the ubiquitin chain topology and coat requirement for lysosomal sorting of ubiquitinated cargo at early endosomes.

The Pathways of Protein Cellular Delivery with Transportan

M. Pooga,1 2 K. Padar,3 P. Säälä,2 A. Niiwatt4,2 M. Hamsten4,2 U. Langel4; 1Estonian Biocentre, Tartu, Estonia, 2Institute of Zoology and Hydrobiology, University of Tartu, Tartu, Estonia, 3Institute of Cell and Molecular Biology, University of Tartu, Tartu, Estonia, 4Department of Biochemistry and Genetics, Tartu University, Tartu, Estonia, Sweden

Cell penetrating peptides (CPP) consisting of up to 30 amino acids are capable of translocation through cell membranes and delivering different cargoes. Despite numerous efforts the internalization mechanisms of CPPs have not been fully understood. The uptake of CPPs is dependent on the properties and concentration of peptide, cellular energy and lipid rafts of plasma membrane. Binding to the cell surface proteoglycans, followed by endocytic uptake is considered as the main mechanism of highly cationic CPPs’ cell-entry. However, the type of endocytosis induced by CPPs, further intracellular targeting, and liberation from vesicular structures are still under debate. We have focused on the characterization of the interaction sites with cells and intracellular trafficking of transportans (TP). The results of fluorescence and transmission electron microscopy show that TP and its constructs with proteins associate both with transferrin and transferrin receptor-positive vesicles and flat areas of cell surface. Interaction of TP-protein constructs with the plasma membrane induces formation of invaginations and vesicles pinch off into cells. The size and shape of forming vesicles is dependent primarily on the concentration of peptide and properties of cargo protein. Big non-homogenous vesicles with irregular shape, reminiscent macropinososomes, form at high TP concentration, while at lower peptide concentration small vesicles are induced suggesting the raft- or caveolae mediated uptake. At the initial steps of uptake, the cargoes coupled to transportans show moderate colocalization with proteins characteristic for main endocytic pathways - transferrin, caveolin or flotillin. Later cargoes translocated into cells concentrate in LAMP-positive vesicles in perinuclear area. A small fraction of protein targeted into cells is not confined to vesicular structures but localizes in cytosol, both in cortical and central area. Our results suggest the involvement of different endocytic pathways in the transportans-mediated cellular delivery of proteins and several routes may be used in parallel.

Multiple Factors Associate with the SH3 Domain of Hse1 to Mediate Cargo Sorting into Multivesicular Bodies (MVB)

J. Ren,1 Y. Kee,2 J. Hubbrecht,3 R. Piper1; 1Physiology and Biophysics, University of Iowa, Iowa City, IA, 2Institute for Cellular and Molecular Biology, University of Texas at Austin, Austin, TX, 3Institute for Cellular and Molecular Biology, University of Texas at Austin, Texas, USA

Ubiquitinated integral membrane proteins are delivered to the interior of the lysosome/vacuole for degradation. This process relies on specific ubiquitination of potential cargo and the recognition of ubiquitin by sorting receptors at multiple compartments. The protein complex Hse1-Vps27 functions as a sorting receptor on yeast endosomes. Hse1 is composed of a N-terminal VHS domain, an UIM domain and an SH3 domain, which are critical for Hse1 function. The SH3 domain is required for MVB formation and proper sorting of vascular hydrolases. Thus, we set out to identify factors that could interact with Hse1 SH3 domain and determine how those interactions contribute to MVB biogenesis. We found the novel protein Hua1 associates with SH3 domain of Hse1. Hua1 also interacts with an E3 ubiquitin ligase, Rsp5, and links Hse1 to the Rsp5-Rsp1-Ubp5 complex. The SH3 domain of Hse1 also binds to the ubiquitin-peptidase complex that regulates the sorting efficiency of proteins into the MVB. The SH3 domain of Hse1 also binds Doa1/Ufd1. We find that Doa1 binds ubiquitin through multiple domains and cells lacking Doa1 have impaired MVB sorting defect. Doa1 is known to interact with multiple factors that are involved in proteasome-mediated ubiquitinated protein degradation. Our data imply that these factors may play additional role in MVB biogenesis.

MVB Sorting: The Assembly of ESCRT-III at the Endosome

S. Saksena, D. Teis, J. Sun, S. D. Emr; CMM, UCSD, HMI, La Jolla, CA

The endosomal system is required for many key cellular processes including down-regulation of activated cell-surface receptors, antigen presentation, and the sorting of biosynthetic cargoes to the lysosome. The Endosomal Sorting Complex Required for Transport (ESCRT) is essential for the sorting of transmembrane receptors/proteins into Multi-Vesicular Bodies (MVB) and into lysosomes. Thus the ESCRT complex contributes critically to the regulation of cell surface receptor signalling during development and disease. Here we address the molecular mechanism that drives assembly and dynamics of the ESCRT-III core complex, Vps20p, Snf7p, Vps24 and Vps30p on endosomes. ESCRT-III function is required for the final protein-sorting step and membrane invagination during MVB vesicle formation. Unlike ESCRT-I and -II, which are recruited to endosomes as preformed complexes, ESCRT-III subunits remain monomeric in the cytoplasm, driven by the cytosolic conformation of the individual ESCRT-III subunits. What are the signals that initiate the assembly of ESCRT-III on endosomes? To address these issues, we initiated a genetic screen for ESCRT-III mutations that trigger premature activation and assembly in the cytosol. We will report on the characterization of certain “constitutively active” mutants. Our results strongly indicate that the assembly of ESCRT-III on endosomes requires an activating conformational switch from an inactive cytoplasmic monomer. This activation is mediated by ESCRT-II. Once activated, ESCRT-III assemblies on endosomal membranes in a tightly regulated cascade-like manner. Disassembly of the membrane complex requires the ESCRT-II into the individual cytosolic monomers is driven by the AAA-protein Vps4. Based on our findings we propose that ESCRT-II triggers a conformational change in Vps20p, which subsequently drives the assembly of ESCRT-III on endosomes to regulate the final steps in the MVB sorting process.
The multivesicular body (MVB) pathway of eukaryotic cells is an endosomal protein sorting system that delivers transmembrane proteins to the lumen of lysosomes/vacuoles for degradation. The MVB pathway functions in the degradation of cell surface proteins and therefore plays an important role in many cellular functions, such as cell signaling, nutrient uptake and immune response. The sorting of MVB cargo is executed by the protein complexes ESCRT-I, ESCRT-II, ESCRT-III which are recruited to the endosomal membrane and assemble into a large protein network. When sorting is completed the AAA-type ATPase Vps4 disassembles the protein network and recycles the ESCRT machinery. Vps4 is the only known enzyme of the ESCRT machinery and therefore is ideally positioned to play a key role in regulating the MVB pathway. We identified Nrv1 as a negative regulator of Vps4 function. For example, an increase in proteasomal activity would result in decreased levels of Nrv1, which consequently would cause a more efficient delivery of cargo through the MVB pathway. This regulatory connection formed by Nrv1 might allow the cell to regulate simultaneously both major protein degradation systems, the proteasome and the MVB pathway.

Cargo Ubiquitination Along the Endocytic Pathway: Regulation by SKD1/Vps4
K. Umebayashi,1 H. Stemman,2 T. Yoshimori1; 1Research Institute for Microbial Diseases, Osaka University, Osaka, Japan, 2Department of Biochemistry, The Norwegian Radium Hospital, Oslo, Norway

Ubiquitin conjugation to plasma membrane proteins, such as the epidermal growth factor receptor (EGFR), triggers their downregulation. Ubiquitin acts as a sorting signal in internalization from the plasma membrane and multivesicular body (MVB) sorting in endosomes, thereby directing cargoes to lysosomes. EGFR undergoes autophosphorylation upon ligand-binding, and the protooncogene product c-Cbl, which turns out to be a ubiquitin ligase, is recruited to the receptor via the resultant phosphotyrosine residues. However, it remains an open question where and how the c-Cbl-dependent receptor ubiquitination takes place in the endocytic pathway. To address this issue, we devised the following events after EGFR stimulation: localization of c-Cbl, binding of c-Cbl to EGFR and ubiquitinated status of EGFR. Strikingly, after 20 min of EGFR addition, c-Cbl was clearly relocated to endosomes. It was colocalized with EGF in endosomal subdomains marked by Hrs, which sorts ubiquitinated cargoes to the MVB lumen. Up to this chase period, coimmunoprecipitation of c-Cbl with EGFR was increased. Ubiquitination of EGFR occurred immediately after the EGFR stimulation, but it proceeded afterwards, as more c-Cbl was communoprecipitated with the receptor. These results strongly suggest that EGFR is progressively ubiquitinated during its transport to endosomes. This may ensure enough ubiquitin to be recognized by the endosomal sorting machinery. At a longer chase period, c-Cbl was not colocalized with EGFR, indicating that it was dissociated from EGFR prior to the MVB sorting. The dissociation of the EGFR/c-Cbl complex was dependent on the function of the AAA ATPase SKD1/Vps4: overexpression of the ATPase-deficient SKD1(E235Q) resulted in prolonged association of c-Cbl with EGFR in aberrant endosomes. Concomitantly, ubiquitinated status of EGFR was not attenuated for a long chase period. We propose that SKD1/Vps4 dissociates c-Cbl from EGFR and thereby terminates receptor ubiquitination in endosomes.

Functional Characterization of the Chorea-acanthocytosis Gene VPS13A in Saccharomyces cerevisiae
L. I. Grad, E. Combear; Medical Genetics, University of British Columbia, Vancouver, BC, Canada

Mutations in the gene VPS13A are responsible for chorea-acanthocytosis, a neurodegenerative disorder that closely resembles Huntington’s disease. VPS13A is one of four human genes that encode proteins homologous to the yeast protein, Vps13. The function of Vps13-like proteins has yet to be determined. However, yeast Vps13 appears to regulate protein sorting between the endosome and Golgi compartments. In addition, previous studies have demonstrated that Vps13 behaves as part of a large proteinaceous complex that is peripherally associated with intracellular compartments. Since vesicle traffic is highly conserved in eukaryotes and Vps13-like proteins are ubiquitously expressed, they are likely to play analogous roles in vesicle-mediated protein trafficking in humans. We have therefore utilized the highly amenable yeast model system to further investigate the role of Vps13 in the regulation of endosomal transport processes. Results from our genome-wide phenotypic analysis of yeast knockout collections support a role for Vps13 in the regulation of multiple endosomal sorting pathways. We predict that Vps13 is a multifunctional protein that associates with different adaptor proteins to carry out cargo sorting or vesicle formation. Therefore, we have undertaken genetic and biochemical approaches to identify interacting proteins. We have identified a Vps13-interacting protein that co-immunoprecipitates from cell lysates. This protein represents the first known binding partner for Vps13. We have also identified proteins required for the intracellular localization of Vps13. Further characterization of these relationships and the identification of other interacting proteins will allow us to characterize the pathways regulated by Vps13 and contribute to our understanding of the molecular mechanisms of neurological disease pathogenesis caused by defective Vps13-like proteins.

New Roles for an Old Player: Daxx as a Mitotic Regulator That Determines Taxane Sensitivity
C. R. Lindsay, A. Scholz, A. M. Ishov; Anatomy & Cell Biology, University of Florida, Gainesville, FL

Daxx, originally identified as a pro-apoptotic Fas-interacting partner and later demonstrated to have anti-apoptotic activity, is a ubiquitously expressed and highly conserved nuclear protein that accumulates in PML bodies and at condensed heterochromatin during interphase. Daxx knock out mouse embryos are lethal by E11.5 and are characterized by extensive apoptosis. Increased prometaphase index in Daxx deficient embryos, aneuploidy of Daxx knockout cells and an elevated level of Daxx in mitotic cells suggest a potential function of Daxx in mitotic progression. During prometaphase and metaphase, Daxx is released from PML bodies and is associated with mitotic spindles where it co-localizes and interacts with tumor suppressor Rassf1. This mitotic Daxx/Rassf1 interaction disrupts Rassf1/Cdc20 binding thus releasing Cdc20, which activates APC to catalyze the degradation of cyclins A and B and promotes the prometaphase/metaphase transition. Increased stability of mitotic cyclins in anti-Daxx siRNA cell lines confirms this model. Dereguulation of most mitotic checkpoint proteins leads to altered response to microtubule affecting drugs, usually enhancing sensitivity to these compounds. Daxx knockout and Daxx-depleted cells have increased resistance to treatment by the taxane paclitaxel, an anti-cancer chemotherapeutic agent that affects mitosis progression by hyper-stabilizing microtubules. While Daxx positive cells commit mitotic catastrophe and micronucleation upon paclitaxel treatment, Daxx deficient cells accumulate in prometaphase and survive after drug withdrawal. Thus, Daxx is a mitotic checkpoint control protein that determines sensitivity to paclitaxel chemotherapy, and is a potential predictive marker for taxane response in cancer patients.

Nucleolar Dynamics Revealed by Monoclonal Antibodies Against Specific Structural Regions of the Nucleus
Y. Hirai,1 M. Kumaeta,1 Y. Hirano,1 S. H. Yoshimura,1 K. Takeyasu,1 Kyoto Univ., Faculty of Integrated Human Studies, Kyoto, Japan, 2Kyoto Univ., Graduate School of Biostudies, Kyoto, Japan
[Background] Recent studies have revealed that a nucleolus is a dynamic nuclear structure which plays important roles in ribosome syntheses, formation of the nuclear speckles and transcriptional regulations. We have constructed a series of monoclonal antibodies against nucleolar proteins and 14 of them recognized nucleolus in immunofluorescence microscopy. So far, several antigens have been identified by mass spectrometrical analysis and cDNA library screening. [Results] (i) One of them, the Junmoni C (JmcC) domain-containing protein (potential histone de-methylase), bound to DNA and localized in the granular compartment (GC) region of the nucleolus. This protein dispersed into the cytoplasm at the onset of prophase and gradually assembled into the PNs (pre-nuclear body) on the mitotic chromosomes. A comparison of the cell-cycle dynamics of this protein with those of well-characterized nucleolar proteins (Fibrillarin (DFC) and B23 (GC)) revealed that the JmcC domain-containing protein may be one of the leading proteins in the reorganization process of the nucleolus at telophase. (ii) The antigen of 2-30C antibody, the human homologues of Suppressor-of-Hairy-Wing localized to the fibrillar compartment (FC) region of the nucleolus. Co-immunostaining of this protein with UBF (upstream binding factor) suggested that this protein localized to rDNA regions on the chromosomes throughout the mitosis. (iii) ObgH2, a human homologue of Bacillus Subtilis GTPase, localized in the dense fibrillar compartment (DFC) region of the nucleolus. Co-staining with DFC markers revealed that its reassembly to the nucleolar region at telophase was completely merged with Fibrillarin, but slightly earlier than Ki67 antigen.

Human Small G Proteins, ObgH1 And ObgH2, Participate in the Maintenance of Mitochondria and Nucleolar Architectures
K. Kimura,1 Y. Hirano,1 R. L. Ohtniwa,2 C. Wada,1 S. H. Yoshimura,1 K. Takeyasu,1 Faculty of Integrated Human Studies, Kyoto University, Kyoto, Japan, 2Graduate School of Biostudies, Kyoto University, Kyoto, Japan
The small G proteins act as molecular switches and play crucial roles in the regulation of fundamental cellular processes, such as protein synthesis, nuclear transport, membrane trafficking and signal transduction. The Obg sub-family proteins belong to the P-loop GTPase super class and their primary structures are highly conserved in many organisms from bacteria to human. The Obg homolog in Escherichia coli, ObgF, is essential for chromosome partitioning as well as cell growth. Our previous study revealed that ObgE coexists with 23S and 16S rRNA in vitro in the present of GTP and bind to 30S and 50S subunits, but not 70S. These evidences suggested that ObgE functions in ribosome maturation. Although all species in other kingdoms have only one sub-family protein, exploring the genomic database revealed that animals and plants have multiple obg homologs as well. In fungi Aspergillus nidulans, the obg gene is an essential gene for cell proliferation. A knockdown of ObgH1 by RNAi induced a mitochondria elongation and abnormal nuclear morphology, whereas a knockdown of ObgH2 resulted in a disorganization of the nucleolar architecture. These results implicated that ObgH2 may go through the specific evolutionary process and has an important role for the maintenance of nucleolar structure.

Nucleolar Proteins of Aspergillus nidulans Are Segregated via a Cytoplasmic Nucleolar Remnant
L. Ueki,1 C. De Souza,1 H. Liu,2 S. A. Osman1; Molecular Genetics, The Ohio State University, Columbus, OH
The nucleolus is a prominent nuclear structure whose mitotic segregation is poorly understood. During yeast mitosis the nucleolus segregates intact with rDNA. In contrast, during open mitosis the nucleolus is disassembled then reassembled. In Aspergillus nidulans, nuclei synchronously complete mitosis in a common cytoplasm. This model filamentous fungus also undergoes partially open mitosis, which is an evolutionary intermediate between open and closed mitosis. We therefore determined how A. nidulans nucleoli are segregated during mitosis. Unlike Saccharomyces cerevisiae nuclear proteins, few A. nidulans nucleolar proteins segregate with DNA. Instead we have defined three patterns by which different nucleolar proteins segregate during mitosis: (1) Dispersal into the cytoplasm at the onset of mitosis and re-accumulation into daughter nucleoli during G1, (2) Same as pattern 1 but with some protein remaining bound to DNA, (3) A novel pattern in which nucleolar proteins remain surrounded by nuclear envelope in a nucleolar remnant, distinct from daughter nuclei, before re-accumulating into daughter nucleoli during G1. Dual labeling of nucleolar proteins and nuclear envelope markers reveal the nucleolar remnant in segregation pattern 3 is generated as a result of a double nuclear envelope fission event. This double fission occurs around a nucleolar protein mass during telophase. This mechanism generates two transport competent daughter nuclei and a very transient nucleolar remnant containing class 3 nucleolar proteins. This study indicates A. nidulans undergoes mitotic disassembly then reassembly of its nucleolus, as do higher eukaryotes, and that generation of daughter nuclei occurs via a double fission mechanism, not a single fission as occurs in yeasts. We suggest the novel mitotic nucleolar remnant we have defined may serve as a sink for unwanted cytoplasmic proteins or RNAs that gain access to nuclei during A. nidulans mitosis and can also serve as a positional cue for double nuclear envelope fusion.

Initial Characterization of Mugsy, a Drosophila Nucleostemin-like GTPase
R. O. Rosby,1 P. DiMario; Biological Sciences, Louisiana State University, Baton Rouge, LA
Nucleostemin is a nucleolar GTPase implicated in stem cell and cancer proliferation (Tsai and McKay, 2002, 2005; Misteli, 2005). We have identified a nucleostemin-like protein in Drosophila. It is encoded by CG3983 in cytological region 89E11 on chromosome 3R. We refer to the encoded protein as Mugsy. It is 581 amino acids in length, and it displays 33.7% identity and 64.2% similarity to mammalian nucleostemin. Immuno-staining localized the endogenous protein to nuclei of larval Malpighian tubule cells, and to nuclei of nested imaginal (stem) cells within the larval midgut. Other than yet unidentifed cells also contained Mugsy. Preliminary RNAi observations include larval and pupal lethality, delayed development, and melanotic tumor formation in the hemocoel of third instar larvae. The few adults that managed to eclose displayed bristle, eye, and wing deformities. Some of these phenotypes fall within the Minute syndrome. RNAi knockdown of Mugsy also caused an apparent reduction in the number of midgut imaginal cells in larvae. A p-element disruption of CG3983 displayed a similar loss of midgut imaginal cells and a more penetrant larval lethality.

A Test of NuMA as a Structural Element of Nuclei and Spindle Poles
A. D. Silk, D. W. Cleveland; CMM, UCSD, La Jolla, CA
NuMA (Nuclear Mitotic Apparatus protein) is a large, abundant, coiled-coil protein component of the nucleus in vertebrates, which localizes to the spindle poles during mitosis. A role at spindle poles has long been implicated, especially from NuMA’s requirement as a microtubule crosslinker that in vertebrates acts, in concert with its partner cytoplasmic dynein, to tether spindle microtubules into a focused pole. Building on its abundant, intranuclear localization and likely assembly into coiled-coil nuclear filaments, a role as an essential element in structuring the interphase nucleus has also been proposed. To test NuMA’s functional roles in both of these contexts, two alleles of the NuMA gene have been generated through homologous recombination in embryonic stem cells. A constitutive disruption was created by the insertion of a transcription unit into a downstream intron so as to preclude normal NuMA RNA splicing, thereby producing a hyposmorphic, nearly null allele. As anticipated, NuMA is essential, as embryos homozygous for this allele die between E3.5 and E10.5. A conditional allele has also been generated in which the exon encoding the nucleolar localization sequence (NLS) is flanked by loxP recombination sites. After Cre recombinase action in primary fibroblasts homozygous for this allele, NuMA is relocalized to the cytoplasm. This produces normal mitoses in vitro and nuclei deficient in NuMA. A definitive test for a functional role for NuMA in nuclear organization and structure, including effects on long term gene expression, has been posed by following the consequences of in vivo deletion of the NuMA NLS through activity of Cre within the nuclei of long lived cells, including motor or Purkinje cell neurons.

Lamin A-dependent Nuclear Defects in Human Aging
P. Scalff, T. Mischel; NICI, NIH, Bethesda, MD
Mutations in the nuclear envelope structural protein lamin A are responsible for the childhood premature aging disease Hutchinson-Gilford Progeria Syndrome (HGPS). The molecular basis of HGPS is the generation of a truncated, dominant gain-of-function lamin A protein. Although HGPS individuals show several typical aging symptoms, it has been difficult to envision a role of lamin A in the normal aging process since the dominant gain-of-function protein was thought to be exclusively present in HGPS patients. We find that the same molecular mechanism responsible for HGPS is active at a low level in healthy cells. Cell nuclei from old individuals acquire similar defects as HGPS patient cells including downregulation of specific nuclear
2538 Molecular Characterization of the Ran-binding Zinc Finger Domain of Nup153
M. M. Higa; Oncological Sciences, Huntsman Cancer Institute/University of Utah, Salt Lake City, UT
The nuclear pore complex is the gateway for selective traffic between the nucleus and cytoplasm. To learn how building blocks of the pore create specific docking sites for transport receptors and regulatory factors, we have studied a zinc finger module present in multiple copies within the nuclear pores of higher eukaryotes. Biophysical studies indicate that all four zinc fingers found in human Nup153 can bind the small GTPase Ran, with dissociation constants ranging between 5 and 40 μM. Nuclear Magnetic Resonance (NMR) structural studies reveal that a representative Nup153 zinc finger adopts a zinc finger ribbon structure previously characterized as the Npl4 zinc finger (NZF) module. Chemical shift analysis was used to map the amino acids involved in Ran binding and a three amino acid motif (Lx3/Vx4/Ax3) located within the two zinc coordination loops was found to be key to Ran recognition. Mutational analysis confirmed the importance of these residues within the context of the zinc finger scaffold. Although this zinc finger domain has been previously reported to interact preferentially with RanGDP, we found, surprisingly, that a Nup153 zinc finger binds GDP- and GTP- forms of Ran with similar affinities, indicating that this interaction is not dependent on conformational determinants in Ran that are influenced by the nucleotide bound. Taken together, these studies elucidate the Ran-binding interface on Nup153 and, more broadly, provide insight into the versatility of this zinc finger binding module.

2540 X- Chromosome Inactivation in the Tetraploid Rodent Tympanoctomys barareae
C. N. O. Bacquet1, T. Neidez1, A. Paldi1, M. Gallardo2, Instituto de Ecología y Evolución, Universidad Austral de Chile, Valdivia, Chile, 1Génétique, Evry, France
To balance the unequal X-chromosome dosage between the XX female and XY male, mammals have adopted a unique form of dosage compensation in which one of the two X chromosomes is inactivated in the female. Initiation of X-chromosome inactivation (XCI) involves ‘counting’ of the X chromosomes to ensure that only one X remains active per autosome set, and a ‘choice’ as to which chromosome to inactivate. In addition, the inactivated X chromosome acquires particular heterochromatic characteristics. In the present study we have investigated for the first time the XCI in a naturally-occurring tetraploid mammal. To detect inactive X chromosome(s) we used immunofluorescence on interphase nuclei with specific antisera raised against MeSH2K7 and macroH2A1. We detect one inactivated X in female cells, indicating that this species presents a diploid-like XCI process, most probably due to the presence of a single pair of sex chromosomes. To further understand nuclear organization in T. barareae, the distribution of H3K4, and the acetylated variants of H3 and H4 was examined. The overall intensity of antibody signal in these proteins was not significantly different in T. barareae compared with the diploid controls. However, the spatial distribution of fluorescence was strikingly different when tetraploid and diploid cells were compared. We conclude that T. barareae behaves like a diploid species in the process of XCI, but it keeps important differences with diploids in terms of chromatin organization of its duplicated genome.

2541 Is ADP Unblocking in the Hexameric Structure of Human RuvBL1 the Key to its Functional Activity?
S. Gorynia,1,2 P. Matias,3 P. Donner,1 M. Carrondo2; 1Proteinchemistry/ET, Schering AG, Berlin, Germany, 2Protein Crystallography, ITQB, Oeiras, Portugal
RuvBL1 is an evolutionarily highly conserved eukaryotic protein related to the AAA+ family of ATPases (ATPase associated with diverse cellular activities) and plays important roles in essential signalling pathways like e-Myc and Wnt, in chromatin acetylation and remodelling, in transcriptional and developmental regulation, in DNA repair and apoptosis. Although its closest homolog is the bacterial helicase RuvB, no helicase activity could be detected from purified human RuvBL1. Tests of DNA/RNA binding and ATPase activity of RuvBL1 show that it binds ssDNA/RNA and dsDNA, but has a marginal ATPase activity. We have solved the three-dimensional structure of human RuvBL1, refined using diffraction data to 2.2 Å resolution. The crystal structure of the hexamer bound to ADP reveals that human RuvBL1 consists of three domains, of which the first and the third are involved in ATP binding and hydrolysis. Structural homology suggests that the second domain, which is weakly associated to AAA+ proteins and not present in RuvB, is a novel DNA/RNA binding domain. The structure of the RuvBL1/ADP complex, combined with our biochemical results, suggest that, while RuvBL1 has all the structural characteristics of a molecular motor, even of an ATP-driven helicase, one or more of yet undetermined co-factors are essential to its activation.

2542 Barrier-to-Autointegration Factor (BAF) Regulates Histone Acetylation In Vitro and In Vivo
R. Montes de Oca1, K. L. Wilson2; Cell Biology, Johns Hopkins Medical School, Baltimore, MD
To balance the unequal X-chromosome dosage between the XX female and XY male, mammals have adopted a unique form of dosage compensation in which one of the two X chromosomes is inactivated in the female. Initiation of X-chromosome inactivation (XCI) involves ‘counting’ of the X chromosomes to ensure that only one X remains active per autosome set, and a ‘choice’ as to which chromosome to inactivate. In addition, the inactivated X chromosome acquires particular heterochromatic characteristics. In the present study we have investigated for the first time the XCI in a naturally-occurring tetraploid mammal. To detect inactive X chromosome(s) we used immunofluorescence on interphase nuclei with specific antisera raised against MeSH2K7 and macroH2A1. We detect one inactivated X in female cells, indicating that this species presents a diploid-like XCI process, most probably due to the presence of a single pair of sex chromosomes. To further understand nuclear organization in T. barareae, the distribution of H3K4, and the acetylated variants of H3 and H4 was examined. The overall intensity of antibody signal in these proteins was not significantly different in T. barareae compared with the diploid controls. However, the spatial distribution of fluorescence was strikingly different when tetraploid and diploid cells were compared. We conclude that T. barareae behaves like a diploid species in the process of XCI, but it keeps important differences with diploids in terms of chromatin organization of its duplicated genome.

2543 The Physical Plasticity of the Mammalian Nucleus Is Related to the Epigenetic State
I. Pajerowski,2,3 D. E. Discher; Bioengineering, University of Pennsylvania, Philadelphia, PA
Molecular mechanisms of nuclear remodeling include changes in gene expression during differentiation and refers, in particular, to the ability of epigenetic modifications to influence ultrastructural reorganization. We hypothesized that such changes would parallel changes in nuclear rigidity, and have used biophysical methods to demonstrate that naïve human hematopoietic stem cells are on average 2.2 times softer than differentiated human skin fibroblasts. We explore the mechanism behind this observation in an epithelial cell line ideally suited to such measurements. The histone deacetylase inhibitor Trichostatin A is used to model chromatin decondensation that is typical of undifferentiated cells, and excess divalent salts are used to hyper-condense nuclei to varying degrees perhaps mimicking drug treated nuclei. Several different mechanisms of reorganization or relaxation were assessed by Fluorescence Recovery After Photobleaching (FRAP) coupled to Fluorescence Imaged Microdeformation (FIMD). FRAP-FIMD of GFP-Histone-H2B during micropipette aspiration demonstrate stable association of H2B during chromatin extension and relaxation in situ. However, between Trichostatin A decondensation that softens the nucleus and salt-induced condensation that stiffens the nucleus, a ten-fold change is seen in the susceptibility to conformational remodeling, with decondensed states remodeling fastest. Nuclear distortions that persist longer than ~8 seconds lead to irreversible reorganization of chromatin and nucleoli. Comparisons between the remodeling kinetics non-linearly suggest that slow post-translational modifications are often rate-limiting for the ultrastructural changes associated with nuclear plasticity.

2544 Programmed DNA Elimination in the Ciliate Stylonychia lemnac Is Accompanied by DNA Methylation
C. K. Maercker,1,2 C. Rutenberg,1,3 C. Schmitt,3 J. Marhold1; 1Biotechnology, University of Applied Sciences, Mannheim, Germany, 2RZPD German Research Center for Genome Research, Heidelberg, Germany, 3Epigenetics, German Cancer Research Center (DKFZ), Heidelberg, Germany
466
Ciliates contain micronuclei which are degraded and transcriptionally inactive, whereas the small DNA molecules of the DNA-rich macronuclei are transcribed during vegetative life cycle. After conjugation, mitotic products of the micronuclei are exchanged between conjugating partners and fuse with the stationary haploid micronuclei, resulting in a diploid zygote nucleus. Following mitotic division, one of the daughter nuclei differentiates into a new macronucleus, and the other differentiates into new micronuclei. The development of the somatic macronucleus from the germ-line micronucleus is accompanied by genome-wide DNA elimination. Several rounds of DNA replication to form polyploid chromosomes. These chromosomes are degraded again, and most of the DNA is eliminated. The remaining DNA is fragmented into the small DNA molecules of the macronucleus. We asked if in addition to small RNAs, H3K9 methylation, and chromodomain proteins, DNA methylation also is involved in the epigenetic mechanism of DNA elimination in electrophoresis method detected a cytosine methylation grade of 1.38 % in genomic DNA from fractionated macronuclei. For experiments on the sub-cellular level, we used an antibody specifically recognizing 5-methylcytosine (5mC) in order to investigate cells after conjugation and starvation. We found cytosine methylation in macronuclei of both types of cells. Interestingly, the antibody also stained polyene chromosomes bands, which are eliminated during macronuclear differentiation. This indicates that specific DNA sequences are cytosine-methylated before elimination.

2545  Cell Rounding Induced Global Histone Decacytation in Mammary Epithelial Cells
R. Xu,1 J. Lehbeyec,2 S. Moonee,2 C. M. Nelson,1 A. Richk,1 M. J. Bissell1; 1Life Science Division, Lawrence Berkeley National Laboratory, Berkeley, CA, 2Centre des Cordeliers, Unite mixte 505 INSERM / U1096, Paris, France
Extracellular matrix (ECM) regulates cell morphology, gene expression in vivo; these relationships are maintained in three-dimensional (3D) cultures of mammalian epithelial cells. In the presence of laminin-rich ECM (lECM), mammary epithelial cells become less adhesive to the substratum and undergo global histone deacetylation, which we previously showed was critical for their phenotypic differentiation. Here, using 3D culture models as well as nonadherent and micropatterned substrata, we showed that the cell rounding caused by ECM was sufficient to induce global deacetylation of histones H3 and H4 in human mammary epithelial cells. Microarray analysis demonstrated that this deacetylation correlated with a global reduction in gene expression. Whereas cells cultured on plastic substrata formed prominent stress fibers, those rounded in 3D lECM or on micropatterns lacked these cytoskeletal structures. These results indicate a tight link between ECM-controlled cell morphology and chromatin structure mediated by the actin cytoskeleton, supporting the concept of a tissue matrix in the control of gene expression.  

2546  Sumoylation of Tip60 Forms a Link between UV Irradiation Signaling to DNA Lesion Repair
Z. Cheng,1 X. Ding,1 H. Wang,2 Z. Liu,1 P. Wang,1 Y. Ke,2 Q. Wu,1 Y. Xu,1 H. Huang,1 X. Yao1; 1Laboratory of Cellular Dynamics, University of Sci. & Tech. of China, Hefei, China, 2Beijing University of Chinese Medicine, Beijing, China
Sumoylation-dependent acetylation of Tip60 regulates DNA damage response following genotoxic stress by acetylyzing histone and remodeling chromatin, the molecular mechanisms underlying the Tip60-dependent response to UV-induced DNA damage remain poorly understood. To systematically analyze proteins that regulate Tip60 activity during UV irradiation, we perform a proteomic analysis of Tip60-containing complexes. Our results show that Tip60 forms part of a stress-specific complex with KAP1. This complex contains proteins such as CIZ, belonging to the YAB subfamily, and ZC3H7B. Modulation of Tip60 acetylation by KAP1 is essential forTip60-dependent DNA damage response. Our biochemical characterization demonstrates that Tip60 is sumoylated by SUMO1 at its C-terminal in response to UV irradiation. This sumoylation targets Tip60 to the PML nuclear body. Interestingly, the sumoylation recruits p53 to the nuclear body and facilitates the trans-activation of its target genes. As a result, p21 protein expression is elevated in a Tip60-sumoylation-dependent manner, which induces a G1 arrest in response to UV irradiation. Inhibition of Tip60 sumoylation abrogates the p53-dependent DNA damage response while sumoylation of Tip60 augments its acetytransferase activity in vitro and in vivo. Significantly, this sumoylation-amplified HAT activity of Tip60 induces ATR activation cascade. This mechanism provides an explanation for how Tip60 links the UV-irradiated DNA damage response signaling to DNA lesion repair.  

2547  Using Multiplex ELISA to Obtain an Acetylation Profile of Three Core Histones and p53
C. R. Lyman,1 T. Lam,1 B. K. Baumgartner2; 1Quansys Biosciences, Logan, UT, 2Cell Signaling Technology, Danvers, MA
Acetylation of core histone lysine has been associated with increased gene transcription. CBP, CREB-binding protein, is a transcriptional co-activator endowed with histone acetytransferase (HAT) activity, transferring an acetyl-group to the ε-amine group of a lysine residue. The acetylation level of histones in chromatin has been established to be a key mechanism in regulating gene transcription can be controlled by both transcription factors and chromatin remodeling proteins. Multiple studies have suggested that chromatin remodeling proteins can manipulate the binding affinity between histones and through modification of core histone tails. Histone covalent modifications include acetylation, methylation, phosphorylation and ubiquitination. Acetylation of core histone lysine has been associated with increased gene transcription. CBP, CREB-binding protein, is a transcriptional co-activator endowed with histone acetytransferase (HAT) activity, transferring an acetyl-group to the ε-amine group of a lysine residue. The acetylation level of histones in chromatin has been established to be a key mechanism in regulating gene transcription. Recently, many studies have indicated that Ezrin, a member of the Rho GTPase family, binds to actin filaments and to the membrane skeleton and regulates cell migration and invasion. Ezrin expression is upregulated in the metastases of mammary and pancreatic adenocarcinoma, osteosarcoma, melanoma and rhabdomyosarcoma. Little is known about the regulation of Ezrin gene expression. We performed a series of experiments to determine the effect of Tip60 on Ezrin gene expression. We used a Tip60 knockdown HeLa cell line and a Tip60 overexpression stable cell line. We found that Tip60 knockdown resulted in a decrease in Ezrin expression, while Tip60 overexpression resulted in an increase in Ezrin expression. These results indicate a tight link between ECM-controlled cell morphology and chromatin structure mediated by the actin cytoskeleton, supporting the concept of a tissue matrix in the control of gene expression.

2548  The CREB-binding Protein Has a Dual Effect on Ezrin Gene Transcription
Y. Yu, G. Merlino; National Cancer Institute, Bethesda, MD
Gene transcription can be controlled by both transcription factors and chromatin remodeling proteins. Multiple studies have suggested that chromatin remodeling proteins can manipulate the binding affinity between histones and through modification of core histone tails. Histone covalent modifications include acetylation, methylation, phosphorylation and ubiquitination. Acetylation of core histone lysine has been associated with increased gene transcription. CBP, CREB-binding protein, is a transcriptional co-activator endowed with histone acetytransferase (HAT) activity, transferring an acetyl-group to the ε-amine group of a lysine residue. The acetylation level of histones in chromatin has been established to be a key mechanism in regulating gene transcription. Recently, many studies have indicated that Ezrin, a member of the Rho GTPase family, binds to actin filaments and to the membrane skeleton and regulates cell migration and invasion. Ezrin expression is upregulated in the metastases of mammary and pancreatic adenocarcinoma, osteosarcoma, melanoma and rhabdomyosarcoma. Little is known about the regulation of Ezrin gene expression. We performed a series of experiments to determine the effect of Tip60 on Ezrin gene expression. We used a Tip60 knockdown HeLa cell line and a Tip60 overexpression stable cell line. We found that Tip60 knockdown resulted in a decrease in Ezrin expression, while Tip60 overexpression resulted in an increase in Ezrin expression. These results indicate a tight link between ECM-controlled cell morphology and chromatin structure mediated by the actin cytoskeleton, supporting the concept of a tissue matrix in the control of gene expression.

2549  Transcriptional Reprogramming of Gene Expression in Bovine Somatic Cell Nuclear Transfer Embryos
N. Rodriguez-Osorio,1 Z. Wang,2 S. Kasinathan,2 G. Page,1 E. Memilli1; 1Animal and Dairy Sciences, Mississippi State University, Starkville, MS, 2Hematech LLC, Sioux Falls, SD, 3Public Health, University of Alabama-Birmingham, Birmingham, AL
Successful reprogramming of a somatic genome to produce a healthy clone by somatic nuclear transfer (SCNT) is a rare event and the mechanism(s) involved in this process are poorly defined. We took a unique approach by performing multiple rounds of cloning to produce bovine clones up to four generations (NT4), and then using cDNA microarray (Affymetrix), to compare the transcriptomes of blastocysts derived from NT1 and NT4 to those derived from IVF blastocysts. In parallel, we analyzed gene expression of the donor cells used to produce the NT1 and NT4 clones (DC1 and DC4, respectively). Since calving rate declines with the increased rounds of cloning, such comparisons would reveal epigenetic errors accumulated through each round of cloning, shedding lights on the reprogramming process. We found that there were 270 differentially expressed transcripts between IVF and NT1 (147 upregulated in IVF), and 411 differentially expressed between NT4 and NT1 (218 upregulated in IVF). We also found that there were 193 differentially expressed transcripts between NT1 and NT4. A large number of differentially expressed transcripts were found between NT1 and DC1, and between NT4 and DC4 (2459 and 2276, respectively). Of the 83 differentially expressed transcripts between both donor cells, 49 were at higher level in DC1 and 34 in DC4. The majority of genes upregulated in both NT groups compared with IVF embryos included those involved in protein folding and signal transduction such as LEC2 and DNAJC5. Genes with upregulated expression in IVF compared to both NT groups included those with receptor and catalytic activities such as PLAUR, PTGER4 and PDE1A. There were 23 differentially expressed genes in NT1 vs. NT4. Such study provides a unique data set for identifying the epigenetic errors in somatic cloning and may allow us to better understand the epigenetic reprogramming process in SCNT.

Trophoblastic Invasion In Vitro and In Vivo: A Comparison
C. Helige, A. Hammer, G. A. Dohr; Institute of Cell Biology, Histology and Embryology, Medical University of Graz, Graz, Austria

The basic mechanisms of trophoblast invasion are far from being completely understood. This may be due to the lack of suitable in vitro models, which contain several cell types considered to be involved in trophoblast invasion and which enable an experimental modulation of this complex process. The study aims to compare two factors considered to be implicated in trophoblast invasion, the expression of HLA-G by trophoblastic cells and apoptosis, in vitro and in vivo. A three-dimensional tissue culture model, which closely resembles the in vivo conditions during placentation was used. For that purpose, tissue fragments of human 1st trimester decidua parietalis (800 µm in diameter) were put in close contact with multicellular spheroids of AC-1:MW9 trophoblast/choriocarcinoma hybrid cells (300 µm in diameter) as a model of the invasive trophoblast. Cryostat sections from these co-cultures were immunohistochemically stained and compared with 1st trimester decidua basalis. The trophoblastic cells on the invasion front as well as the cells, which had already invaded deeply into the decidual tissue showed an intensive staining for HLA-G, whereas the cells on the periphery of the confrontation culture exhibited only a weak staining. A similar staining pattern was found in vivo. Invasive extravillous trophoblast cells were highly HLA-G positive, whereas the trophoblast cells of the cell columns were only weakly stained. Both in vitro and in vivo CD45+ apoptotic leukocytes were frequently detected in close proximity to the invasive trophoblastic cells. Only a few of the trophoblastic cells were apoptotic and most of them were not in close contact with the decidual leukocytes. In conclusion, in this three-dimensional tissue culture model key factors considered to be implicated in trophoblast invasion in vivo can also be demonstrated in vitro. Therefore, it can be used to study cellular interactions and factors regulating trophoblast invasion.

Effect of Melatonin on Development of Porcine Preimplantation Embryos In Vitro
N. Rodriguez-Osorio,1 I. Kim,1 S. Jung,1 A. Kaya,2 E. Memili,1 1Animal and Dairy Sciences, Mississippi State University, Starkville, MS, 2Department of Animal Sciences, University of Wisconsin-Madison, Madison, WI

Melatonin, a reactive oxygen species scavenger, plays a role in prevention of apoptosis and has been used to promote in vitro development of mouse, sheep and cow embryos. The aim of this study was to determine the effects of melatonin on in vitro porcine embryo development, particularly on cleavage, blastocyst rates, and blastocyst cell number. Porcine abattoir-derived oocytes were subjected to standard in vitro maturation and fertilization procedures. Fertilized oocytes were randomly allocated to groups in PZM-3 medium supplemented with Melatonin at concentrations of 10^{-3}, 10^{-6}, 10^{-9} and 10^{-12} M, starting 5 hours after insemination (hpi), and cultured in a humidified incubator with 5% CO₂ at 39ºC. Cleavage rates were assessed 48 hpi, and blastocyst rates were determined at day 6 post fertilization. Number of cells per embryo was assessed after epifluorescent staining with DAPI. The experiments were repeated 8 times and the results were analyzed using t-test. The study showed that Melatonin at 10^{-9} M concentration had a positive effect on cleavage rates with 45%±1.94 (mean±SEM) compared to 39%±2.01 in the control group (p<0.05). There were no differences in embryo development from the groups with Melatonin at concentrations 10^{-12} M and 10^{-6} M. Blastocyst cell numbers were higher in the Melatonin 10^{-9} M group, with 65±3.22 (cell number±SEM), compared to 50±2.07 for the control group (p<0.01). Our data indicate that melatonin (10^{-9} M) supports development of porcine preimplantation embryos and increases total number of cells in the blastocysts.

Individual and Collective Neural Crest Cell Migration Requires Cdc42 and RhoA
P. A. Rupp, P. M. Kulesa; Stowers Institute for Medical Research, Kansas City, MO

Programmed cell invasion is a key aspect of many developmental and adult processes, yet despite knowing many of the extrinsic guidance molecules involve in shaping migratory patterns, the function of cell extensions in accurate pathfinding remains unclear. The neural crest is a major migratory cell population in the vertebrate embryo that sorts into complex patterns of discrete migratory streams. Previously, we have shown that filopodial extensions may influence a trailing neural crest cell’s choice of direction through contact with other neural crest cells. We analyze the in vivo role of small Rho GTPases in neural crest cell dynamics and migratory patterning. We show that when the ability of a neural crest cell to correctly form filopodia and make meaningful cell-cell contacts is perturbed by altering Cdc42 or RhoA function, individual cell trajectories are less directional and cells are delayed in reaching the peripheral targets. Disrupted cell filopodial dynamics lead to a breakdown or delay of the follow-the-leader chain migratory behavior observed in post-otic neural crest. This altering of Cdc42 or RhoA signaling at the individual cell level perturbs the normal two-phase process of neural crest cell migratory patterning. We conclude that Cdc42 and RhoA are required for the accurate pathfinding and timely migration of avian neural crest cells.

Characterization of the Role of Planar Cell Polarity during Axial Elongation Movements in PTK7-null Mouse Embryos
W. Yen,1 A. Periasamy,2 C. Burdsal,3 X. Lu,2 A. E. Sutherland 1; 1Dept. of Cell Biology, University of Virginia, Charlottesville, VA, 2W. M. Keck Center for Cellular Imaging, University of Virginia, Charlottesville, VA, 3Dept. of Cell and Molecular Biology, Tulane University, New Orleans, LA

In Drosophila melanogaster, a ‘core’ group of planar cell polarity (PCP) genes including frizzled (ft), flamingo (fln), disheveled (dsh), Van Gogh (vang)/strabismus and prickle, function through a non-canonical Wnt-like pathway to regulate the orientation of specialized cells, such as wing hairs, bristles and ommatidia, within the plane of epithelial tissues. This PCP pathway is conserved in vertebrates and functions in regulating the planar polarization of cell protrusive activity and intercalation that drives the convergent extension movements of Xenopus gastrulation. It also plays a major role in mouse neural tube closure, although the mechanism is unknown. Recent studies have identified protein tyrosine kinase 7 (PTK7) as a novel regulator of PCP in mouse sensory hair cells and in Xenopus neural convergent extension and tube closure. We have used both static and live (time-lapse) confocal microscopy and three-dimensional reconstruction software to investigate the role of PTK7 in the PCP pathway in the anteroposterior elongation movements of developing mouse embryos. Embryos from heterozygous crosses mutant for PTK7 were dissected at 8.5 days of gestation and labeled with phalloidin, to examine actin organization and cell shape, and with antibodies to fibronectin to examine tissue organization. We found that there are major morphological differences between homozygous mutants for PTK7 and their wild-type counterparts that are consistent with a defect in anterior-posterior elongation. These include the lack of a visible node and notochord, a shorter and thicker primitive streak, somites that are wide mediolaterally and narrow anteroposteriorly, and an open neural tube that is convoluted in both the dorsoventral and mediolateral axes. There is also a difference in localized deposition of fibronectin fibrils at tissue boundaries. We propose three models for how PTK7 may regulate axial elongation in the mouse: through regulating cell division planes, by directing cell motility or by polarizing fibronectin fibril deposition.

Functional Disruption of the p23 Gene in a Mouse Leads to Perinatal Death
I. Grad,1 C. A. Miller,2 T. A. McKee,3 S. M. Ludwig,2 G. W. Hoyle,2 P. Ruiz,4 W. Wurst,4 D. Picard 1; 1Cell Biology, University of Geneva, Geneva, Switzerland, 2Environmental Health Sciences, Tulane Univ. School of Public Health and Tropical Medicine, New Orleans, LA, 3Service de Pathologie Clinique, University of Geneva, Geneva, Switzerland, 4GSF-Forschungszentrum fur Umwelt und Gesundheit, Neuherberg, Germany

The p23, a component of the Hsp90 chaperone complex, is thought to stabilize the client-interacting form of Hsp90. Among its various activities, it is crucial for assembly of mature steroid receptor complexes and in vitro it exhibits prostaglandin E2 synthase activity. To address the question of the in vivo function of p23, we have generated a mouse model using gene-trap approach, where p23 is functionally disrupted. Two independent mouse lines have shown that the p23 null is not crucial for overall prenatal development and morphogenesis, however p23 null neonates exhibit premature infant phenotype. The transition into air environment requires extensive changes in lung and skin of the embryo, which normally appear in the last phase of intrauterine development. The p23 null neonates die upon birth, their lungs are atelectatic with reduced expression of surfactant genes, but unaltered proportions of surfactant-composing lipids and their skin barrier is compromised. Correlating with the known function of glucocorticoids in promoting lung and skin maturation and the role of p23 in the assembly of a hormone-responsive glucocorticoid receptor-Hsp90 complex, p23 null fibroblast cells have a defective glucocorticoid response. Thus, p23 contributes a non-redundant, temporally restricted, and tissue-specific function during mouse development which, at least in part, is connected with its role in maturation of glucocorticoid receptor.
Identification of Genes Differentially Expressed in Endometrium from Women with Unexplained Recurrent Spontaneous Abortion

J. Lee, C. Cho; Life Science, Gwangju Institute of Science and Technology, Gwangju, Republic of Korea

Recurrence spontaneous abortion (RSA), defined as three or more clinically consecutive miscarriages during the first trimester, occurs in approximately 1% of pregnant women. The etiology in approximately 40% of RSA is unexplained, but it has been suggested that a proportion of unexplained RSA is due to endometrial factors that cause alteration of essential components for implantation and pregnancy. In this study, to identify the endometrial factors in unexplained RSA, we selected 31 genes of which expression levels are altered during the implantation period (between proliferative and secretory phases) from various microarray data sets previously reported. We compared the expression levels of these implantation-related, 31 genes in the endometrium between normal controls and patients with unexplained RSA, using a real time PCR assay. We found for the first time that four genes were differentially expressed between the controls and unexplained RSA patients with statistical significance. They were cellular retinoic acid binding protein 2 (CRABP2), neuronal olefimothionin related ER localized protein (Olf1), B-cell CLL/Jymphoma 6 (BCL6) and complement component 4-binding protein alpha (C4BPs).

Regulation of Muscle Plasticity by the Homeobox Factor Barx2

K. Gonzalez, H. Makarenkova, C. Wen Tsau, R. Meech; 1Dept. Neurobiology, The Scripps Research Institute, La Jolla, CA, 2The Neurosciences Institute, San Diego, CA

Muscle development is a dramatic example of terminal differentiation: myoblasts differentiate into myocytes that exit the cell cycle and fuse to form multinuclear myotubes. An intriguing question in skeletal muscle biology is the extent to which differentiated myofibers in adult animals retain developmental plasticity. Studies in different vertebrate phyla suggest that two different mechanisms for muscle repair exist: 1) recruitment and differentiation of satellite cells; and 2) dedifferentiation of existing myofibers to produce a pool of proliferative cells that can redifferentiate into new fibers. Satellite cell-mediated repair has been extensively studied; however the ability of muscle fibers to dedifferentiate remains controversial. Dedifferentiation and/or transdifferentiation of muscle have been reported in various vertebrates and low phyla vertebrates. For example, in jellyfish striated muscle undergoes transdifferentiation and S-phase re-entry and in urodile amphibians transacted myofibers dedifferentiate and contribute to multiple tissues during limb regeneration. Mammalian myotubes also retain developmental plasticity as indicated by observations that treatment of cultured myotubes with extract from regenerating newt limbs, or ectopic expression of the homeodomain transcription factor Msx1, can induce their dedifferentiation. However, whether muscle dedifferentiation occurs endogenously in mammals is presently unclear. Here we present evidence that another homeodomain factor that is expressed in skeletal muscle, Barx2, may regulate muscle plasticity. Ectopic expression of Barx2 in C2C12 myotubes and in MyoD-induced C1H10T1/2 myotubes causes cleavage and de-differentiation concomitant with down-regulation of muscle differentiation markers. Moreover, BrdU labeling suggested that Barx2 induced entry of muscle cells into S-phase. Among several homeodomain proteins studied, only Barx2 and Msx1 could induce myobrade breakage and downregulation of muscle specific markers, indicating that this phenomenon is specifically regulated by these proteins.

Changes in Muscle Fiber Properties of Murine Digastric Muscle Before and after Weaning

K. Ohkubo, K. Sakiyama, K. Kurokawa, S. Abe; 1Anatomy, Tokyo Dental College, Chiba, Japan, 2Sports Dentistry, Tokyo Dental College, Chiba, Japan

The importance of muscle plasticity is a major topic of research during several stages of an individual's life. Several studies have focused on changes in muscle fiber properties before and after weaning. We studied the digastric muscle before and after weaning to understand the changes in muscle fiber properties and to analyze the potential mechanisms involved.

Expression of the Regulatory Gene Pax-6 Precedes the Initial Stages of Corneal Epithelial Cell Differentiation

R. Garcia-Villegas, M. Hernandez-Quintero, E. Sanchez-Guzman, F. Castro-Munozzolo; 1Dept. of Physiology, Biophysics and Neurosciences, CINVESTAV-IPN, Mexico City, Mexico, 2Dept. of Cell Biology, CINVESTAV-IPN, Mexico City, Mexico

Pax6 is a regulatory gene, which plays a major role during development ofvisual and nervous systems in Metazoans. Although Pax-6 expression was described in several eye tissues, its involvement in corneal epithelial development is not understood. In order to analyse Pax-6 function during corneal epithelial differentiation, we used the RCE1 rabbit corneal epithelial cell line, previously described as a model that mimicks corneal differentiation. After RT-PCR with specific oligos, we cloned the full-length messengers encoding two Pax-6 isoforms. Both isoforms were found in vitro in confluent stratified epithelia formed by corneal keratinocytes, but not in proliferating cells. Northern blot and RT-PCR experiments showed that Pax-6 is not expressed in early cell cultures; afterwards, the transcription factor shows low levels in proliferating colonies. These results were supported by immunostaining of proliferating colonies with antibodies specific for Pax-6. In such colonies, the transcription factor was only found in the cells that were already positive for K3 keratin and therefore suggest that Pax-6 is expressed in cells that begin the differentiation process. After confluence, Pax-6 mRNA’s levels raised up to 5-fold. The authors conclude that the expression of this transcription factor preceded the increase in those messengers encoding for LDH isozymes H and M, previously shown as early markers of corneal epithelial cell differentiation. Similarly, the expression of the mRNA’s encoding these isozymes preceded by 2.5 days the expression of the differentiation-linked K3/K12 keratin pair. Finally, the ectopic expression of Pax-6 in corneal epithelial keratinocytes led to a decrease in the proliferative ability of these cells. Together, the results suggest that Pax-6 expression switches on the differentiation of corneal keratinocytes, leading to a knock down of proliferation. Supported in part by CONACyT grants 39690-Q and 1314P-N9507 (to FCML) and 43128-Q (to MRGV).

Elucidating the Activation Function of Msx Homeodomain Proteins

F. Zhang, C. Shuler, Y. H. Lee; Center for Craniofacial Molecular Biology, University of Southern California, Los Angeles, CA

The importance of Msx genes in regulating development of oro-craniofacial structures has been well established. It was shown that null mutations in the Msx1 gene can result in facial and palatal clefting, adontia, palatal bone synostosis and loss-of-function mutations in the Msx2 gene could lead to delayed closure of palatine foramina. Overexpression and ectopic expression of the Msx2 gene in transgenic animals can accelerate membrane bone formation and cause microphthalmia. Previous studies have shown that Msx proteins regulate gene transcription.
predominantly through repression by forming transcriptionally inactive heteromeric complexes. In contrast to their known suppressor activities, gene expression studies using either the gain-of-function or the loss-of-function mutants revealed many gene targets whose expression relies on functional Msx proteins. In order to study the activator function of Msx proteins, we established transcriptional assay system based on the mouse Hspa1b promoter. Mxs proteins activate Hspa1b promoter through a mechanism that relies on their conserved C-termini and Heat Shock Factors. DNA binding by Mxs proteins is not essential although the homeodomain does contribute to the over all activation activity.

2561 Smos2, a Sphingomyelin Synthase Gene Expressed in Calculifying Osteoblasts and Osteocytes

N. Ishikura, C. Shinotsuka, H. Akizuki, K. Ikeda, K. Watanabe; Dept. Bone & Joint Disease, National Center for Geriatrics & Gerontology, Obu, Japan

Osteocytes are thought to play crucial roles in bone metabolism, although limited information has been available on their specific products and physiological function. To isolate genes expressed in osteocytes, we employed subtractive PCR method and microarray techniques, and identified 5 novel genes expressed in osteocyte-enriched bone fraction. One of the genes encodes a novel enzyme involved in phospholipid metabolism, which has recently been found as a sphingomyelin synthase (Smos2: Huitema et al. (2004); Yamaoka et al. (2004). Expression of Smos2 was detected in long-term cultured osteoblasts, but not in bone marrow stromal or embryonic carcinoma cell lines. To determine the expression of Smos2 in vivo, LacZ gene was introduced into mouse Smos2 locus so its expression was driven by the endogenous Smos2 promoter. At E11.5, the expression, as monitored by X-gal staining, was detected only in skeletal elements, especially in the areas enriched in osteoblasts. The expression was observed not only in osteoblasts but also in osteocytes of E16.5 embryo. Smos2 was expressed in some differentiated chondrocytes of long bones, but not in notochord or cartilage elements which remain uncalcified. It has been reported that sphingomyelinase activity was detected in matrix vesicles, which play a pivotal role in matrix mineralization, and that sphingomyelin was hydrolyzed upon mineralization, which prompted us to hypothesize that sphingomyelin may have some inhibitory effects on mineralization. In fact, when Smos2 gene was overexpressed in osteoblasts, mineralization was significantly suppressed. Also, a sphingomyelinase inhibitor, Bn09, reduced mineralization when added to osteoblast cultures. It is suggested that sphingomyelin metabolism is tightly regulated in matrix mineralization and that Smos2, specifically expressed in calcifying osteoblasts and chondrocytes, may be involved in the regulation of mineralization.

2562 Phospholipase C-delta1 and -delta3 Are Required for Normal Development of Placenta

Y. Nakamura,1 T. Takenawa,2 K. Fukami; 1Tokyo University of Pharmacy and Life Sciences, Tokyo, Japan, 2Department of Biochemistry, Institute of Medical Science, University of Tokyo, Tokyo, Japan

Phosphoinositide-specific phospholipase C (PLC) is a key enzyme in phosphoinositide turnover and is involved in a variety of physiological functions. PLC can be categorized into six types, beta, gamma, delta, epsilon, zeta, and eta on the basis of sequence homology and activation mechanism. PLC-delta types are evolutionarily conserved from lower to higher eukaryotes and these isoforms are thought to be the primary forms expressed in mammals. To elucidate physiological functions of PLC-delta types, we generated PLC-delta1 and PLC-delta3 mice lacking both PLC-delta1 and PLC-delta3 died at embryonic day 11.5 (E11.5) to E13.5. PLC-delta1/PLC-delta3 double-knockout mice exhibited severe disruption of the normal placental architecture in the placenta and decreased placental vascularization, as well as abnormal proliferation and apoptosis of trophoblasts in the labyrinth area. Furthermore, PLC-delta1/PLC-delta3 double-knockout embryos supplied with a normal placenta by the tetraploid aggregation method survived beyond E14.5, clearly indicating that the embryonic lethality is caused by a defect in trophoblasts. On the basis of these results, we conclude that PLC-delta1 and PLC-delta3 are essential in trophoblasts for placental development.

2563 Conditional Functional Deletion of Rb within Chondrocytes Results in Dwarfed Phenotype

D. S. Vale-Cruz, P. A. LoValle; Anatomy and Cell Biology, University of Florida, Gainesville, FL

Longitudinal bone growth occurs through the process of endochondral ossification. Cartilage cells i.e. chondrocytes, undergo proliferation and terminal differentiation in order to provide the cartilage template for ossification into calcified bone. Our lab has previously described the expression profiles of the cell cycle regulatory proteins retinoblastoma (Rb), p107 and p130 in developing bone in response to wild-type or mutant activating transcription factor-2 (ATF-2) protein. ATF-2 has also been shown to regulate Rb promoter activity. ATF-2 regulation of the Rb promoter within chondrocytes was verified by chromatin immunoprecipitation. In order to assess the role Rb plays in normal skeletal development, a conditional knockout mice were generated. Rbloxp mice were crossed with Cre recombinase expressing mice under the control of the collagen type 2 promoter (Col2Cre) specific to chondrocytes. Heterozygous animals developing bone in response to wild-type or mutant activating transcription factor-2 (ATF-2) protein. ATF-2 has also been shown to regulate Rb promoter activity. ATF-2 regulation of the Rb promoter within chondrocytes was verified by chromatin immunoprecipitation. In order to assess the role Rb plays in normal skeletal development, a conditional knockout mice were generated. Rbloxp mice were crossed with Cre recombinase expressing mice under the control of the collagen type 2 promoter (Col2Cre) specific to chondrocytes. Heterozygous animals (Rbloxp+/−; Col2Cre+/-) were crossed with Rbloxp homozygotes to maximize the number of knockout animals. Resulting offspring were genotyped and assessed for skeletal abnormalities. Rb conditional knockout (Rbloxp−/−) animals exhibited reduced size and some skeletal abnormalities. Immunohistochanism analysis showed disruption of normal growth plate architecture. There was an increase in extracellular matrix combined with a decrease in overall cell number. Primary chondrocytes from Rbloxp mice were infected with an adenovirus expressing Cre to determine changes in cell cycle progression in response to Rb deletion. Cell cycle progression was altered in chondrocytes following Rb deletion. Rb expression is required for normal skeletal development. Disruption of Rb expression yields a dwarfed skeletal phenotype as a result of changes in chondrocyte proliferation and differentiation.

2564 Improper Notochord Detachment Due to Abrupt Bmp Signaling in the Pathogenesis of Esophageal Atresia

Y. Li,1 Y. Litingtung,2 P. T. Djike,2 C. Chiang; 1Cell and Developmental Biology, Vanderbilt University, Nashville, TN, 2Department of Molecular Biology, Leiden University Medical Center, Leiden, The Netherlands

Human foregut malformation known as esophageal atresia with tracheoesophageal fistula (EA/TEF) occurs in 1 in 4,000 live births with unknown etiology. We found that mice lacking PTEN activity, a tumor suppressor gene normally expressed in the notochord, had a phenotype similar to human EA/TEF. Our results showed that loss of PTEN expression is not essential for proper development of the notochord, because Noggin expression was reduced in the EA/TEF notochord. Indeed, normal notochord branches were evident in Noggin−/− embryos, and cellular and molecular examinations indicated delayed detachment of the notochord from the underlying dorsal foregut endoderm. Consistently, non-nothochordal, likely endodermal, cells were found in Noggin−/− notochord, suggesting Noggin function is required in the notochordal plate for its proper delamination from the dorsal foregut. Notably, ablating Bmp7 in Noggin−/− embryos rescued EA/TEF and notochordal branching defects, thus establishing a critical role of Noggin-mediated Bmp7 antagonism in EA/TEF pathogenesis.

2565 Alteration of Intestinal Epithelial Architecture and Proliferation in Mice with Impaired PTEN Expression

M. J. Langlois, B. A. Auclair, S. Roy, S. Turgeon, N. Rivard, N. Perreault; Anatomy and Cell Biology, University of Sherbrooke, Sherbrooke, PQ, Canada

PTEN is a tumor suppressor gene localized in a chromosomal region frequently altered in human tumors (10q23). PTEN dephosphorylates phosphatidylinositol 3-kinase (PI3K) activation. Germlinal mutations of PTEN have been identified in juvenile polyposis syndrome, a disease characterized by the development of hamartomatous polyps in the digestive tract and associated with an increased risk of cancer. Objective. To investigate the role of PTEN in the development, regulation of cell function and maintenance of the intestinal epithelium. Methods and Results. With the use of the Cre/loxP system, we have generated a mouse with a deletion of PTEN exclusively in the intestinal epithelium by crossing floxed PTEN mice with the Villin-Cre line. Macroscopically, we observed in mice with loss of intestinal epithelial PTEN expression, a dramatic lengthening of the digestive tract in addition to an hypertrophy and dilatation of its circumference. A disorganization of the intestinal epithelium architecture and an important thickening of the muscular layer are also observed in the mutants. Villin-Cre/LoxP (-90 min) and Cre/LoxP (90 min) mice develop similar phenotypes. Immunohistochemical analysis of fixed tissue revealed a delay in the appearance of villin staining, consistent with a delay in villin expression. ALDH activity was decreased in the villus tips of the mutants. The decrease in the ALDH activity may indicate decreased bile salt, which are known to be required to promote proliferation. Furthermore, a delay in the appearance of proliferating cell nuclei may indicate that the expression of cell cycle regulatory proteins may be delayed in the villus tips of the mutants. In summary, our data indicate that PTEN expression is required for normal development of the intestinal epithelium.
Localizing CDC-42 Activity in the Early C. elegans Embryo

K. Kumfer, J. G. White; Laboratory of Molecular Biology, University of Wisconsin, Madison, Madison, WI

Attaining a defined axis of polarity is necessary for a cell to execute diverse functions, such as directed motility, the generation of daughter cells with disparate fates and for the morphogenesis of ensembles of cells into organs. In C. elegans, the site of sperm entry defines the posterior end of the major axis of the fertilized oocyte. The paternally provided centrosome triggers actinomyosin-driven cortical flows toward the anterior, leading to the segregation of cytoplasmic determinants that maintain polarity and signal asymmetric cell division. The establishment and transition of a polarized microtubule cytoskeleton directs the localization of Cdc-42, which is required for anterior localization of several polarity factors and for the cytoskeletal reorganization that occurs during cell division.

Localizing CDC-42 Activity in the Early C. elegans Embryo

K. Kumfer, J. G. White; Laboratory of Molecular Biology, University of Wisconsin, Madison, Madison, WI

Attaining a defined axis of polarity is necessary for a cell to execute diverse functions, such as directed motility, the generation of daughter cells with disparate fates and for the morphogenesis of ensembles of cells into organs. In C. elegans, the site of sperm entry defines the posterior end of the major axis of the fertilized oocyte. The paternally provided centrosome triggers actinomyosin-driven cortical flows toward the anterior, leading to the segregation of cytoplasmic determinants that maintain polarity and signal asymmetric cell division. The establishment and
Correlation between β-catenin and APC Inhibits Nuclear Localization of β-catenin during Asymmetric Division in C. elegans

H. Sawa; Center for Developmental Biology, Riken, Kobe, Japan

Asymmetric division is fundamental for generation of cellular diversity. In C. elegans, asymmetry of most cell divisions is regulated by the Wnt signaling pathway. In other organisms, β-catenin has two separate functions in cell adhesion at cell cortex and in Wnt signaling in the cytoplasm and nucleus. In C. elegans, we previously showed that WRM-1/β-catenin that does not function in cell adhesion localized asymmetrically on the anterior cell cortex before and during divisions and to the posterior nucleus at telophase and after division. To know the function of cortical β-catenin, we expressed membrane target form of β-catenin to find that nuclear localization of β-catenin was inhibited in both nuclei. In contrast, in mutants of APC, β-catenin localized in both daughter nuclei, even if cortical WRM-1 was still asymmetric. Furthermore, we found that APC and Axin localized to the anterior cortex as β-catenin and that the APC localization was regulated by β-catenin. These results suggest that asymmetric cortical β-catenin recruits APC to the anterior cortex which inhibits nuclear localization of β-catenin. Our results indicate that β-catenin has antagonistic functions at the cortex and in the nucleus during asymmetric cell division in C. elegans.

The Planar Cell Polarity Protein Vangl2 Signals via Scribble - βPIX Complex to Modulate Epithelial Cell Migration

A. Gangar, S. Audebert, M. Montcouquiol, J. Borg; INSERM UMR599, Marseille, France, Institut F. Magendie des Neurosciences, INSERM, Bordeaux, France

Vangl2, a core planar cell polarity (PCP) protein is required for the uniform orientation of cells within the plane of an epithelium and convergent extension movements. The development of animal tissues requires dynamic remodeling of epithelial structure. For this remodeling, cells must balance two opposing but essential influences on cell-cell junctions: the active maintenance of contacts between all cells in an epithelial sheet. This balance maintains widespread epithelial integrity during morphogenesis but its molecular bases have been unclear. Here, we identify a novel role for the polarity regulator atypical Protein Kinase C (aPKC) as a key regulator of adherens junction (AJ) symmetry during Drosophila gastrulation. aPKC regulates apical microtubule organization to counterbalance planar polarized AJ assembly required for cell intercalation events. Without aPKC, centrosomal microtubules become abnormally dominant cues for planar polarized AJ clustering--AJs form discrete puncta associated with microtubule asters at the dorsal and ventral sides of each epithelial cell, sites where new contacts form as the cells intercalate. With aPKC, AJ symmetry and epithelial structure are maintained. aPKC appears to disrupt microtubule-cadherens associations in the apical domain, thereby inhibiting the AJ-microtubule interactions that otherwise break symmetry. In apparent contrast to microtubules, the actin cytoskeleton maintains AJ symmetry around the apical domain. In other tissue types as well, actin and microtubules appear to compete for AJ interactions and have distinct effects on AJ assembly and maintenance around the apical domain. This work reveals that specific molecular mechanisms regulate AJ symmetry during morphogenesis. Interplay between actin and microtubules, regulated by cell polarity regulators such as aPKC, functions in orchestrating the balanced remodeling of AJs during epithelial development.

E-cadherin Mediated Cell-Cell Adhesion Assembles a Targeting Patch That Specifies Basal-Lateral Vesicle Delivery to Initial Cell-Cell Contacts

L. N. Nejum, L. Edgington, W. J. Nelson; Molecular and Cellular Physiology, Stanford University Medical School, Stanford, CA

Formation of apical and basal-lateral membrane domains in polarized epithelial membranes requires cell adhesion to the extracellular matrix and to other cells, but the mechanisms involved are unknown. We tested whether assembly of the basal-lateral cell polarity complex is required for initial targeting of E-cadherin mediated cell-cell contacts in MDCK cells. Using aquaporin-3 (AQP3) and AQP5 as homologous marker proteins of kidney epithelial cell (basal-) lateral and apical membrane domain respectively, we show that AQP3, but not AQP5, was delivered in post-Golgi structures directly to cell-cell contacts where it co-accumulated precisely with E-cadherin during initial assembly of cell-cell adhesion. Components of the Exocyst and the t-SNARE complex also localized precisely with E-cadherin upon cell-cell adhesion, and selective disruption of microtubules, the Exocyst or the t-SNARE complex inhibited delivery of AQP3 to forming cell-cell contacts. These results show that E-cadherin mediated cell-cell adhesion initiates the rapid, localized assembly of a targeting patch for selective delivery of basal-lateral vesicles thereby initiating the specification of that site as the forming (basal-) lateral membrane domain.

The Exocyst Complex Regulates Multiple Post-Endocytic Trafficking Pathways in Polarized MDCK Cells

A. Oztan, L. Leiva-Vega, M. Sivis, N. Bradbury, S. Hsu, J. Goldenberg, C. Yeaman, G. Apodaca; Department of Medicine, University of Pittsburgh, Pittsburgh, PA, Department of Pharmacology, University of Pittsburgh, Pittsburgh, PA, Department of Cell Biology and Physiology, University of Pittsburgh, Pittsburgh, PA, Department of Physiology and Biophysics, Rosalind Franklin University, North Chicago, IL, Department of Cell Biology and Neurosciences, Rutgers University, Piscataway, NJ, Department of Surgery and Cell & Developmental Biology, Vanderbilt University, Nashville, TN, Department of Anatomy and Cell Biology, University of Iowa, Iowa City, IA

The exocyst is an octomeric complex that regulates delivery of the newly synthesized trans-Golgi network (TGN) proteins to the basolateral plasma membrane domain of polarized Madin-Darby canine kidney (MDCK) cells. In these cells, the exocyst has been variously localized to the lateral plasma membrane near the junctional complex, the trans-Golgi network, and transferrin-positive recycling endosomes. At present, it is unknown whether the exocyst is localized to additional endocytic compartments or whether it regulates transport within the endosomal system of polarized epithelial cells. Analysis of the distribution of the exocyst subunits Sec6, Sec8, and Exo70 in polarized MDCK cells by confocal microscopy confirmed that in addition to the lateral membrane, these proteins were partially localized to vesicles that are positive for the basolateral recycling marker transferrin. There was also a significant subapical pool of Sec6/Sec8/Exo70 that showed extensive colocalization with transcytosing IgA and the apical recycling endosome marker Rab11. Immunolocalization experiments further confirmed that Sec8 subunit was found on Rab11-positive endosomes. Streptolysin-O (SLO)-permeabilized MDCK cells were used to analyze the involvement of the exocyst complex in endocytic trafficking pathways. Recycling of transferrin in this assay was inhibited 46% by the addition of function blocking Sec8 antibodies, but was not affected by the addition of a non-specific control antibody. Furthermore, Sec8 antibodies inhibited IgA transcytosis 57% and IgA recycling 50%. Previously Sec15 subunit of the exocyst complex was shown to interact with Rab11. In order to test the role of this interaction in IgA trafficking, Rab11 binding domain of Sec15 (Sec15CT) fused to EGFP was expressed in MDCK cells. Rab11 and IgA receptor pGFP co-localized with Sec15CT and expression of this domain inhibited IgA trafficking. These results indicate that the exocyst complex is localized to endocytic compartments and regulates multiple post-endocytic pathways in polarized epithelial cells.

Control of Adherens Junction Symmetry during Embryogenesis

T. J. Harris, M. Peifer; Dept. of Cell and Systems Biology, University of Toronto, Toronto, ON, Canada, Dept. of Biology/Lineberger Comprehensive Cancer Center, University of North Carolina at Chapel Hill, Chapel Hill, NC

The development of animal tissues requires dynamic remodeling of epithelial structure. For this remodeling, cells must balance two opposing but essential influences on cell-cell junctions; the disassembly and assembly of individual cell-cell contacts and the active maintenance of contacts between all cells in an epithelial sheet. This balance maintains widespread epithelial integrity during morphogenesis but its molecular bases have been unclear. Here, we identify a novel role for the polarity regulator atypical Protein Kinase C (aPKC) as a key regulator of adherens junction (AJ) symmetry during Drosophila gastrulation. aPKC regulates apical microtubule organization to counterbalance planar polarized AJ assembly required for cell intercalation events. Without aPKC, centrosomal microtubules become abnormally dominant cues for planar polarized AJ clustering--AJs form discrete puncta associated with microtubule asters at the dorsal and ventral sides of each epithelial cell, sites where new contacts form as the cells intercalate. With aPKC, AJ symmetry and epithelial structure are maintained. aPKC appears to disrupt microtubule-cadherens associations in the apical domain, thereby inhibiting the AJ-microtubule interactions that otherwise break symmetry. In apparent contrast to microtubules, the actin cytoskeleton maintains AJ symmetry around the apical domain. In other tissue types as well, actin and microtubules appear to compete for AJ interactions and have distinct effects on AJ assembly and maintenance around the apical domain. This work reveals that specific molecular mechanisms regulate AJ symmetry during morphogenesis. Interplay between actin and microtubules, regulated by cell polarity regulators such as aPKC, functions in orchestrating the balanced remodeling of AJs during epithelial development.
Roles of the Discs Large SH3-GK Intramolecular Interaction in Asymmetric Cell Division
R. A. Newman, K. E. Prehoda, University of Oregon, Institute of Molecular Biology, Eugene, OR
Members of the membrane-associated guanylate kinase (MAGUK) superfamily are involved in organizing molecular assemblies that regulate the formation and function of specialized regions of the membrane. Allosteric regulation of an intramolecular association of MAGUK SH3 and GK domains is thought to play a central role in regulating MAGUK function. For example, all genetically identified mutations in the SH3 and GK domains from the tumor suppressor Discs large (Dlg) have been shown to disrupt the SH3-GK intramolecular interaction. One such allele, dlg⁶⁵⁴, encodes a form of Dlg that disrupts the intramolecular association while leaving the SH3 and GK domains intact, providing an excellent model system for assessing the role of this interaction in MAGUK function. To determine the functional role of the SH3-GK intramolecular interaction in asymmetric cell division of Drosophila neuroblasts we assessed localization of cortical polarity markers in Drosophila neuroblasts. While the intramolecular interaction plays no role in Dlg localization, as the sw form of Dlg localizes like wild-type Dlg, it is required for restriction of the protein Miranda to the basal cortex. This similarity to the Dlg null phenotype suggests that while the dlg⁶⁵⁴ is properly localized it is unable to associate with protein partners that allow for restriction of cell fate determinants to the basal cortex. This hypothesis is currently being addressed by comparison of Dlg-associated proteins in dlg and dlg⁶⁵⁴ cell extracts by gel filtration of clarified cell extracts followed by co-immunoprecipitation and mass spectrometry. These studies will contribute to our understanding of the molecular mechanism by which Dlg regulates asymmetric cell division.

PAR-3 and PAR-1 Cooperate to Generate the LET-99 Band Pattern during Asymmetric Cell Division
J. Wu, R. Leslie; MCB, UC Davis, Davis, CA
During asymmetric cell divisions in early worm embryos, cell polarity is regulated by PAR proteins. PAR proteins also act as a through G protein signaling pathway to generate forces that position nuclei and spindles. Our lab has previously shown that the LET-99 protein acts downstream of the proteins and negatively regulates G protein signaling. Unlike several PAR proteins that localize to either the anterior or posterior cortex, LET-99 localizes in a distinct pattern as a posterior cortical band. We previously showed that cortical LET-99 asymmetry is dependent on the anterior PAR-3/PAR-6/PKC-3 complex. To further elucidate how the LET-99 band pattern is generated, we examined LET-99 localization in other polarity and spindle positioning mutants. We found that LET-99 localization is dependent on cortically localized proteins of the PAR pathway, but not on several cytoplasmically localized components. In the absence of low LET-99 levels at the anterior cortex in par-1 mutants shows that PAR-3 inhibits LET-99 localization independently of PAR-1. Further, quantification of staining intensities revealed a gap between the anterior LET-99 band and the posterior PAR-1 domain that correlates with the region of highest cortical LET-99 intensity. In a par-1 kinase mutant, LET-99 is also mislocalized to the entire posterior cortex, which suggests that LET-99 localization is regulated by phosphorylation. We propose that the anterior PAR-3/PAR-6/PKC-3 complex and posterior PAR-1 both inhibit LET-99 localization through their kinase activities, and the resulting cortical LET-99 band is required for asymmetric spindle positioning events. We are currently examining if LET-99 is phosphorylated by PAR-1 and PAR-3/PAR-6/PKC complex using 2D gel analyses.

Lentiviral Transduction of Bone Marrow Hemopoietic Progenitor Cells Ex Vivo
Methods of gene transfer into mammalian cells has been significantly progressed over recent years. Gene transfer by means of lentiviruses-based vectors permits to introduce a foreign gene into non-dividing cells, including stem cells. This work was performed with the aim to optimize the method of transducing hematopoietic progenitor cells with such a genetic construct ex vivo. The differentiation potential of transduced cells was studied by analysing spleen colonies. Cell subpopulation enriched with Lin- c-kit- hemopoietic progenitor cells (LK) was isolated from murine bone marrow by magnetic separation. This population was characterized by FACS-analysis of cells pre-treated with MAb against c-Kit, Sca-1 and CD34 antigens (BD). LK-cells were incubated in vitro for 24 h with HIV-based pseudoviral particles harboring genes of red fluorescent protein (dsRed) under the control of MSCV promoter. Transduced cells were cultured for 1 week, and dsRed expression was then determined using FACS-analysis. Spleen colonies were generated in lethally irradiated female CBA/C57Bl6 mice after administration of 3000 transduced LK-cells from syngenic males. In 10 days spleens from chimeric mice were used for morphological investigation and for isolation of single colonies, FACS-analysis of dsRed expression, and PCR-detection of Y-chromosomal marker and a fragment of integrated provirus genome. In 1 week post transduction 21% of cultured cells were shown to express dsRed. Spleen colonies were non-differentiated, and most of them cells expressed dsRed. In isolated colonies, percent of fluorescent cells varied from 0.5 to 78%. Y-chromosomal marker was detected in all colonies, while a fragment of integrated provirus genome was detected in most of them. Thus, HIV-based lentiviral vector can stably and effectively transduce LK-cells in vitro. LK-cells containing transgene are capable of giving rise to fully viable spleen colonies of megakaryocyte differentiated type in vivo. Supported by grant of RF President NS-7675.2006.7 and CRDF grant RUB1-576-MO-04.

Characterization of Cytoplasts from Embryonic Stem Cells
A. Kijima,1,2 S. Tone,1 Y. Nagahara,1 M. Ikekita,1 T. Shinomiya2; 1Tokyo University of Science, Tokyo, Japan, 2National Research Institute for Child Health and Development, Tokyo, Japan,

Cellular Characteristics of the Distal Tip Cell, a Somatic Cell Required for Maintenance of Germline Stem Cells in C. elegans
D. T. Byrd,1 S. L. Crittenden,2 K. J. Schmidt,1 K. A. Leonhard,1 J. Kimble2; 1Department of Biochemistry, University of Wisconsin-Madison, Madison, WI, 2Howard Hughes Medical Institute, Madison, WI
Germ cells in adult C. elegans hermaphrodites are spatially organized with mitotically dividing cells at the distal end adjacent to the somatic distal tip cell (DTC), which provides a niche for germ cell proliferation. As cells move away from the DTC, they enter the meiotic cell cycle and undergo oogenesis. The region of mitotically dividing germ cells (the mitotic region) includes germline stem cells since it is self-renewing and produces cells that can differentiate into gametes. To investigate how germline stem cells are maintained, we examined the self-renewal and...
division patterns of germ cells in the mitotic region. We found that all germ cells within the mitotic region are actively cycling, as assayed by BrdU labeling, and that there is no consistent orientation of the mitotic divisions with respect to the DTC. Therefore, germline stem cells are likely maintained by proximity to the DTC rather than by programmed oriented cell divisions. To further investigate what other cellular characteristics of the DTC are important for its function in providing a niche for the germline stem cells, we made a panel of fluorescent protein markers to examine the cellular structure of the DTC in vivo. Using a membrane marker, we found that contact between the DTC and germ cells in the mitotic region is extensive and dynamic. The DTC extends membrane processes that surround adjacent germ cells. The intimate contact between the niche and germ cells may provide a mechanism to physically anchor the distal-most germ cells within the niche and provide more localized signaling to maintain the germline stem cells.

Cellular Basis for Autologus, Adult Stem Cell Mediated Regeneration of Damaged Myocardium in a Canine Model for Myocardial Infarct
C. Culshaw,1 G. Wisenberg,2 F. Prato,3 H. Kong,2 K. Leks,1 J. Sykes,1 R. Mann,4 P. Merrifield3; 1Anatomy & Cell Biology, University of Western Ontario, London, ON, Canada, 2Cardiology, London Health Sciences Complex, London, ON, Canada, 3Imaging, Lawson Health Research Institute, London, ON, Canada

Heart failure, as a consequence of myocardial infarction, is the leading cause of death in North America. The use of autologous, adult stem cell therapy to sustain and/or regenerate damaged myocardium has been successfully used in rodents, but clinical trials are in development. In this study, we report a canine model of myocardial infarct. BMSCs were isolated from adult dogs, expanded in vitro, labeled with the fluorescent marker PKH26 and injected into myocardium damaged by 3 hrs of ischemia. Animals were imaged using MRI at weekly intervals to determine infarct size and left ventricular ejection fraction, sacrificed at 12 weeks post-injection and the hearts dissected and frozen for immunohistochemical analysis using a panel of vascular, myogenic and cardiomyogenic specific antibodies. MRI revealed that, compared to 5 control dogs (which received an infarct but no stem cells), dogs receiving BMSCs (5) experienced a greater recovery of damaged myocardium (ie reduction in infarct size over time). Immunohistochemical analysis with Mab CD31 demonstrated more neovascularization of infarcted regions in dogs receiving BMSCs compared to control dogs. Similar results have been reported by others for MSCs. The extent of neovascularization is currently being analysed. These studies will provide insight into the relative contributions of neovascularization and neocardiogenesis in improving cardiac function following stem cell therapy. 1 Ye et al (2006). Exp. Biol. Med 231, 8-19. 2 Oshima et al, 2005 Mol. Ther. 12, 1130-1141. (Supported by grants from HSFO and CCHR).

The W-57 Allele of the Mouse Kit Oncogene Confers Advantages for HSC Function
Y. Sharma, C. Astle, D. Harrison; Hematology and Immunology, The Jackson Laboratory, Bar Harbor, ME

Throughout the life of an animal, cells for the blood and immune systems are descended from hematopoietic stem cells (HSC). The best-defined adult stem cell. HSC development organizes as a hierarchy, from the unipotent stem cells to the specialized blood cells. One essential regulator of HSC function is the Kit oncogene (c-Kit), previously identified as the White-spotting locus. Our objective is to define the effects of 3 Kit alleles on HSC and progenitor function. Several mutant Kit alleles have been identified with varying degrees of defects on hematopoiesis. This study focuses on 3 mutations - Kit-W-57 (W-57), Kit-W-41 (W-41), and Kit-W-42 (W-42). The W-57 mutation deletes 2.5 Kb of the minimal promoter, leaving the coding region intact, while W-41 and W-42 are single residue changes in the Kit intracellular phosphotransfer domain. Interestingly, the W-57 mutation increases HSC function. On the other hand, the defect caused by the W-42 mutation is so severe that homozygous die before birth; effects of W-42/+ on HSC differentiation are comparable to W-41/W-41. These 2 deleterious Kit mutations have normal numbers of progenitor cells in the HSC pathway, so they reduce HSC and progenitor functions rather than numbers. With the competitive repopulation assay, HSC from W-42/+ and W-41/W-41 mice have similar degrees of repopulating defects, which are significantly less functional than +/- W-57/W-57 BMC repopulate about twice as well as +/- controls. Progenitor cell function is also tested with colony spleen assays. We looked at allelic interactions between W-57 and each mutation to determine if the W-57 mutation confers advantages to HSC and progenitor cell function. Each mutation has a unique pattern of effects on specific stages of precursor cell differentiation when placed with W-57. These studies will improve understanding of KIT receptor in HSC function and could suggest clinical therapies for hematopoietic stem cell disorders.

Enrichment of Muscle Satellite and Stem Cells with Chemotherapeutic Drugs: A Paradigm for Enhanced Stem Cell Transplantation
E. C. Hardeman1, P. Kahatapiyita1, B. Kramer1,1 E. J. Joya1, R. Liu1, J. Hook1, G. Schevova2, F. Lemnicker3, T. Borovina1, I. Alexander3, G. McCowage4, P. W. Gunning5; 1Muscle Development Unit, Children's Medical Research Institute, Westmead NSW, Australia, 2Oncology Research Unit, Children's Hospital at Westmead, Westmead NSW, Australia, 3Department of Oncology, Children’s Hospital at Westmead, Westmead NSW, Australia, 4Gene Therapy Research Unit, Children’s Hospital at Westmead, Westmead NSW, Australia

We describe a novel application of a selective enrichment strategy, initially established for hematopoietic cells, in a skeletal muscle system. Cells expressing a mutant form of the drug MGMT-P140K were selected and transplanted into regenerating muscle beds. These studies will provide insight into the relative contributions of neovascularization and neocardiogenesis in improving cardiac function following stem cell therapy. 1 Ye et al (2006). Exp. Biol. Med 231, 8-19. 2 Oshima et al, 2005 Mol. Ther. 12, 1130-1141. (Supported by grants from HSFO and CCHR).

Regulatory Mechanism for Reprogramming
M. Nakagawa, K. Takahashi, K. Okita, T. Ichisaka, S. Yamanaka; Stem Cell Biology, Institute for Frontier Medical Sciences, Kyoto University, Kyoto, Japan

Embryonic stem (ES) cells derived from inner cell mass of mammalian blastocysts grow rapidly and infinitely while maintaining pluripotency. Although human ES cells could be used in cell transplantation therapy, their clinical application faces ethical objections against utilizing human embryos. One solution is to generate pluripotent cells directly from somatic cells. As candidates for factors inducing pluripotency, we selected 24 factors, which are specifically expressed in ES cells and/or play important roles in the maintenance of pluripotency. These include transcription factors Oct3/4, Sox2, and Nanog, as well as several (proto) oncogenes. We have also developed an assay system in which nuclear reprogramming can be detected as marker gene expression. By using this system, we have recently shown that retrovirus-mediated transfection of four factors, including Sox2, Oct3/4, c-Myc, and Klf4, could induce pluripotent cells, which we designated induced pluripotent stem (iPS) cells, directly from mouse embryonic and adult fibroblast cultures. However, the molecular mechanisms for this phenomenon remain to be resolved. One open question is whether sustained expression of the four factors is required for the generation and maintenance of IPS cells. To answer this question, we are introducing some of the factors transiently by adenoviral vectors, with the remaining factor(s) by retroviral vectors. We are also trying to express some of the four genes conditionally by the tetracycline-controlled system. Another important question is whether the four factors can be replaced by their mutants, their family genes, or other (proto) oncogenes. In this meeting, we will present progress in these experiments.

Temporal-Spatial Emergence of HSC in the Fetal Mouse Liver
M. L. Edwards, M. Ferkowicz, S. Khan, W. C. Shelley, M. C. Yoder; Pediatrics, IU School of Medicine, Indianapolis, IN

Published data supports the origin of definitive hematopoietic stem cells (HSC) in the yolk sac, primitive spleenoplerue and aorto- gonado-mesonephros. The molecular signals that promote engraftment and expansion of definitive HSC in the newly developing fetal liver remain undefined. The object of this work was to define the earliest time and place that HSC arrived at the developing fetal liver to provide an optimal frame of reference for subsequent molecular studies. The nascent liver is formed as the vitelline veins invade the septum transversum and foregut endoderm differentiates into hepatoblasts. Definitive progenitor assays and transplantation data have been used to indirectly support the presence of HSC in the fetal liver as early as 28 somite stage (post conception day 19.5). Groups of ES 8.5-11 embryo mice were fixed and dissected at post conception day 19.5 to optimally demonstrate the developing abdominal structures and then incubated with fluorescein-labeled antibodies for a variety of cell lineage specific antigens including FLK1 and VE Cadherin (vascular endothelium), Proxl and HNF3B (hepatoblasts), and CD150 and CD41 (HSC). The tissues were imaged using a Biorad single photon confocal microscope system. The raw images were processed with Metamorph and Vox software and composite images compiled with Adobe Photoshop. Results support the hypothesis that small numbers of HSC arrive at the
nascent liver hematogenously and cross the vascular endothelium to engraft the extra-vascular hepatic parenchyma 3-4 somite pairs earlier than the 28 somite stage. Three-dimensional images in separate color channels support a direct interaction of individual HSC with vascular endothelial cells and hepatoblasts. We conclude that signals in 24-28 somite stage fetal murine liver may promote diapedesis of HSC to the extra-vascular region and that the hepatic microenvironment during this period should be the focus of future molecular studies of engraftment signaling.

Optimizing Conditions for Low Toxicity, High Efficiency Transfection of Difficult-to-Transfect Cells Such as Primary Fibroblasts and Stem Cells Using Lipofectamine™ LTX
Transfection is an essential tool for numerous in vitro applications including studies of gene expression, promoter analysis, intracellular signaling pathways, epigenetics, and for therapeutic strategies such as tissue engineering and gene therapy. Common methods used in delivery of DNA into cells include calcium phosphate precipitation, liposome mediated transfer, electroporation, and virus-based delivery. Of these, cationic liposomes consistently provide the simplest and most effective method without requirements for additional equipment, cloning, or production of recombinant virus. Lipofectamine™ LTX is a new and novel reagent that provides high transfection efficiency and high levels of transgene expression in a range of mammalian cell types in vitro using a simple protocol. Optimal transfection efficiency and subsequent cell viability depend on a number of variables such as cell culture conditions, liposome and DNA concentrations, liposome-DNA complexing time and type of media in which the complexation occurs. Based on these general conditions, optimized protocols for transfection of a variety of cell lines have been established, including cell types often regarded as hard to transfect. The importance of these factors in Lipofectamine™ LTX mediated transfection is evaluated and used in the development of specific applications for transfection of several primary cell types, stem cells, and disease relevant (NCI60) cell lines.

Self-Tolerance and Vascularization of Tissue Mediated by “Non-Coding” RNA Bioaptamers
J. H. Wissler, J. E. Wissler, E. Legermann; ARCONS Institute for Applied Research & Didactics, Bad Nauheim, Germany
OBJECTIVE: Tolerance concerns development and immune self-nomelf recognition and discrimination processes with spatiotemporal, basic and clinical problems associated with tissue vascularization alike. As evident from paradigmatic Le Dorain phenomena and peptideiton complexity, involved mechanisms are not fully understood [Burnet, Medawar: http://nobelprize.org/nobel_prizes/medicine/laureates/1960/index.html; Coutinho, Int.J.Dev.Biol. 4:131-136,2005; Yewdell, Science 301:1334-1335,2003]. Therefore, RNA/RNP functions in tolerance and associated epigenetic [non-Mendelian] phenotype alterations were investigated. METHODS were developed for isolation of endogenous mammalian [oligo+] RNA, extracellular DNA and RNP, guided by self-tolerance bioassays of cellular differentiation and tissue morphogenesis [Wissler et al. Proteins Biol.Fluids 34:517-536,1996; Arch.Surg. 124:693-698,1999; Materialwiss.Werkstofftech. 32:994-1008,2001; Ann.N.Y.Acad.Sci. 961:292-297,2002; TET 213:163-184,2004; FEBIS J. 27:1-116,4-5P,2005; Mol.Biol.Cell Suppl. 12:149a150a,2001; FASEB J. 20:A30-A31 & A930-A931,2006]. RESULTS: By fluid shear stress, Fenton-type redox reactions, hypoxia [reactive oxygen species], metal [Ca,Cu,Zn] ions and mitogens, cells form many endogenous bioactive redox- and metalloregulated, edited and modified "non-coding" small hairpin shRNA bioaptamers [200 bases] and extracellular RNP cytokines [ribokines]. shRNA that feedback protein structure/folding to translation and transcription were sequenced. By copper ion-structured UCUG-hairpin loops, they address binding domains in epigenetic regulator protein conformers, termed KRX3H [KRXxXH], i.e. t/sx/Rg/x/RxxRx/y/n/q/dx/x-hh/y,x-x/Rx-x/KRx/q/eh with accessory basic [RK], R/K-zipper, SR/K/Rx and/or Hhx/h/Hyy/q segments. shRNA apparently represent cryptic codes for epigenetic alteration: By sequence edition, base modification [e.g. to isoguanine], redox- and metalloregulation, i.e. code extension/alteration, they are not directly retranslatable to inheritable genome codes. CONCLUSIONS: The results suggest that such shRNA are specific clonal recognition addresses for epigenetic phenotype alterations in RNA-, redox- and metalloregulated conformation phase pathway-locked loops. In estimated repertoires of recognition entities, RNA bioaptamers are effective and superior in diversity/specificity [~1017] than blood group type [~104], antibody [~108], T-cell receptor [~1010], and MHC [~1012] protein systems. For tolerance, all attributes make such RNA bioaptamers efficient and competent to recognize and integrate information flow on all possible molecular facets back to genomic mechanisms.

Membrane Bound Cardiomyocyte Differentiation from Embryonic Stem Cells
S. Sheridan, M. Wilgo, S. Gil; Cell Based Assay Development, Millipore Corporation, Danvers, MA
Cardiomyocytes are an important model system to evaluate potential drug interactions that may affect the development and/or activity of heart tissue. However, cardiomyocytes from primary sources are limited, particularly when human cardiomyocytes are required. Embryonic stem cells (ESCs) have the capacity to differentiate into all three somatic germ layers and are a potential source for tissues for a variety of uses. The ability to differentiate these cells into specific tissue types has extensive implications in the areas of regenerative medicine, tissue engineering and drug discovery. Several studies have demonstrated that ESCs can be differentiated into cardiomyocytes, expressing the same markers and showing equivalent electrophysiology as isolated cardiomyocytes. These results support the idea that engineered cardiac tissue from embryonic stem cells can be used as a model for studies of tissue development and function in vitro and may provide a cell source for cell therapy and drug discovery screening. We have evaluated the use of porous synthetic polymer substrates in facilitating the tissue-specific differentiation of embryonic stem cells into cardiomyocytes. Cardiomyocyte differentiation was initiated via embryoid body formation followed by adherent growth to a porous lum polymer (PET) membrane surface. Phenotype was verified over time by visual observation of beating cell clusters, immunohistochemistry and flow cytometry. Typically, differentiation studies have been carried out on 2D solid bottom plastic growth substrates. However, such cultures have limitations, such as lack of nutrient and gas exchange in the interior of cell clusters. Membrane-based growth and differentiation overcomes these limitations by providing a more in vivo like 3D surface topography conducive to adherence while the pores allow for both nutrient and gas exchange from multiple directions. In addition, membrane-based differentiation culture allows for co-culture experiments to examine indirect cell-cell interactions.

Expansion of Embryonic Stem Cell Clones by Porous Membrane Based Co-Culture
S. Sheridan, S. Gil, M. Wilgo; Cell Based Assay Development, Millipore Corporation, Danvers, MA
Embryonic stem cells (ESCs) are essential tools in the developmental genetics of modern genetically modified mouse models. The requirement that the ESCs are maintained in the undifferentiated state is a general challenge during microwell plate based clone isolation and expansion. Current methods typically accomplish this by a labor-intensive multi-step direct co-culture of ESCs on a mouse embryonic fibroblast (MEF) feeder layer in 96 well tissue culture treated plates. We have investigated the ability to expand undifferentiated clonal colonies in a 96 well membrane based cell culture plate. Porous membranes allow for the co-culture of cells from different origins in order to study how cells interact through indirect signaling or by providing a conditioned niche for the proper growth and identity of cell type. In this study, we examine the ability of MEFs to condition the media for the growth and undifferentiated clonal isolation of ESCs in a porous membrane based indirect co-culture system. The configuration of this co-culture setup involves growing the MEFs in a feeder tray below wells containing ESCs separated by a porous membrane filter. This arrangement allows for a physical separation between the two cell types eliminating the need for mitotically inactivating the MEFs while continuing to allow the MEFs to condition the media for maintenance of ESCs pluripotence. Since the ESC containing wells share a larger volume of media, media change frequency can be reduced. In addition to improving the culturing efficiency/specificity of embryonic stem cell clones, the separation of the cell types during this filter based co-culture eliminates the requirement for removing the MEFs before blastocyst injection. Variations in media for maintenance of ESCs pluripotence. Since the ESC containing wells share a larger volume of media, media change frequency can be reduced. In addition to improving the culturing efficiency/specificity of embryonic stem cell clones, the separation of the cell types during this filter based co-culture eliminates the requirement for removing the MEFs before blastocyst injection. expression of liprotein lipase and peroxisome proliferator activated receptor γ mRNA, however, by 30 PDLs, calcium deposits were also apparent. In summary, proliferative and differentiation capacity of adipose derived hMSCs is relatively unchanged for 25 PDLs following isolation. These data suggest large numbers of multipotent hMSCs can be derived from a single isolation. Potential applications include tissue engineered autologous bone grafts, where a patient’s own cells could be used in a custom designed implant to repair a specific defect or injury.

Selection of Smooth Muscle Cells from Differentiating Mouse Embryonic Stem Cells
A. Kumar, J. Szucz, J. L. Lessard; Developmental Biology, Cincinnati Children’s Hosp Med Ctr, Cincinnati, OH
Disorders of smooth muscle affect both vascular and visceral organ systems. The goal of this study was to develop a strategy to select smooth muscle cells from cultures of differentiating mouse embryonic stem cells. Toward this end, we have exploited a 13.7-kb DNA fragment containing the promoter, upstream regions and all sequences up to the translational start codon in the Smooth Muscle Gamma-Actin (SMGA) gene (Qian et al., Dev. Dynamics 207:135-144, 1996). This promoter drives expression of reporter genes in a tissue specific and developmentally-regulated manner that is similar, if not identical, to that of the endogenous SMGA gene which is expressed almost exclusively in smooth muscle. Moreover, unlike Smooth Muscle Alpha-Actin (SMAA), SMGA is not expressed in early cardiomyocytes, developing skeletal myocyte, or other non-smooth muscle cell types. SMGA expression occurs subsequent to SMAA expression during smooth muscle development; thus, SMGA expression is a hallmark of a mature and/or highly differentiated smooth muscle phenotype. We have generated a construct containing a selectable puromycin marker and the 13.7-kb SMGA promoter to drive the expression of neomycin phosphotransferase. Puromycin resistant, undifferentiated ES cell clones were selected after electroporation of this construct into feeder-independent E14TG2E ES cells. Following differentiation of these ES cells and selection with neomycin, populations of cells were obtained in which most, if not all, cells stained for both SMGA and SMAA. Furthermore, these cells displayed a characteristic morphology of cultured smooth muscle cells and Northern analysis and microarray analysis confirmed the expression of numerous smooth muscle-related mRNAs in these cells. These cells provide an important resource for the study of smooth muscle differentiation that may lead to insights into the smooth muscle myopathies and form the basis for novel cell-based therapies.

Nanoscale Topography Modulates Human Embryonic Stem Cell Self-Renewal
D. R. McFarlin, K. J. Finn, P. F. Nealey, C. J. Murphy; 1School of Veterinary Medicine, University of Wisconsin-Madison, Madison, WI, 2Chemical and Biological Engineering, University of Wisconsin-Madison, Madison, WI
Significant challenges in human embryonic stem cell biology include the maintenance of an undifferentiated lineage as well as devising optimal strategies to coax large populations of cells down pathways of preferred differentiation (e.g. neurons). Numerous environmental factors influencing stem cell behavior have been investigated including surface chemistry, growth factors, and mechanical forces. Our laboratory has previously reported, for a number of cell types, that topographic features, independent of surface chemistry, profoundly modulate fundamental cell behaviors. We hypothesized that topographic cues, in the nano to micron scale range, would play a role in modulating stem cell behaviors. Soft lithography was used to stamp polyurethane substrates containing nanoscale through micron scale grooves and ridges, ranging from 4000 nm down to 400 nm pitch (pitch = ridge width + groove width). H1 HES cells were cultured for five days on flat and topographically patterned substrates. Cells were fixed and scored for the presence of alkaline phosphatase, a known marker of undifferentiated stem cells. The provision of topographically patterned substrates (in the nanoscale through microscale range) improved maintenance of the self-renewing phenotype (p ≤ 0.0009). To our knowledge these are the first experiments documenting that the physical topography of cell culture surfaces influences HES cell differentiation and self-renewal. Nanoscale topographic cues should be considered a fundamental environmental factor that has relevance to emerging strategies of stem cell engineering.

Microfluidic Platform for Live Cell Screening
P. J. Lee, P. J. Hung; CellASIC Corporation, Richmond, CA
We have developed an innovative microfluidic chip for multiplexed cell culture and high content analysis. The current chip enables a researcher to control 16 independent perfusion experiments on adherent cells over time periods of days to weeks. The design of the microfluidic culture regions and nutrient flow paths resemble the physiological microcirculation, and ensure uniform culture conditions while eliminating cross-contamination. The “tubing free” construction of the system overcomes many of the current limitations of microfluidic screening. Each experimental unit contains a volume in the nanoliter range with flow rates on the order of nanoliters per minute. The cells can be directly imaged through the #1 thickness borosilicate glass bottom, enabling high magnification light and fluorescence microscopy. Our microfabrication process enables reliable production of features down to 1 micron, with a cost per data point over 10X lower than current flow cell systems. This chip has been used to demonstrate cytotoxicity of anti-cancer drugs on cultured cell lines. An alternate geometry has also been used to create and maintain well defined multicellular tumor models in a multiplexed microfluidic format. Due to the small volume requirements for the microfluidic chip, multiplexed screening of primary cell cancer models can be readily implemented. The continued development of microfluidic tissue culture technologies will enable more accurate in vitro results for primary cell screening experiments.

Microfabricated Arrays for Separating Adherent Cells
C. E. Sims, Y. Wang, M. Bachman, G. Li, G. Young, G. Salazar, N. Albritton; 1Physiology and Biophysics, University of California-Irvine, Irvine, CA, 2Integrated Nanosystems Research Facility, University of California-Irvine, Irvine, CA, 3Biomedical Engineering, University of California-Irvine, Irvine, CA, 4Physiology and Biophysics, Biomedical Engineering, University of California-Irvine, Irvine, CA
A fundamental need in almost all areas of biomedical research is the ability to separate single or small groups of cells from within a heterogeneous population. In order to obtain a living cell possessing a desired characteristic, individual or homogeneous groups of cells within the population must be analyzed followed by identification and isolation of the target cell(s). Most live-cell separation methods require that cells be dispersed into a single-cell suspension, but removal of adherent cells from their growth surface may at times be undesirable. A flexible cell array platform composed of releasable microfabricated “pallets” and an integrated laser microscope system has been developed for analyzing, sorting and collecting viable cells from a mixed population while the cells remain adherent to their growth surface. Individual pallets containing single cells or colonies can be released and collected with minimal perturbation. Preliminary studies have shown that adherent cells cultured on the array can be analyzed and selected using standard imaging methods. Furthermore, target cells can then be collected with high viability and efficiently cloned. Benefits of this new approach include improved cell viability, smaller sample size requirements, and broader alternatives for cell selection. Mating of the technique with image cytometry can be expected to provide a valuable tool for selection of adherent cells for cloning or further analysis.

Islet on a Chip: A Novel Array of Living Beta Cells Reveals Functional Subclasses
M. Hibo, J. Wikstrom, B. Corkey, S. Katz, B. Israel, O. Shirihai; 1Pharmacology, Tufts University, Boston, MA, 2Obesity Research Center, Boston University, Boston, MA
Pancreatic beta cells form a functionally heterogeneous population within the islets of Langerhans. Currently, the understanding of beta cell population dynamics in response to glucose and other physiologically relevant agents is limited. This limitation is caused by the lack of a suitable tool with which to study a large population of primary cells over time at the single cell resolution. Here we present the first such study of beta cell heterogeneity using a novel imaging approach that enables real-time, ongoing observation of cellular events from thousands of individual living cells, followed by structural and post-fixative measurements on the same cells. This technology is based on a densely packed array of transparent micron-sized wells. Each well is designed to contain an individual cell, facilitating visual observation and manipulation of the individual cells. Using this slide-based imaging technology, we have demonstrated that beta cells can be sorted into distinct subpopulations based on their individual responses to glucose stimulation. Mitochondrial membrane potential was used as an indication of beta cell function and was correlated to distinct non-responding, weak responding, and strong responding sub-populations. This methodology facilitates the characterization of the different metabolic phenotypes of beta cell populations and potentially establishes predictive parameters for beta cell function and susceptibility to glucolipotoxicity.
X-ray Tomography: New Tool for Imaging Whole, Hydrated Cells

W. Gu, M. A. Le Gros, L. D. Ekin, C. A. Larabell; Department of Anatomy, University of California, San Francisco, CA, 2Physical Biosciences Division, Lawrence Berkeley National Lab, Berkeley, CA, 3Department of Molecular and Cell Biology, University of California, Berkeley, CA, 4Department of Anatomy, University of California, San Francisco, CA.

X-ray microscopy is a new imaging technique that bridges the gap between light and electron microscopy. Whole, hydrated cells are examined using photons with energies in the so-called 'water window,' where organic material absorbs approximately ten times more than water. This generates high contrast images of cellular structures in their native state, without the need for contrast enhancement reagents. Immunolocalizations are conducted in hydrated cells using metal, rather than fluorescent, probes. Unlike fluorescence microscopy, however, information about the location of the protein is superimposed upon the cellular structures. Using tomographic techniques it is possible to acquire 3D images of whole cells and, since we use the x-ray absorption coefficient, the information obtained is quantitative. We report here the use of soft X-ray tomography to examine cell division in the fission yeast, Schizosaccharomyces pombe. The cells were rapidly frozen and maintained at cryogenic temperature during imaging. No fixatives or contrast enhancement reagents were used, so the cell structures observed in these images closely approximate the natural state. During S. pombe mitosis, F-actin reorganizes at the cell equator to form a contractile actomyosin ring. X-ray tomography reveals the filaments that form the actomyosin ring using the natural contrast mechanism, revealing structural differences between the early and late stages of cell division. The unlabeled actomyosin ring-like structure forms a circumferential ring just beneath the cell membrane in early cell division, and forms a solid planar sheet bisecting the two cells at the culmination of cell division. Using X-ray tomography, we can now localize the macromolecules involved in cell division to the division plane throughout the cell cycle.

Development of a 'Trap and FRAP' Microscopy System for Cell Migration Studies

W. D. Shin, S. Ross; C. M. Waterman-Storey; Cell Biology, The Scripps Research Institute, La Jolla, CA, 2Nikon Instruments Inc., Melville, NY

Cell migration is dependent on forces generated by the actin cytoskeleton to the extracellular environment through focal adhesions. We are interested in understanding how the pulling force on focal adhesions between the extracellular environment and the actin cytoskeleton is regulated by how tightly the molecules make up the focal adhesions bind to one another. In order to address this question, we have developed a microscopy system that allows simultaneous measurement of the forces exerted by the actin cytoskeleton and focal adhesions on an extracellular structure and at the same time allows measurement of the tightness of binding of focal adhesion molecules to one another. The microscope system combines optical gradient trapping and Fluorescence Recovery After Photobleaching (FRAP) capabilities using a Nikon TE2000-E2 motorized inverted microscope. A 1 W 1064 Nd:YAG laser provides the optical gradient trapping force, while FRAPing is accomplished with a 65 mW Ar laser and/or a 10 mW 561 nm solid state laser. Laser light, which is focused to a diffraction limit spot at the specimen plane, is used to move and position objects with precision. FRAPing is accomplished with a 65 mW Ar laser and/or a 10 mW 561 nm solid state laser. Time-resolved microscopy is the ultimate tool for investigating dynamic events in cells and sub-cellular structures. Its applications previously have been limited to wavelengths longer than 370 nm because microscope optics does not transmit in the deep UV. We have introduces a filter-based confocal system (the DynaMic™) to measure fluorescence lifetime and intensity directly under the microscope in the deep UV and visible wavelength range of 240-850 nm. The system features TCSPC single photom sensitivity and fast acquisition for any fluorescence lifetimes of 100ps-100 ns. An Oxford BX51 microscope was modified to transmit light for both excitation and emission down to 240nm in the deep UV. To maintain maximum light throughput, both the excitation light source and the detector are directly coupled to the microscope. A pinhole turret is placed in the emission light path with variable pinholes sizes from 0.1 up to 10mm for different spatial resolutions. With a laser diode as excitation light source, confocal measurements can be achieved with this system. This system can also be used for mapping of fluorescence lifetimes and intensity with variable spatial resolution (<1μm) with an automated stage. The paper will present fluorescence lifetime measurement from a single protein crystal with diameter of ~70 μm, and lifetime mapping obtained from stained mouse kidney section. The potential application for detection of single protein molecules without fluorescence label will be discussed.

**Structured Illumination Microscopy on Meiotic Chromosomes**

P. M. Carlton, R. Wang, W. Z. Cande, J. W. Sedat; 1Department of Biochemistry and Biophysics, University of California, San Francisco, San Francisco, CA, 2Department of Molecular and Cell Biology, University of California, Berkeley, Berkeley, CA

In order to bridge the gap between the high resolution of electron microscopy and the high labeling specificity of conventional optical microscopy, we have developed a new optical microscope that utilizes structured illumination. Structured illumination uses a sine wave pattern of light to excite fluorophores, rather than a uniform field of light. The light emitted from the specimen contains high-frequency spatial information in the form of interference fringes, which can be reconstructed into an image that reveals features below the Rayleigh limit. To demonstrate the high resolution and specificity of this technique, we took advantage of the well-established dimensions of the synaptonemal complex (SC), a proteinaceous, ribbon-like structure that holds homologous chromosomes together at a distance of 200nm during prophase I of meiosis. Maize meiotic cells were immunostained for two components of the SC (AFD1, a maize Rec8 homolog; and ASY1, a Hop1 homolog) and imaged in three dimensions. While the two axial elements of the SC appear as a single fiber in conventional optical microscopy, SI microscopy reveals their dual nature and 200nm spacing, as well as their tendency to twist around each other. The exceptional quality of this 3D image data allows the full path of each of the ten maize chromosomes to be traced and analyzed. Additionally, the morphology of DNA, visualized by DAPI staining, can be directly correlated to the pairing state of each chromosome. This demonstrates that structured illumination microscopy is a powerful new tool for exploring basic cell biological questions, and should be readily adaptable toward a variety of systems.

**Fluorescence Correlation Imaging for Biophysics and Cell Biology Applications**

D. J. Needelman, T. J. Mitchison; 1Department of Molecular and Cell Biology, University of California, Berkeley, Berkeley, CA

We have developed a novel imaging technique, Fluorescence Correlation Imaging (FCI), which will allow the dynamics of soluble molecules to be studied in detail. FCI is a radical extension of Fluorescence Correlation Spectroscopy (FCS), transforming this technique from a spectroscopy, which measures dynamics at one point, to a microscopy. FCS can be used to determine binding constants and to measure diffusion in a fluid. Fluorescence Correlation Imaging offers two advantages over conventional FCS: it can be used to image molecules on substrates, and it can be used to image a single point in a sample due to movement of labeled molecules relative to a small, fixed illumination volume. However, FCS is only applied to a single point at a time, so no spatial detail is obtained. FCI performs FCS type measurements simultaneously on ~10,000 points, essentially creating an “image” of FCS measurements which provides quantitative temporal and spatial data. In addition to enabling multiple FCS measurements, which can be used to characterize heterogeneous structures like cells, entirely new information can be obtained from FCI by analyzing the correlations in the fluctuations at different points, including component resolution and large length scale, collective motions. We have used FCI to study the dynamics of colloids, globular proteins, networks of cytoskeletal filaments, and soluble molecules inside cells.

**Live Cell Imaging of Activated Human Umbilical Cord Blood Derived Cultured Mast Cells**

J. Malakal, T. Dvori, D. Kempuraj, M. Tagen, I. Biran; 1Molecular Cytomics Inc., Boston, MA, 2Tufts University School of Medicine, Boston, MA

mast cells are target effector cells in the onset of IgE-mediated allergic and inflammatory response. When the mast cells are activated they undergo regulated release of intracellular granules by exocytosis. This includes inflammatory cytokines such as IL-6, TNF-α and other cytokines and chemokines. In this study we examined mast cell activation using a microscope slide based pico-well array at a single cell resolution. The CD34 positive cells were isolated from human umbilical cord blood and cultured with Stem Cell Factor (SCF) to obtain mature mast cells. The mast cells were sensitized with human IgE for 48 hours, counted and 2.5μl of cell suspension were added to the pico-wells of the array (LCA, Molecular Cytomics, Inc. Boston, MA). The cells in the array were covered with a sliding cover slip allowing each cell to settle into an individual well. The cover slip also allowed for repeated treatment and washing of reagents via capillary flow. The cells were treated with anti-human IgE to induce activation and were labeled with anti-CD63 PE, a fluorescently tagged marker of mast cell activation. During the entire washing and labeling procedure the cells remained in their individual wells. Time-lapse and single time-point live cell imaging showed activated mast cells and varying degree of activation as indicated by levels of fluorescence. Following activation, the cells fluoresced nonspecifically under various wavelength filters; however, when tagged with anti-CD63 PE, only activated mast cells exhibited fluorescence. Among the activated mast cells, significant heterogeneity was observed and only less than 50 percent of the cells exhibited activation. The ability to culture, treat and image non-adherent mast cells in the pico-well array allowed us to study single cell response in a mast cell population.

**High Efficiency Peptide and Antibody Delivery for Cell Functional Study Using Flow Cytometric Analysis**

N. Quan, J. Wu, S. Huang, J. Li, G. McMasters, F. Witney, F. Heitz; 1Molecular Detection, Panomics, Fremont, CA, 2Molecular Biophysics and Therapeutics, CRBM-CNRS, Montpellier, France, 3CRBM-CNRS, Montpellier, France, 4Cellular Analysis Business, Beckman Coulter, Inc., Fullerton, CA

Cell deliveries of peptides and proteins are critical to the study of cellular function of proteins. However, conventional lipid-based or electroporation technologies are not always capable of efficiently delivering these macromolecules into many cell types such as Jurkat and K562. Here we demonstrate that the viral derived amphiphatic delivery peptide “MPG” efficiently imports both peptides and proteins into cells. MPG that consists of hydrophobic and hydrophilic domains interacts non-covalently with its cargo forming nano size particles capable of passive diffusion through the cell plasma membrane and avoiding the endosomal pathway. Peptides and proteins were labeled with FITC or TAMRA and delivered to cells using MPG. Delivery efficiencies were determined using the CellLab Quanta SA flow cytometer. Viability of transfected and non-transfected cells was quantified by both staining with propidium iodide (PI) or 7-amino-actinomycin D and determining the electronic volume and side scattering of the cells. We delivered peptide inhibitors to Cdk2 and G-protein βγ, subunit with MPG and carried out cell functional studies. The effect of the Cdk2 peptide inhibitor on cell cycle was analyzed by staining the cells with Hoechst 33342 and PI and determining Cyclin A2 expression using an anti-cyclin A2 antibody conjugated to FITC. Inhibition of the G-protein βγ resulted in activation of Erk1/2 as measured by phospho-specific antibodies. We conclude that the combination of MPG delivery and flow cytometry analysis provides a powerful tool to study cell function of proteins. Note: For research use only. Not for use in diagnostic procedures.

**Three-dimensional Visualization of Cell and Tissue Architecture Using Dual Beam Electron Microscopy**

J. Heymann, S. Subramaniam; Laboratory of Cell Biology, National Cancer Institute, NIH, Bethesda, MD

Current approaches to 3D imaging at subcellular resolution using confocal microscopy and electron tomography, while powerful, are limited to relatively thin and transparent specimens. We have recently reported on the use of a new generation of dual beam electron microscopes capable of site-specific imaging of the interior of cellular and tissue specimens at spatial resolutions about an order of magnitude better than those currently achieved with optical microscopy [1]. The principle of imaging is based on using a focused ion beam to create a cut at a designated site in the specimen, followed by viewing the newly generated surface with a scanning electron beam. Iteration of these two steps several times results in the generation of a series of surfaces maps of the specimen at regularly spaced intervals, which can be converted into a three-dimensional map of the specimen. We demonstrate here that this strategy can be successfully used for site-specific 3D imaging of entire individual cells or of one or more tissues within a tissue. We show that such images can be obtained at resolutions adequate to detect molecular machines such as the nuclear pore and ribosomes. Imaging of melanocytes and melanoma cell lines in 3D reveal the distribution of melanosomes and other organelles providing a new base to investigate localization and organization of cellular components in diseased and healthy cells or tissues. Such information might provide unprecedented opportunities for understanding the structural mechanisms underlying the onset of diseases such as malignant melanoma especially when combined with molecular labeling techniques. [1] Heymann JA, Hayles M, Gestmann I, Giannuzzi LA, Lich B, Subramaniam S., J. Struct. Biol. 155: 63-73, 2006. Site-specific 3D imaging of cells and tissues with a dual beam microscope.
Thin Sectioning Improves Visualization Quality in Imaging Mass Spectrometry

Y. Sugura, 1 S. Simma, 2 M. Setou 3 1Department of Bioscience and Biotechnology, Tokyo Institute of Technology, Tokyo, Machida, Japan, 2Okazaki Institute for Integrative Biosciences, National Institutes of Natural Sciences, Okazaki, Aichi, Japan, 3The Graduate University for Advanced Studies, School of Life Science, Okazaki, Aichi, Japan

The direct molecular imaging of biological tissue using mass spectrometry (MS) is the new technique to image distribution of biomolecules, such as proteins, peptides, and lipids in the tissue section. This method has already been shown to provide useful biological information for biological applications, pathological applications and drug discovery. To carry out successful profiling and mapping of biomolecules, though, techniques for correct sample preparation are required. Here we focus on the influences of tissue thickness on mass spectra. We obtained the mass spectra and imaging results of proteins as a function of thickness from 2 to 40 µm, then evaluated the spectrum quality. The peak intensity and number of observed peaks drastically increased as the sections became thinner (< 10 µm). Significant images of high molecular weight proteins were acquired only from the thinner slices. We thus concluded that the thickness of biological tissue slices was an important factor in obtaining high quality mass spectra. There could be two reasons for inefficient analyte ionization of thicker slices: electrical nonconductive properties and impurities in thick tissue sections. Furthermore, we applied this technique to the direct analysis of lipid species. Improved ionization efficiency permitted not only MS but also MS/MS of neutral lipid and phospholipid species. Enriched neutral lipid and phospholipid species were used to obtain high-quality MS imaging results and structural information of these molecules. In conclusion, this investigation extends the capability of imaging mass spectrometry by optimizing the thickness of the tissue samples.

Modification and Conjugation of Proteins, Peptides, Oligonucleotides, and Carbohydrates to Cell Surfaces

D. Schwartz; Solulink Biosciences, San Diego, CA

Methods to transport small molecule drugs, especially antiviral and anti-cancer drugs, antibodies, siRNA and other polynucleotides across cell membranes is an area of intense research. TAT-like cationic peptides have been shown to be able to mediate transport of both proteins and oligonucleotides across membranes. As is well recognized with lipid-based plasmid transfection reagents transfection efficiency can be reagent dependent. Solulink has engineered a series of chemically activated cationic peptides containing cleavable disulfide bonds for release of the payload in the endosome or cytoplasm. These peptides are readily conjugated to any protein or oligonucleotide of interest. A series of linkable cationic peptides will be used to compare transfection efficiency across various cell lines using both antibodies and labeled siRNA.

A Transgenic Mouse System with Bioluminescent and Color-Switching Dual Fluorescent Cell Tracers

L. Zheng, C. Njauw, M. Martins-Green; Cell Biology and Neurosciences, University of California, Riverside, CA

Interleukin-8 (IL-8) is a prototype chemokine that plays multiple roles in the wound healing process. Human IL-8 has two receptors, CXCR1 and CXCR2, which mediate its different functions. In order to establish an animal model system to decipher the functions of IL-8 in vivo, we have made a transgenic mouse model system that: (i) can express CXCR1 in specific tissues in a Cre/loxP controlled manner; (ii) incorporates bioluminescence and color-switching dual fluorescence as tracer systems that allows us to distinguish the transgene-activated tissues/cells (labeled with eGFP/luciferase) from the wild type tissue (labeled with mRFP). A transgenic mouse line with this vector carrying CXCR1 has been generated and here we show validation of various features of this transgenic system. The F1 founder line expresses mRFP whereas no CXCR1 or eGFP/luciferase activity has been detected. The offspring of F1 founder crossed with different lines of Cre mice enabled us to examine the Cre-dependent color-switching and transgene expression in the designated tissues. In the tissues/cells in which the transgene CXCR1 expression has been activated by Cre, the original mRFP gene is genetically deleted and the protein lost within 8 days and these cells have been relabeled with another multifunctional marker which is a membrane-localizing eGFP/luciferase fusion protein. The mRFP/eGFP conversion has been examined in most of the tissues of the transgenic mice. The luciferase activity is also being examined to turn on along with the transgene expression and colorswitching. This transgenic model system is a versatile and flexible system that allows temporal and spatial control of the transgene expression. It also allows using different imaging techniques to localize, quantify and even manipulate the cells of interest in vivo.

Image Informatic Tools for Multidimensional Light Microscopy

C. T. Rueden, M. Linkert, F. Wong, C. Peterson, P. Huettl, M. Hvalenka, E. Hathaway, K. W. Eliceiri; Molecular Biology, University of Wisconsin-Madison, Madison, WI

With the increasing use of digital image capture microscopy in the biomedical sciences, it has become a major challenge to locate, view and interpret large numbers of images collected in a diversity of formats. Many biological research laboratories have a pressing need to archive and annotate vast numbers of images collected by video, laser-scanning microscopy and other photonic-based imaging techniques. Multidimensional images, such as four-dimensional images from multi-focal plane time-lapse recordings, or images from spectral and lifetime microscopy, make the challenge even greater. Without careful organization, important research data can be difficult or impossible to find, much less visualize and analyze effectively. We are developing a complete, open system for handling biomedical images, including image acquisition, data storage, metadata (experimental data associated with an image), visualization, analysis, annotation, and database interconnectivity. The software makes extensive use of several established open source systems for handling images: the Open Microscopy Environment (OME; image database), VisAD (image visualization), and ImageJ (image processing). We have also developed an open file format called OME-TIFF: fully compatible multi-page TIFF with rich metadata embedded in OME-XML format, the OME standard. Other major components of the software include: Bio-Formats, a Java library for reading and writing dozens of common microscopy file formats, including processing and conversion of metadata into OME/TIFF format; VisBio, a biological visualization tool for facilitating visualization and analysis of complex multidimensional image data; an OME plugin for ImageJ for transferring images between ImageJ and an OME database; and a multidimensional Data Browser plugin for ImageJ to enable more effective visualization of 3D image data within ImageJ. We are working to integrate these packages into a cohesive whole to provide microscopists with a complete toolkit for overcoming the challenges of working with digital multidimensional images.

Automated Image Analysis of Protein Translocations and DNA Content for Cell- and Tissue-based High Content Screening Assays

N. L. Prigoshina, L. Zheng, E. A. Hunter, J. Mikie, D. R. Roop, M. A. Mancin, D. A. Zacharias, J. T. Price, P. M. McDonough; 1The Burnham Institute, La Jolla, CA, 2Baylor College of Medicine, Houston, TX, 3Hunter Miki & Callaway, San Diego, CA, 4The Whitney Laboratory for Marine Bioscience, St. Augustine, FL, 5Vala Sciences, La Jolla, CA

High throughput (HT) image cytometers analyze individual cells in digital photomicrographs by first assigning pixels within each image to plasma membrane (PM), cytoplasm, nucleus or other regions. In this study, we tested a novel algorithm that identifies PM regions to measure changes in PM-associated proteins (protein kinase C alpha, N-cadherin, E-cadherin, VE-cadherin, and pan-cadherin) that regulate cell division, migration, and adhesion. Validation assays were performed for these proteins on cells cultured in 96-well plates and also for tissue sections obtained from transgenic and chemical carcinogenic models of skin cancer. The algorithm successfully quantified phospho-PM (PMA) induced PM localization of protein kinase C (PKCalpha) in HeLa cells (Z′ of 0.88). Additionally, PMA activated translocation to the PM of N-cadherin (in HeLa cells), E-cadherin (in A431 cells), and VE-cadherin (in human dermal microvascular endothelial cells (HDMECs)), suggesting a relationship between PKCα activity and cadherin localization. For VE-cadherin, a Z′ of 0.52 was observed between serum-free media, which increased VE-cadherin, and EGFα, which diminished VE-cadherin at the PM. For sections obtained from the transgenic skin cancer model, analysis of images with the PM algorithm revealed that tumor cells exhibited cadherin expression that was just 34% of that expressed by surrounding normal tissue; furthermore, tumor cells expressed elevated DNA content, consistent with development of aneuploidy. In contrast, increased DNA content did not occur for tumor cells produced by chemical carcinogenesis. The results demonstrate that this new algorithm for PM image cytometry enables analyses in a variety of applications in both cultured cells and tissue sections.

Manual Tracking: A Semi-Automated Tool to Keep a Track of Movements in 2 and 3D

F. P. Cordelières; Plateforme d’Imagerie Cellulaire et Tissulaire, Institut Curie - Centre de recherche/CNRS UMR 146, Orsay, France

Over the past 5 years, development of 2D and 3D video-microscopes has made it possible to record the dynamic behavior of objects within the full volume of samples. While the acquisition techniques are now widely available, as part of imaging workflows, a new pole of interest has emerged, aiming to get dynamics’ quantization out of the images. Two main approaches may be used to characterize object’s motion: 1- fully automated approaches based on isolation and recognition of structures over time series; 2- manual identification and tracking. The first kind

VisBio, a biological visualization tool for facilitating visualization and analysis of complex multidimensional image data; an OME plugin for ImageJ for transferring images between ImageJ and an OME database; and a multidimensional Data Browser plugin for ImageJ to enable more effective visualization of 3D image data within ImageJ. We are working to integrate these packages into a cohesive whole to provide microscopists with a complete toolkit for overcoming the challenges of working with digital multidimensional images.
of methods requires a good segmentation of the objects, which may be tricky in highly noisy corrupted situations. The second approach is more widely applicable, while being somewhat slower as it requires user’s input. We here introduce the “Manual Tracking” plugin to the ImageJ software as a new tool to keep a track of objects’ motion in 2 and 3D. It offers a way to record the coordinates of objects on two-dimensional time series’ images, together with their velocity and intensity. “Manual Tracking” may also be used to generate graphical representation of tracks as overlays to the original images or synthetic views. In the particular case of tracking recovered from 2D+time projections of 3D time series, “Manual Tracking” proposes a semi-automated retrieval of the third coordinate (z coordinate). Parameters such as velocity and volumetric intensity are calculated on a sub-volume which boundaries are user defined. Finally, “Manual Tracking” offers a 3D representation of tracks and object movements as VRML files which may be opened with freely available plugins to web browsers.

2615 Co-localisation Studies in Cell Biology: Specificity and Limits Highlighted by JACOp
F. P. Cordélies,1 S. Bolté,2 Plateforme d’Imagerie Cellulaire et Tissulaire, Institut Curie - Centre de recherche/CNRS UMR 146, Orsay, France, 2Plateforme d’Imagerie et de Biologie Cellulaire, IFR 87-CNRS, Gif-sur-Yvette, France

In optical microscopy applied to cell biology, it is commonly admitted that co-localisation is achieved when two proteins are found at the same location, provided that they are seen on overlapping pixels, using the most appropriate sampling rate and magnification for image acquisition. However, two observers might not draw the same conclusions from this coincidental event. Cell biologist would conclude that two proteins co-localise while physicist would rather say that under current conditions, it can not be excluded that the two proteins are at the same location! These simplistic interpretations are already a first step of controversy. The situation is even more complicated when the localisation pattern of two proteins is mixed (partial co-localisation). The use of appropriate coefficients and/or representation methods is therefore crucial to estimate more accurately the co-localisation event. A plethora of methods exists and is used despite the absence of appropriate guidelines on how and when to use these methods. As a consequence, the most well known co-localisation indexes (such as correlation coefficients) are most frequently used beyond their domain of application and quite often resulting in mis-interpretation, over- or underestimation of the cellular reality. We provide an overview of the three levels of co-localisation evaluation: 1-visualisation, 2-quantification by considering the image as a collection of “intensities”, 3-quantification by considering the image as a collection of “objects”. For each level, we provide insights into the methods that might be employed, the coefficients that might be calculated, their limits and the conclusions that might be drawn. We furthermore introduce a new tool encompassing all reviewed methods in a single toolbox, named JACOp (Just Another Colocalisation Plugin, http://rsb.info.nih.gov/ij/plugins/track/jacop.html) as plug-in to the public domain ImageJ software (Rasband, W.S., 1997-2006).

2616 Rab6 Acts Upstream of ZW10 and COG in the Maintenance of Golgi Apparatus Structure in HeLa Cells
Y. Sun, A. Shestakova, V. Lupashin, B. Storrie; Physiology and Biophysics, University of Arkansas for Medical Sciences, Little Rock, AR

The maintenance of Golgi apparatus structure is a balance between proteins involved in anterograde and retrograde trafficking. We have taken an epistatic approach to order the role of Rab6 relative to ZW10 or COG (Conserved Oligomeric Golgi), all proteins implicated in Golgi trafficking and organization. Depletion of ZW10 resulted in inhibition of Golgi enzyme recycling to the endoplasmic reticulum (ER) during a 5 h ER-exit block. siRNA transfection to silence ZW10 or COG results in disruption of Golgi organization. With ZW10 silencing, we found that the Golgi apparatus was broken down into a perinuclear cluster of small fragments while with COG silencing scattered vesicles were observed in addition to larger Golgi fragments in agreement with previous results. In contrast, silencing of Rab6 using an siRNA directed against a sequence common to both Rab6a and Rab6b resulted in, if anything, a more continuous juxtanuclear Golgi apparatus as revealed by the distribution of Golgi glycosyltransferases. Co-depletion of Rab6 selectively inhibited the disruptive effects of both ZW10 and COG inactivation on Golgi organization. The effects of Rab6 loss-of-function were specific with no cross-talk observed between either Rab6 and endosomal Rab5 or Rab7 and the p115 Golgi-associated anterograde tether. ZW10 depletion induced disruption of Golgi structure was also inhibited when the dominant negative protein, GDP-Rab6a, was overexpressed. Overexpression of the C-terminal fragment of Binacudal D, a protein that bridges between Rab6 and dynamin, inhibited ZW10 depletion induced disruption of Golgi organization suggesting that the upstream effect of Rab6 is likely mediated by a dynin motor as effector. We conclude that Rab6 acts upstream of ZW10 and COG in the maintenance of Golgi apparatus organization. Supported by grants from the NSF (MCB-0549001 to B.S. and MCB-0234822 to V.L.).

2617 Role of Rab33b in the Cycling of Proteins through the Golgi Apparatus
T. Starr,1 Y. Sun, K. Forest-Williams,2 B. Storrie,3 Physiology and Biophysics, University of Arkansas for Medical Sciences, Little Rock, AR, 2Chemical Engineering, Virginia Tech, Blacksburg, VA

We tested the role of a medially located Golgi apparatus Rab GTPase Rab33b, in the cycling of proteins through the Golgi apparatus. We examined the transport of three proteins: GPP130 (a cis Golgi protein that cycles to endosomes), Shiga-like toxin B subunit (SLTB, the targeting subunit of Shiga toxin that moves from endosomes to the Golgi and then ER), and GaNAcT2-GFP (a stably expressed Golgi glycosyltransferase chimeric protein that cycles to the ER). In the case of GPP130, the protein was accumulated in endosomes by treatment of HeLa cells with monensin and then transported to the Golgi initiated by drug washout. SLTB fed to HeLa cells was also accumulated in endosomes by a 19.5°C temperature block and then entered the Golgi via temperature shift. Upon shift to permissive conditions, GPP130 resumed a steady-state-like cis Golgi distribution with a half-time of 30 min. By confocal microscopy, cis and trans Golgi markers could be resolved and the Rab6-positive trans-Golgi apparatus appeared to be an intermediate step in GPP130 re-equilibration to the cis Golgi apparatus. For GalNAcT2, RNAi silencing of Rab33b, as indicated by a pronounced reduction in protein levels by immunoblotting, appeared to inhibit GTP-Rab6a induced redistribution of GaNAcT2-GFP. Further experiments are in progress to test in a detailed manner if Rab33b and the medial Golgi apparatus act as intermediaries in Golgi protein cycling from the trans to cis Golgi. Initiated with support from NIH grant GM65233 and continued with support from NSF grant MCB 05.

2618 TRAPP-specific Subunits Are Required for the Specificity Switch of a Ypt/Rab Nucleotide Exchanger
N. Morozova,1 Y. Liang,2 A. A. Tokarev,2 S. H. Chen,3 V. Secora,2 S. Ernö; N. Seges1; 1Biological Sciences, University of Illinois, Chicago, IL, 2Cellular and Molecular Medicine, University of California at San Diego, San Diego, CA

Intracellular trafficking in eukaryotes is regulated by GTPase Rab and Rab GTAPases. These GTAPases are activated by guanine-nucleotide exchange factors (GEFs). When in the GTP-bound state, Ypt/Rabs interact with effectors that mediate individual steps of the protein trafficking pathways. An attractive possibility is that Ypt/Rabs and their accessory factors not only regulate the separate steps of protein transport pathways, but also coordinate these separate steps. Here, we propose a novel mechanism for such coordination in the Golgi. The modular multi-protein Golgi-associated complex, TRAPP, acts as a GEF for Ypt1 and Ypt31/32, the GTAPases that regulate entry into and exit from the yeast Golgi, respectively. TRAPP comes in two configurations: the seven-subunit TRAPP is required for ER-to-Golgi transport, whereas the ten-subunit TRAPP functions in late Golgi. The two essential TRAPP-specific subunits, Tns130 and Tns120, are conserved from yeast to man, and are candidates for several human disorders. We show that Tns120/130 determine the specificity of the dual-GEF complex; they are required for switching the GEF activity of TRAPP from a Ypt1-GEF to a Ypt31/32-GEF. Moreover, a tns120/130 mutation confers opposite effects on the intra-cellular localization of Ypt1 and Ypt31/32. We propose that TRAPP acts as a Ypt1 GEF in early Golgi, whereas in late Golgi the Tns120/130 sub-complex is required for switching this activity off, and turning the Ypt31/32 GEF activity on. Such a switchable dual-specificity GEF would ensure activation of Golgi Ypts at the correct cisterna, thereby coordinating entry into and exit from the Golgi apparatus.

2619 The GARP (Vps52-Vps3-Vps4) Complex Is Essential for Transport from Endosomes to the TGN in Mammalian Cells
F. P. Perez-Victoria, J. S. Bonifacino; Cell Biology and Metabolism Branch, NICHD, National Institutes of Health, Bethesda, MD

Tethering factors are required in every major transport step within the secretory, endocytic and lysosomal trafficking pathways. A multi-protein complex known as GARP associated retrograde protein (GARP; also known as VFT) has been shown to function as a tethering factor for transport from endosomes to the late Golgi in yeast. A similar complex consisting of at least three subunits, Vps52, Vps53 and Vps54, exists in mammalian cells. GARP is an effector of the Rab6 GTAPase, and co-immunoprecipitation studies have shown that it also interacts with the t-SNARE, syntaxin 10. We have studied the function of this complex by examining the trafficking phenotypes of cells depleted of GARP complex subunits using siRNA oligonucleotides. We find that depletion of GARP subunits from the TGN to the periphery GARP mRNA and GARP protein is reduced. In contrast to their transport to the TGN in control cells. The steady-state levels of mature cathepsin D are decreased by more than 10-fold in GARP-depleted cells, most likely due to the inability
of the CI-MPR to return to the TGN. Likely as a consequence, lysosomes are swollen and not fully functional, as assessed by a delay in the degradation of EGF-R. These observations indicate that the GARP complex is involved in retrograde transport from endosomes to the TGN.

The TGN Accessory Protein p56 is Necessary for Vesicular Transport to the Endosomal-Lysosomal System

G. Mardones, P. Burgos, J. Bonifacino; NICHD, Cell Biology and Metabolism Branch, Bethesda, MD

The paradigm of TGN-endosome trafficking is the mannose 6-phosphate (M6P) receptor system. In the TGN two M6P receptors bind M6P-containing soluble acid hydrolases (such as cathepsin D), and transport them to endosomes. This process involves binding of the hydrolases to the receptor, packaging of the ligand-receptor complexes into vesicular carriers, transport to endosomes and recycling of the receptors back to the TGN. The formation of these vesicular carriers starts with the association of cytosolic adapter proteins that link the cytosolic tail of M6P receptors to clathrin coats. Clathrin adapters functioning at the TGN are the heterotetrameric AP-1, and the monomeric GGA proteins (GGAs-1-3), all of which have been implicated in M6P receptor trafficking. A number of accessory proteins interact with these adapters, but little is known about their functions. One of these accessory proteins is p56, which was identified through its ability to interact in vitro with the γ-adaptin subunit of AP-1 and the GGAs. To get insight on p56 function, we performed a combination of microscopic imaging and RNA interference (RNAi) experiments. Using fluorescence microscopy we observed that p56 is recruited to TGN membranes by GGAs overexpression, suggesting that p56 interacts with GGAs in vivo, an observation confirmed by Fluorescence Resonance Energy Transfer. RNAi of GGA-3, but not of γ-adaptin, resulted in reduced levels and decreased TGN association of p56. RNAi of p56 restricted the movement of GGA1-containing vesicles and the processing of cathepsin D. Our results indicate that p56 is necessary for normal vesicular transport from the TGN to the endosomal-lysosomal system.

Comprehensive Protein Analysis of Naked2-associated Exocytic Vesicles by LC/MS-MS

Z. Cao, C. Li, R. Graves-DeAl, J. Franklin, J. Higginbotham, A. Ham, R. Coffey; Gastroentontology, Vanderbilt University, Nashville, TN, Pediatric Infectious Diseases, Vanderbilt University, Nashville, TN, The Proteomics Core of the Mass Spectrometry Research Center, Vanderbilt University, Nashville, TN

Polarized epithelial cells have developed specialized mechanisms for targeting transGolgi network (TGN)-derived vesicles to the apical or basolateral membrane. We have reported that Naked2, but not Naked1, interacts with Golgi-processed form of TGFβ and escorts TGFβ-containing exocytic vesicles from the TGN to the basolateral surface of polarized MDCK cells, where the vesicles dock and fuse in a Naked2 myristoylation-dependent manner. In myristoylation-deficient (G2A) Naked2-expressing MDCK cells, Naked2-associated TGFβ-containing vesicles are trapped in the cytoplasm and TGFβ is unable to reach the plasma membrane. To determine the protein compositions of these Naked2-associated vesicles, we performed a biochemical enrichment followed by flow cytometric purification. Using a 10-40% iodixanol gradient centrifugation, we first isolated G2A Naked2-EGFP-containing vesicle fractions de-enriched in plasma membrane markers as measured by western blotting for Naked2 and markers of subcellular compartments. This pool of vesicles was then subjected to dual flow sorting using GFP and DiD enrichment followed by flow cytometric purification. Using a 10-40% iodixanol gradient centrifugation, we first isolated G2A Naked2-EGFP-containing vesicle fractions de-enriched in plasma membrane markers as measured by western blotting for Naked2 and markers of subcellular compartments. This pool of vesicles was then subjected to dual flow sorting using GFP and DiD enrichment followed by flow cytometric purification.

Regulation of Beta-1AR Delivery to the Cell Surface by Golgin-160

D. M. Zuckerman, D. Sagaram, C. E. Machamer; Cell Biology, Johns Hopkins University School of Medicine, Baltimore, MD

Golgins are a family of peripherally associated Golgi residents that have been implicated in vesicle tethering and maintenance of Golgi structure. Golgin-160 is a cis- and medial-Golgi resident involved in transducing certain apoptotic signals. Unlike several golgins, knockdown of golgin-160 by RNAi did not lead to an overall trafficking phenotype, nor a change in Golgi morphology. However, the trafficking of specific cargos, for example, beta-1-adrenergic receptor (beta-1AR), was perturbed. Beta-1AR is a seven transmembrane G-protein coupled receptor, and stimulation by epinephrine or norepinephrine leads to activation of adenylyl cyclase and increased cAMP production. We previously found that overexpression of golgin-160 lead to an increase of surface levels of beta-1AR, and knockdown of golgin-160 by RNAi lead to a decrease, though total beta-1AR levels remained consistent. We reason that since golgin-160 is not on the trans-Golgi, it likely is involved in a step prior to Golgi exit. While much research has focused on signaling and post-signaling events related to adrenergic receptors, very little is known about the mechanisms of surface delivery, including post-translational modifications. To characterize the contribution of golgin-160 to beta-1AR biogenesis, we are analyzing the trafficking of GFP-tagged beta-1AR in live cells in the presence or absence of golgin-160. To investigate the interaction of beta-1AR and golgin-160, we are performing in vitro binding experiments. A small region of the soluble N-terminal head domain of golgin-160 binds to beta-1AR, and mapping the region of beta-1AR recognized by golgin-160 is in progress. We are also examining post-translational modifications of beta-1AR, including dimerization and palmitoylation, addressing where in the secretory pathway these modifications take place, and the role of golgin-160. These studies will expand our understanding of golgins beyond vesicle tethers and Golgi structural proteins, and give insight into the biogenesis of beta-1AR, including the modifications early in the secretory pathway.

Study of the Suborganellar Organization of the Golgi Apparatus by Using a Novel In Vivo Biotinylation Approach for Purification Coupled with the Selection of Recombinant Antibodies

O. Vielmeoyer, S. Motel, B. Goud, F. Perez; Cnr/c im144, Institut Curie Research Section, Paris, France

In mammalian cells the Golgi apparatus maintains a distinct ribbon-like structure throughout interphase despite a large bidirectional flux of membranes and cargo. To maintain this distinct architecture it contains several structural and regulatory proteins. We are particularly interested in golgins and Golgi associated Rab proteins. The former are stably associated with membranes and function as structural elements/vesicle tethers while the latter bind to target membranes in a highly regulated manner via nucleotide exchange. Traditionally, rat livers have been used for purification of Golgi stacks and only immunopurification would lead to separation of suborganellar fractions. Animal tissues, however, are not easily amenable to drug/siRNA treatment prior to purification. In order to better understand how golgins and Golgi associated Rab-proteins organize Golgi subdomains, we have developed a new approach, which allows for rapid purification of suborganellar fractions from cultured cells. Golgins of interest, fused with a biotinylation tag, are overexpressed and efficiently and specifically biotinylated inside mammalian cells. Stable clones expressing such in vivo biotinylated proteins are used as starting material for rapid streptavidin-based affinity purification. After washing on a magnet, such enriched and purified fractions are specifically eluted using an integral TEV recognition site. In this fashion GI130, Rab6A, Rab8A and Rab1A positive suborganellar membrane fractions are characterized by comparative mass spectrometry analysis and Western blotting. In addition, novel Rab effectors are being sought after addition of detergent. Lastly, purified protein complexes are used as starting material for in vitro extension of highly specific recombinant antibodies using the phage display technology. In summary, purification of subcellular fractions after in vivo biotinylation of target proteins is a powerful novel approach to study the suborganellar organization of the Golgi apparatus. This approach can easily be adopted for any organelle of interest and can be coupled with gene silencing techniques.

Novel Regulation of Golgi Complex Structure and Function by a Transmembrane Lysophosphatidic Acid Acyltransferase

J. A. Schmidt, W. J. Brown; Molecular Biology and Genetics, Cornell University, Ithaca, NY

Phospholipase (PLaG) and lysophospholipid acyltransferase (LPAT) activities appear to have antagonistic roles in the formation of Golgi membrane tubules and retrograde trafficking to the Endoplasmic Reticulum (ER) Golgi terminal. A Golgi tube formation is promoted by PLaG activity and inhibited by LPAT activity. These enzymes may alter the shape of membrane bilayers to regulate the formation of trafficking intermediates. The human genome encodes six transmembrane (TM) PLaGs, however, the function of only one is known. Here we report the identification of a specific TM LPAT (LPATγ) that regulates Golgi membrane tubule formation. When transfected into HeLa cells, LPATγ-GFP was localized primarily to the Golgi complex and also to ER membranes. Interestingly, over-expression of LPATγ significantly inhibited the rapid formation of Golgi membrane tubules that are induced by brefeldin A (BFA). Additionally, retrograde trafficking of Golgi membranes to the ER in BFA-treated cells was significantly slower. This phenotype was also observed when tubules were induced by CI-976, an LPAT inhibitor. LPATγ with mutations in the catalytic region did not show this phenotype. Cells with knocked-down expression of LPATγ that are hyper-sensitive to BFA. We also show that Golgi membranes from LPATγ over-expressing cells have elevated lysophosphatidic acid acyltransferase activity. LPATγ may control Golgi membrane dynamics and trafficking either by aiding in the fission of Golgi-derived vesicles that consume membrane tubules, or by re-acylating tube-forming lysophospholipids that were generated by PLaGs. These data are the first to show a direct role for a TM LPAT in regulating Golgi membrane trafficking.
Identification of Effector Proteins That Mediate Signaling between Golgi Vesicles and the Cytoskeleton

W. Xu, M. Starmer; Department of Physiology & Biophysics, University of Iowa, Iowa City, IA

Efficient intracellular protein trafficking requires regulation of cytoskeleton-mediated motility. For example, the Golgi-localized GTP-binding protein Cdc42 coordinates Golgi vesicle assembly with the recruitment of the motor protein dynein. Cdc42 in a complex with the COPI coat protein, coatimer, regulates both actin polymerization and dynein recruitment. Cdc42 regulates actin polymerization through the WASP and the Arp2/3 complex. However, the effectors that mediate the effects of Cdc42 on microtubule motors at the Golgi complex remain undefined. Here we present evidence that the actin binding protein, mAbs, is a candidate effector for Cdc42 at the Golgi complex. Like Cdc42, mAb binding is regulated by the GTP-binding protein ARF1 and is sensitive to the presence of the putative cargo receptor p23. Interestingly these properties of mAb are conferred by the actin-binding domains. Also, we show that ARF1-dependent recruitment of dynein can be reconstituted on liposomal membranes. As we found previously with Golgi membranes, the actin-plus-end-binding toxin cytochalasin D causes an increase in ARF1-dependent dynein recruitment to liposomes. This suggests that a specific cytochalasin D-dependent mAb-bound actin pool may regulate dynein. This reconstitution system has been exploited to identify and characterize effectors that function during dynein recruitment. Finally, we provide evidence that phosphorylation is involved in regulating these effectors. Together, our data indicate that the Cdc42 complex may act through a cascade of proteins to ensure that dynein recruitment occurs with correct spatial and temporal regulation.

The Conserved Oligomeric Golgi (COG) Complex Regulates Formation of the Intra-Golgi SNARE Complex

A. Sheshakova, E. Suvorova, O. Pavlyuk, G. Khaidakova, V. Lupashin; Physiology and Biophysics, UAMS, Little Rock, AR

Vesicle tethering factors mediate the initial loose tethering of transport vesicles to their target membranes. This loose interaction is followed by the more stable docking and consequent fusion of membranes involving the SNARE molecules. We used both yeasts and mammalian cells to demonstrate that the formation of the intra-Golgi SNAREs complex is regulated by the putative vesicle tethering COG complex. In yeast, the COG complex was specifically co-immunoprecipitated (co-IP) with intra-Golgi SNAREs Sed5 (yeast homolog Syntaxin5), Gos1 and Yk6. The highest recovery of the t-SNARE Sed5 was observed with anti-Cog4 IP. Purified COG complex in vitro preferentially interacted with the pre-formed intra-Golgi SNARE complex and the SNARE domain of Sed5. In mammalian cells the COG complex was co-IP with the Golgi SNAREs Syntaxin5 and Gs28. Yeast two-hybrid assay identified the Cos4 and Cog6 as the potential direct partners of the Syntaxin 5. Immunofluorescence microscopy showed that cells depleted of the Cog7 or Cog3p accumulated uncompled form of Syntaxin5. Furthermore, in Cog3 depleted cells intra-Golg SNAREs Gs28 and Gs15 were re-localized into the non-tethered vesicles. Native IP recovered decreased amount of the intra-Golgi SNARE complexes from the Cos3 siRNA treated cells. In vivo formation of the intra-Golgi SNARE complex was determined by RET in cells co-expressing GFP-GS15 and DoRed-Syntaxin5. We concluded that the COG complex acted to promote formation and/or stabilization of the intra-Golgi SNARE complex. Supported by grants from the NSF (MCB-0234822) and Mizutani Foundation for Glycoscience.

Dysfunction of Golgi Tethers, SNAREs and SNAPs in Monocrotaline-induced Pulmonary Hypertension

S. Mukhopadhyay; 1P. B. Sehgal; 1Cell Biology and Anatomy, New York Medical College, Valhalla, NY, 2Cell Biology and Anatomy and Medicine, New York Medical College, Valhalla, NY

Monocrotaline (MCT) is widely used to produce pulmonary hypertension in experimental animals. At the pulmonary arterial endothelial cell (PAEC) level, MCT produces loss of caveolin-1 (cav-1) in plasma membrane rafts and consequent hyperactivation of promitogenic STAT3 and ERK1/2 signaling. We have investigated the initiating mechanism involved. PAEC in culture showed trapping of cav-1 in Golgi membranes as early as 6 hr after exposure to MCT pyrrole (MCTP). Phenotypic megaloctysis and a reduction in interorganelle trafficking through the Golgi was analyzed in a gene transfer-based assay of horseradish peroxidase secretion was evident within 12 hr. Cell function and immunofluorescence techniques revealed the marked trapping of cav-1, eNOS, bone morphogenetic factor type 2 receptor (BMPR2), and of Golgi tethers, SNAREs and SNAPs which regulate vesicular trafficking (GM130, p115, giantin, golgin 84, clathrin heavy chain; syntagmin-4, -6, -Vit-1a, Vit1b, Gs15, Gs28, Gs28; SNAP23 and α-β-SNAP) in the enlarged/circumnuclear Golgi organelle in megalocytic PAEC and A549 cells (a “Golgi blockade”). Live-cell imaging of caveolar and intracellular NO production was carried out using the membrane-permeant reporter DAF2-DA. While control PAEC showed both caveolar and cell-centric NO production, MCTP-treated endothelial cells showed loss of caveolar but increased cell centric NO consistent with the trapping of eNOS in perinuclear vesicular elements. Immunofluorescence studies of lung tissue from MCT-treated rats confirmed enlargement of perinuclear Golgi elements in target lung cells as early as 4 days after MCT, thus preceding the development of symptomatic PH. These data provide the novel insight that pulmonary hypertension represents a disease state involving dysfunction of Golgi tethers, SNAREs and SNAPs and, thus, reduced trafficking of diverse vaso-relevant proteins (such as cav-1, eNOS, BMPR2, Tie-2, PEMAC-1) to the vascular cell surface.

Role of a Golgin-160 Fragment in Transducing Golgi Stress Signals

S. Chandran, C. Machamer; Cell Biology, Johns Hopkins University School of Medicine, Baltimore, MD

Golgin-160 is a coiled-coil peripheral Golgi membrane protein that is cleaved early during apoptosis by caspases. Previous studies from our lab have shown that a potential cleavage product of golgin-160 by caspase-2/caspase-3 (60-311) is targeted to the nucleus when exogenously expressed, potentially suggesting a role for golgin-160 in a Golgi stress sensing pathway. We hypothesize that the nuclear translocated golgin-160(60-311) fragment directly or indirectly modulates gene expression during stress repair. To this end, we performed yeast-2-hybrid assay with HeLa cDNA library using golgin-160(60-311) as bait and identified a few candidate proteins whose functions have been implicated in cell cycle and gene regulation. Confirmation of interaction of these candidates with golgin-160(60-311), and identification of their possible role(s) in Golgi stress sensing are in progress. Our preliminary results taken together with other data from our lab suggest that the golgin-160(60-311) fragment is translocated to the nucleus in response to Golgi stress where it regulates gene expression indirectly via other nuclear proteins and transcription factors.

GCP60 Preferentially Interacts with a Caspase-generated Golgin-160 Fragment

J. L. Shioda, C. Machamer; Cell Biology, Johns Hopkins University School of Medicine, Baltimore, MD

Golgin-160, ubiquitously expressed in vertebrates, localizes to the cytoplasmic face of the Golgi complex. Golgin-160 has a large coiled-coil C-terminal domain and a non-coiled-coil N-terminal (head) domain. The head domain contains important motifs, including a nuclear localization signal, a Golgi targeting domain, and three aspartates that are recognized by caspases during apoptosis. Some of the caspase cleavage products accumulate in the nucleus when overexpressed. Expression of a non-cleavable form of golgin-160 impairs apoptosis induced by some pro-apoptotic stimuli, thus cleavage of golgin-160 appears to play a role in apoptotic signaling. To screen for interactors of the golgin-160 head, we used a yeast two-hybrid assay, and hypothesize that the nuclear translocated golgin-160(60-311) fragment directly or indirectly modulates gene expression during stress repair. To this end, we performed yeast-2-hybrid assay with HeLa cDNA library using golgin-160(60-311) as bait and identified a few candidate proteins whose functions have been implicated in cell cycle and gene regulation. Confirmation of interaction of these candidates with golgin-160(60-311), and identification of their possible role(s) in Golgi stress sensing are in progress. Our preliminary results taken together with other data from our lab suggest that the golgin-160(60-311) fragment is translocated to the nucleus in response to Golgi stress where it regulates gene expression indirectly via other nuclear proteins and transcription factors.

Disrupted Golgi Complex Reorganization during Myogenesis by GSK3-β Inhibitors Leaves VSV-G Trafficking Intact

K. J. Zaal, E. R. Reid, A. Mehta, E. Ralston; Light Imaging Section, NIH, NIAMS, Bethesda, MD

During muscle differentiation, the classic compact juxtanuclear Golgi complex is dispersed into numerous smaller stacks found around the myotube nuclei and throughout the cytoplasm. GSK3-β is central to signaling pathways involved in microtubule stabilization, which is assumed to play a role in Golgi complex reorganization. We have found that the GSK3-β inhibitors lithium chloride and organometallic compound 1-OH disrupt Golgi complex reorganization during differentiation. In treated C2C12 mouse muscle cells, unusual morphologies were observed,
Pulse-chase Experiments with Photoactivatable Proteins Reveal Stress-dependent Turnover Kinetics of Autophagosomes
D. W. Hailey, J. Lippincott-Schwartz; NICHD, National Institutes of Health, Bethesda, MD
Macroautophagy is an inducible process by which proteins and whole organelles are sequestered in vesicles and delivered to lysosomes. Autophagosomes can accumulate in cells via two mechanisms: by increased rates of formation; or by decreased rates of turnover through lysosomal fusion. To discriminate between these mechanisms we used photoactivatable proteins (PAPFs) to monitor autophagosome lifetime. We then asked whether particular stresses result in autophagosomes with distinct lifetime characteristics. LC3 is a marker for maturing autophagosomes. The protein is covalently bound to phosphatidylethanolamine in autophagosomal membranes and persists on those membranes through their fusion with lysosomes. We constructed stable cell lines that express PAPF-LC3 and characterized cellular stresses that accumulate autophagosomes in these lines. We then analyzed the lifetimes of the induced structures using targeted laser illumination to activate PAPF-LC3 and bleach PAPF-LC3 proteins not incorporated in membranes. "Highlighted" autophagosomes were then monitored with live-cell confocal microscopy. Amino acid deprivation, proteasomal inhibition, disruption of ER calcium levels, and lysosomal inhibition all dramatically increased the number of observable PAPF-LC3-labeled structures. Whereas lysosomal inhibition results in an accumulation of LC3-labeled structures that do not turn over, autophagosomes formed in response to starvation are rapidly degraded. In contrast, structure labeled under conditions of amino acid deprivation and calcium disruption have dramatically increased lifetimes. Our data suggest a model in which the autophagic pathway serves different roles under different stress conditions: under conditions of amino acid deprivation, autophagosomes rapidly turn over to recover amino acids and energy; under conditions that induce sudden accumulations of misfolded proteins (proteasomal inhibition or calcium disruption) the pathway serves to sequester deleterious proteins from the functional cellular environment.
Identification and Analysis of a Novel Atg Protein, Atg29
T. Kawamata, Y. Kamada, Y. Ohsumi; Department of Cell Biology, National Institute for Basic Biology, Okazaki, Japan

Autophagy is the primary intracellular catabolic process whereby cytoplasmic components are sequestered for bulk degradation in the vacuole/lysosome. Nutrient starvation induces a high level of autophagy to provide materials required for survival. In the yeast S. cerevisiae, 17 Atg (Autophagy-related) proteins are essential for autophagosome generation. Of these, Atg1 kinase plays a pivotal role in regulation of autophagy, but the substrate of Atg1 remains to be identified. We recently identified Atg29 as an additional protein required for autophagy. Atg29 is phosphorylated under starvation conditions and this phosphorylation does not occur in atg1-delta cells. In vitro kinase assays demonstrate that Atg1 directly phosphorylates Atg29, indicating that Atg29 is a physiological substrate for Atg1 kinase. In atg29-delta cells, induction of autophagy was delayed, and the autophagic activity was severely impaired. We also found that in atg29-delta cells, the Cvt (Cytoplasm to vacuole transport) pathway, which shares mechanistic components with autophagy, proceeds normally. Thus, Atg29 is specifically required for autophagy. Atg29 localizes to the PAS, similar to most of the Atg proteins involved in the Cvt and autophagy pathways. We hypothesize that Atg29 might function as a molecular trigger situated downstream of Atg1 kinase to initiate switching from the Cvt pathway to autophagy. We will also discuss about interactions of Atg29 with known Atg proteins and its role on autophagosome formation.

Dynamic Organization of LAMP-2A, the Receptor for Chaperone Mediated Autophagy at the Lysosomal Membrane
U. Bandopadhayay, A. Cuervo, Anatomy & Structural Biology, Albert Einstein College of Medicine, Bronx, NY

Chaperone-mediated autophagy (CMA) is responsible for the degradation of selective cytosolic proteins inside the lysosomes. This type of autophagy is maximally activated in conditions such as nutrient deprivation or mild-oxidative stress. CMA substrates bind to a constitutive cytosolic chaperone (hsc70), which directs them to the lysosomal membrane. There the chaperone/substrate complex binds to the lysosomal membrane protein type 2-A, LAMP-2A, a receptor for the substrates of this pathway. Substrates are then translocated through the lysosomal membrane into the lumen, assisted by a resident lysosomal chaperone. Binding of substrates to the receptor is limiting for this pathway, but the relationship of the receptor with the translocation complex remains unknown. In this work, we characterize the organization of LAMP-2A in different molecular weight complexes at the lysosomal membrane and the changes in this organization with changes in CMA activity. Using isolated rat liver lysosomes in conjunction with techniques such as native electrophoresis, gel filtration chromatography and sucrose density gradient centrifugation, we have found that LAMP-2A is present in 6-7 different molecular weight complexes at the lysosomal membrane. Conditions that upregulate CMA (starvation, oxidation) stabilize LAMP-2A in a particular high molecular weight complex. Addition of hsc70 favors the presence of monomeric forms of LAMP-2A, pointing toward an active role of this chaperone in the disassembly of the LAMP-2A complexes. Assembly/disassembly of the LAMP-2A complexes is also modulated by GTP. We found that GTP exerts opposite effects on binding and uptake of substrates suggesting the possible involvement of a GTP-binding protein in this process. Our findings support that the organization of LAMP-2A in different size complexes at the lysosomal membrane is a dynamic process and that the step-wise assembly/disassembly of these complexes determines CMA activity.

New Insights on the Mechanism and Function of Sortilin
M. Camel,1 J. Hassan,2 A. Balbiss,3 K. Kommu,4 S. Kiernan,1 C. R. Morales1; 1Anatomy and Cell Biology, McGill University, Montreal, PQ, Canada, 2Polypeptide Hormone Laboratory, McGill University, Montreal, PQ, Canada

Background: Delivery of soluble lysosomal proteins to the lysosomes is dependent primarily on the mannose 6-phosphate receptor (M6P-Rc). However, in 1-cell disease (ICD) fibroblasts, where the M6P-Rc pathway is non-functional, some soluble lysosomal proteins continue to traffic to the lysosomes. Hypothesis: In this investigation, we have tested the hypothesis that cathepsins D and H, two soluble proteases that exhibit M6P-Rc independent trafficking, are targeted to the lysosomes by sortilin. In order to identify differences in trafficking via sortilin and the M6P-Rc, we have investigated that sortilin and its ligands are associated with sphingolipid detergent-resistant membranes (DRMs). Results: Using a dominant-negative sortilin construct and small interfering RNA (siRNA) we have demonstrated that while cathepsin D transport is dependent upon sortilin and the M6P-Rc, cathepsin H requires only sortilin for its transport to the lysosomes. Analysis of DRMs fractions has shown the presence of sortilin, sortilin, cathepsins H and D. On the other hand, the M6P-Rc and its ligand cathepsin B were found to be excluded from DRM fractions. Conclusions: These results suggest that sortilin functions as an alternative sorting receptor to the M6P-Rc for some soluble lysosomal proteins and that ligand-sortilin complexes exit the Golgi apparatus within vesicles containing lipid rafts. Supported by CIHR.

AP-1 and Retromer Play Opposite Roles in the Trafficking of Sortilin
M. Camel,1 S. Lefrançois,1 J. Zeng,2 C. R. Morales2; 1Anatomy and Cell Biology, McGill University, Montreal, PQ, Canada, 2Cell Biology, NIH, Bethesda, MD

Background: Sortilin has been implicated in the sorting and lysosomal targeting of certain soluble hydrolases and sphingolipid activator proteins. The cytoplasmic tail of sortilin contains an acidic cluster-dileucine motif structurally similar to that of the mannose 6-phosphate receptor. Recent studies have indicated that the cytoplasmic tail of sortilin interacts with both AP-1 and retromer complexes to mediate sorting of ligands to the lysosomes. In this investigation, we have tested the hypothesis that retromer is responsible for the retrograde transport of sortilin and also demonstrate a role for AP-1 in the endosomal trafficking of this novel receptor. Depletion of retromer with RNA-interference results in sortilin's accumulation and retention in the lysosomal compartment as well as in the secretion of the sortilin cargo protein, prosaposin, into the extracellular space. These results indicate that GAK plays a critical role in lysosomal enzyme sorting in conjunction with AP-1.

Determinants of the Interaction of GAK/Auxillin-2 with the AP-1 Complex
S. Kametaka,1 S. Koriyama,2 P. Burgess,3 L. Greene,4 E. Eisenberg,4 J. Bonifacino2; 1NICHD, NIH, Bethesda, MD, 2New England Inflammation and Tissue Protection Institute, Boston, MA, 3NIDDK, NIH, Bethesda, MD

Proper sorting of proteins to their corresponding destinations within cells is prerequisite to maintain the homeostasis of living organisms. Many proteins that function at endosomes and lysosomes are sorted out from the secretory pathway at the trans-Golgi network (TGN) by incorporation into clathrin-coated vesicles (CCV). Adapter protein complex-1 (AP-1) is a heterotrimeric complex that recruits clathrin and other factors from cytoplasm to the TGN membrane to facilitate the CCV formation and cargo selection. A large subunit of AP-1, γ-adaptin, possesses a C-terminal globular domain referred to as “ear” that functions as a platform for the recruitment of a variety of accessory proteins. Here, we report that GAK, a known CCV-associated kinase, directly interacts with ear domain of AP-1-γ-adaptin through a canonical tetrapartite motif, G(P/D/E)(Φ/L/M), in the clathrin-binding domain of GAK. Mutation of this motif or RNA-mediated depletion of AP-1 causes decreased association of GAK with the TGN. Depletion of GAK by RNAi impairs the proteolytic maturation of the lysosomal protease, cathepsin D, in cells. Re-expression of RNAi-resistant, wild-type GAK suppresses the defect in cathepsin D maturation caused by GAK depletion, whereas the AP-1-binding mutant cannot reverse the defect. These results indicate that GAK plays a critical role in lysosomal enzyme sorting in conjunction with AP-1.

Sortilin and Mannose 6-Phosphate Receptor Mediate the Trafficking of Acid Sphingomyelinase to the Lysosomes
X. Ni, C. R. Morales; McGill University, Montreal, PQ, Canada

Background: Acid sphingomyelinase (ASM), a member of the saposin-like protein (SAPLIP) family, is a lysosomal enzyme that hydrolyze sphingomyelin to ceramide. Deficiency of ASM causes a variant form of Niemann-Pick disease. The mechanism of targeting of ASM to the lysosomes is poorly known. Previous studies suggest that ASM could use in part the mannose 6-phosphate receptor (M6P-Rc). Sortilin, a type I transmembrane glycoprotein that belongs to a novel family of receptor proteins, presents structural features of receptors involved in lysosomal targeting. Results: We examined the hypothesis that sortilin may be implicated in the trafficking of ASM to the lysosomes. Hypothesis: Using a dominant-negative sortilin construct lacking the cytoplasmic tail, essential to recruit adaptor proteins and clathrin, we have demonstrated that sortilin is also involved in the lysosomal targeting of ASM.
revealed that truncated sortilin partially inhibited the lysosomal trafficking of ASM in COS-7 cells and abolished the lysosomal targeting of ASM in I-cells. Pulse-chase experiments corroborated that sortilin is involved in normal sorting of newly synthesized ASM. Furthermore, over-expression of truncated sortilin accelerated and enhanced the secretion of ASM from COS-7 cells and I-cells. Co-immunoprecipitation assays confirmed the interaction between sortilin and ASM. Conclusion: ASM uses sortilin as an alternative receptor to M6P-Re to be targeted to the lysosomes. Snf7-mediated Protein Interactions at Multivesicular Bodies

M. Wehmer, G. Odorozzi, MCD Biology, University of Colorado, Boulder, Boulder, CO

Multivesicular bodies (MVBs) are late endosomal organelles that function in sorting integral membrane protein cargos to the vacuole to be degraded. The sorting of monoubiquitinated cargo proteins through MVBs is a tightly regulated and highly conserved process. Snf7, a component of the Endosomal Sorting Complex Required for Transport (ESCRT) III in Saccharomyces cerevisiae, is required for the correct sorting of cargo proteins through MVBs. However, the mechanism by which Snf7 regulates sorting is unclear. Using a yeast two-hybrid system, we have discovered that the predicted third coiled coil of Snf7 is required for recognition by Bro1 to the MVB. Disruption of this region abolishes recognition of Bro1 and causes defects in cargo sorting. Additionally, we have mapped the region of interaction between Vps20 and Snf7. These observations provide a deeper understanding of protein recognition and complex assembly that mediate cargo sorting at the multivesicular body.

Reading and Writing the Ubiquitin Code for Gap1p Trafficking

A. L. Risinger, C. A. Kaiser; Biology, Massachusetts Institute of Technology (MIT), Cambridge, MA

The expression, localization, and activity of the high capacity general amino acid permease in S. cerevisiae, Gap1p, is regulated by amino acids such that it transports available amino acids from the surrounding medium into the cell only when internal amino acid levels are low. This dynamic regulation of Gap1p allows the cell to rapidly upregulate amino acid import when internal amino acid levels become limiting while avoiding excess amino acid import that can be lethal to cells expressing a non-sortable form of Gap1p. To completely redistribute Gap1p from the plasma membrane to intracellular compartments, Gap1p present at the plasma membrane is endocytosed while newly synthesized Gap1p is redirected to the vacuole. Both sorting steps require ubiquitination as the non-ubiquitinated Gap1pK9R,K16R mutant is found exclusively at the plasma membrane even in the presence of high levels of amino acids. It has been previously suggested that identical cis and trans acting factors are involved in ubiquitin-mediated delivery of both newly synthesized and endocytosed Gap1p to the vacuole. Intriguingly, upon further dissection, we clearly defined two unique ubiquitin-mediated pathways by which Gap1p can be delivered to the vacuole: 1) a direct path from the trans-Golgi to the endosome via Bul1/2p-dependent internal polyubiquitination of Gap1p on either lysine 9 or 16; 2) endocytosis via Bul1/2p-dependent ubiquitination of Gap1p on either lysine 9 or 16; and 3) endocytosis via Bul1/2p-independent monoubiquitination of Gap1p on lysine 16. Our finding that distinct ubiquitin-mediated sorting steps employ unique trans-acting factors, ubiquitination sites on Gap1p, and types of ubiquitination demonstrates a previously unrecognized level of specificity in ubiquitin-mediated protein sorting. The Leading Role of Microtubules in Endothelial Barrier Dysfunction - Disassembly of Peripheral Microtubules Leaves Behind the Cytoskeletal Reorganization

I. B. Aliev,1,2 K. M. Smarova,3 A. A. Birukova,1 A. D. Verrit;1 Department of Medicine, University of Chicago, Chicago, IL; 3A.N. Belozersky Institute, Moscow University, Moscow, Russian Federation

Pulmonary endothelial cell (EC) barrier dysfunction is often associated with dramatic cytoskeletal reorganization, activation of actomyosin contraction and finally gap formation. The role of microtubules (MTs) in EC barrier regulation is not fully understood, but clinical observations suggest that intravenous administration of anti-cancer drugs and MT inhibitors can lead to the sudden development of pulmonary edema in breast cancer patients. Our observations have been forced us to examine the role of MT reorganization in EC barrier regulation. Substantial studies, including our own, have previously demonstrated that endogenous agent, thrombin, induced rapid and reversible increase of EC barrier permeability. In quiescent EC MT density is highest in the centrosome region and decreases exponentially from the cell center to the cell margin, while actin network consists of thin bundles located mainly at the cell periphery. Thrombin (25 nM)-induced human EC barrier dysfunction associated with rapid (within 5 min) decreasing of peripheral MT density, which preceded formation of actin-stress-fibers and further MT reorganization in the internal cytoplasm. Both effects were reversible (within 1 h cytoskeleton returned to the normal state). From the other side, MTs disassembly by nocodazole (1 μM) itself induced rapid increases in EC permeability, actin cytoskeletal remodeling, activation of focal adhesions and formation of paracellular gaps, indicating EC barrier dysfunction. Collectively, our data demonstrate the leading role of MT disassembly in pulmonary EC barrier compromise - peripheral MT disruption points the way for the following cytoskeleton reorganization. Supported by NIH grants HL 067307, HL 58064 and RBFR grant 06-04-49233.

Characterization of Aortic Endothelial Cells Cultured on Amniotic Membrane

S. H. Tsai,1 Z. W. Zhou,1 Y. W. Liu,2 W. S. Ton,1 C. Y. Huang,1 J. K. Chen,2 V. C. Yang 1; 1Department of Life Science, Tunghai University, Taichung, Taiwan, 2Graduated Institute of Basic Medical Sciences, Chang Gung University, Taoyuan, Taiwan

Arterial occlusive disease remains a leading cause of death in western countries and in Taiwan. The limited supply of suitable vascular graft has led to the development of tissue engineered arteriovenous (TVE) grafts. These grafts rely on the culture of autologous vascular endothelial cells (ECs) for viability, and a major problem has been the loss of EC barrier function. Endothelial permeability increases with age and hypertension, and the use of tissue culture medium may not accurately reproduce in vivo conditions. We investigated the expression, localization, and activity of the high capacity general amino acid permease in S. cerevisiae, Gap1p, regulated by amino acids such that it transports available amino acids from the surrounding medium into the cell only when internal amino acid levels are low. This dynamic regulation of Gap1p allows the cell to rapidly upregulate amino acid import when internal amino acid levels become limiting while avoiding excess amino acid import that can be lethal to cells expressing a non-sortable form of Gap1p. To completely redistribute Gap1p from the plasma membrane to intracellular compartments, Gap1p present at the plasma membrane is endocytosed while newly synthesized Gap1p is redirected to the vacuole. Both sorting steps require ubiquitination as the non-ubiquitinated Gap1pK9R,K16R mutant is found exclusively at the plasma membrane even in the presence of high levels of amino acids. It has been previously suggested that identical cis and trans acting factors are involved in ubiquitin-mediated delivery of both newly synthesized and endocytosed Gap1p to the vacuole. Intriguingly, upon further dissection, we clearly defined two unique ubiquitin-mediated pathways by which Gap1p can be delivered to the vacuole: 1) a direct path from the trans-Golgi to the endosome via Bul1/2p-dependent internal polyubiquitination of Gap1p on either lysine 9 or 16; 2) endocytosis via Bul1/2p-dependent ubiquitination of Gap1p on either lysine 9 or 16; and 3) endocytosis via Bul1/2p-independent monoubiquitination of Gap1p on lysine 16. Our finding that distinct ubiquitin-mediated sorting steps employ unique trans-acting factors, ubiquitination sites on Gap1p, and types of ubiquitination demonstrates a previously unrecognized level of specificity in ubiquitin-mediated protein sorting. Regulation of Actin Dynamics by ANP-modulated Cyclic-GMP Signal Transduction in Endothelial Cells

A. J. Lin,1 H. Chen,2 T. Michel,2 D. E. Golian;1 Biological Chemistry & Molecular Pharmacology, Harvard Medical School, Boston, MA; 2Cardiovascular Division, Brigham and Women's Hospital, Boston, MA

Cyclic-GMP (cGMP) signaling cascades initiated by nitric oxide (NO) and atrial natriuretic peptide (ANP) play an important role in the maintenance of cardiovascular homeostasis. The molecular signaling mechanisms downstream of cGMP are not well understood, however. We here use siRNA technology to specifically knock down a series of signaling proteins in bovine aortic endothelial cells (BAEC), and combine biochemical analyses with laser confocal imaging techniques to investigate cGMP-regulated cytoskeletal dynamics. ANP activation of particulate guanylate cyclase (GC-A) leads to a substantial, dose-dependent, rapid, and sustained increase in intracellular cGMP, whereas NO activation of soluble guanylate cyclase (sGC) yields only a weak and transient response. Furthermore, ANP greatly enhances the phosphorylation at Ser239 of the vasoconstrictor-stimulated phosphorylase (VAP), a protein of the Ena/VASP family that is a major substrate of cGMP-dependent protein kinase (PKG) and that intimately influences actin dynamics. As observed by confocal imaging, enhanced Ser239 phosphorylation is accompanied by an increase in the formation of cellular actin stress fibers. Transfection of BAEC with duplex siRNAs constructs that specifically target GC-A, VASP, or PKG leads to an 80-95% decrease in target protein abundance compared to cells transfected with control siRNA. Knock down of PKG or GC-A completely abolishes VASP Ser239 phosphorylation and ANP-induced enhancement of stress fiber formation. siRNA targeting of PKG also blocks endothelial tube formation on a Matrigel substrate, while control siRNA exhibits no effect. Together with a recent in vivo study reporting that ablation of endothelial GC-A abrogates the ANP-induced endothelial permeability increase in mice, our findings suggest that ANP-mediated cGMP signal transduction regulates actin dynamics through VASP Ser239 phosphorylation, which in turn plays an important role in the regulation of endothelial permeability and angiogenesis.
Amelioration of Acute EA of a Selective Inhibitor of Vascular Endothelial Growth Factor Receptor 2 (VEGFR2)
M. E. Welsh, M. Feng, S. J. Karfik; Physiology and Pharmacology, The University of Western Ontario, London, ON, Canada
Experimental allergic encephalomyelitis (EAE) is a T cell-mediated inflammatory disorder of the central nervous system, frequently used as an animal model for multiple sclerosis (MS). An increased expression of vascular endothelial growth factor (VEGF) by astrocytes and vascular endothelial cells is associated with demyelinated lesions in both EAE and MS. In order to investigate the contribution of VEGF to lesion development in acute EA, we treated immunized mice with SU5416 (Semaxinin), a potent and selective inhibitor of VEGF receptor 2 (VEGFR2). EAE was induced in C57 BL/6J mice by immunization with myelin oligodendrocyte glycoprotein (MOG35-55) and animals were assessed daily by a blinded observer for clinical manifestations of disease. Animals received seven daily injections of SU5416 (50 mg/kg) or vehicle beginning on the day of disease onset. Brain and spinal cord were collected on the day of sacrifice for histology/immunohistochemistry and quantitative microscopy was used to determine demyelination, cell infiltration and VEGF expression. SU5416 treatment produced a significant clinical improvement versus control mice (p<0.001), with less demyelination (37%) and cellular infiltration (23%) in the spinal cord (p<0.05). The amount of cellular infiltration was very strongly correlated with demyelinated lesion size in both control (r=0.943) and SU5416-treated (r=0.913) animals. Total VEGF immunoreactivity was the same in both groups. As well, VEGF expression correlated with lesion size for both control (r=0.723) and treated (r=0.681) animals. VEGFR2 blockade partially decreased the clinical and pathological changes in acute EA without effecting the extent or distribution of VEGF expression. SU5416 treatment produced smaller lesions without altering lesion composition. Therefore, VEGFR2 signaling represents an important component of lesion development in acute disease.

Methylalthoxone Inhibits Opiate and VEGF-induced Angiogenesis: Role of Receptor Transactivation
P. A. Singleton, J. Moss, J. G. N. Garcia; Medicine, University of Chicago, Chicago, IL
Angiogenesis or the formation of new blood vessels is important in the growth and metastatic potential of various cancers. Therefore, agents that inhibit angiogenesis have important therapeutic implications in numerous malignancies. We examined the effects of methylalthoxone (MNTX), a peripheral mu opioid receptor antagonist, on agonist-induced human EC proliferation and migration, two key components in angiogenesis. We observed that MNTX inhibits opioid and VEGF-induced migration and proliferation in a dose-dependent manner using human pulmonary microvascular EC. On a mechanistic level, morphine sulfate (M) and DAMGO induced Src activation which was required for VEGF receptor transactivation and opioid-induced EC proliferation and migration. MNTX inhibited M, DAMGO and VEGF induced tyrosine phosphorylation (transactivation) of VEGF receptors 1 and 2. Further, MS, DAMGO and VEGF induced RhA activation which was inhibited by MNTX or VEGF receptor tyrosine kinase inhibition. Finally, MNTX or silencing RhA expression (siRNA) blocked MS, DAMGO and VEGF-induced EC proliferation and migration. Taken together, these results indicate that MNTX inhibits opioid-induced EC proliferation and migration via inhibition of VEGF receptor phosphorylation/transactivation with subsequent inhibition of RhA activation. These results suggest that MNTX inhibition of angiogenesis can be an useful therapeutic intervention for cancer treatment.

Optimizing Transfection Conditions to Facilitate Cell Migration and Angiogenesis in HUVEC Cells
S. Vasa, L. Vozza-Brown, J. Fan, X. Yu, H. C. Chou; Invitrogen Corp, Carlsbad, CA
HUVEC and other primary endothelial cells represent important tools in studies of cancer, angiogenesis, and cell differentiation. The success of much of this research rests on the ability to manipulate gene expression and/or to deliver specific marker or reporter constructs while maintaining a cell's ability to progress normally through downstream developmental programs. Transfection, the method of choice for gene delivery, can involve tradeoffs since high transfection efficiency and expression often correlate with high levels of cytotoxicity, which can impair cell physiological responses and compromise performance in downstream assays. During development of LipofectamineTM LTX, which is specifically designed as a low toxicity transfection reagent, we observed that different reagents and transfection conditions can exert a significant impact on the cell’s ability to proceed through normal physiological programs. Here we describe optimized conditions for transfection of HUVEC cells using LipofectaminTM LTX that achieves high transfection activity without interfering with normal functioning of the cells, as indicated by cell differentiation indices, cell migration and the ability to undergo angiogenesis as measured in an endothelial tube formation assay.

Inhibition of Angiogenesis by Xanthohumol
M. Negrao, I. Azvedo, R. Soares; Department of Biochemistry, Faculty of Medicine, University of Porto (U38-FCT), Porto, Portugal
Angiogenesis, the formation of new blood vessels from pre-existing ones, is a process that occurs in many physiological conditions, being also essential to the development and progression of several pathologies, such as cancer and cardiovascular disease. Recent Western diet is believed to contribute to an increased lifetime risk of cancer and cardiovascular disorders. On the other hand, diets high in plant-derived foods offer a protective effect. Recent studies indicate that the development of these pathologies is inversely associated with the consumption of natural polyphenolic compounds, which are known to affect angiogenesis. Therefore, an important strategy for prevention of cancer and cardiovascular disease is the identification and characterization of dietary phytochemicals that are able to block, slow, or reverse pathological stages. One of these compounds is xanthohumol, a prenylated polyphenol obtained from the Humulus lupulus and, thus, present in beer. The purpose of this study was to investigate the effect of xanthohumol in angiogenesis, namely evaluating its effects on cell viability, apoptosis, migration, invasion and formation of capillary-like structures in human umbilical vein endothelial cells (HUVEC). Incubation of HUVEC with 10 µM xanthohumol resulted in a significant decrease in cell viability assessed by MTT assay (23.28±7.77%), as well as in an increase in the number of apoptotic cells by TUNEL assay (436.67±52.03%). Xanthohumol treatment also led to a reduction in cell migration to injured areas (injury assay), a strong decrease in the invasive capacity using double-chamber assays (27.85±7.89%) and in the formation of capillary-like structures (53.27±13.25%). Our findings indicate that 10 µM xanthohumol, exerts inhibitory effects on endothelial cell’s proliferation, migration and invasion, processes that are required for the development of physiological and pathological angiogenesis.

Therapeutic Potential of CD31 Negative Dental Pulp SP Cells for Vasculogenesis in Dentin-Pulp Regeneration
M. Nakashima, K. Iohara, L. Zheng, T. Into, K. Matsushita; Laboratory of Oral Disease Research, National Institute for Longevity Sciences, Obu, Japan
Dentin-pulp complex was demonstrated in this study. SP cells contained CD31--;CD146-, CD31++;CD146- and CD31++;CD146+ population, at the concentration of 45%, 48% and 7%, respectively. Only CD31--;CD146- SP cells formed capillary-like structures when cultured with VEGF on Matrigel and expressed activated endothelial cell markers, CEACAM1 and vWF, and mature endothelial cell markers, VE-cadherin and occludin, after seven days. VEGF induced a much stronger chemotactic response in CD31++;CD146+ SP cells compared with CD31- SP cells. VEGF also enhanced the proliferation of CD31++;CD146 SP cells. In addition to vasculogenic potential, CD31-;CD146 SP cells demonstrated neurogenic and odontogenic potential. In conclusion, the potential utility of CD31--;CD146 SP cells for regeneration of dentin and pulp complex was demonstrated in this study.

Human Blood Brain Barrier Disruption by Retrovirus-infected T Lymphocytes: Mechanism of Endothelial Tight-Junctions Disorganization by Proinflammatory Cytokines
P. Afonso; Institut Pasteur, Paris, France
The blood-brain barrier (BBB), which constitutes the interface between blood and brain parenchyma, has been shown to be disrupted during retroviral associated neuroinflammatory diseases. During Human T cell Lymphotropic Virus (HTLV) Associated Myelopathy/Tropical Spastic Paraparesis (HAM/TSP), a slowly progressive neurodegenerative disease associated with HTLV-1 infection, evidence of BBB disruption has been brought by demonstrating the presence of lymphocytic infiltrates and plasma protein leakage through brain endothelium. We have developed a human cellular model to study the mechanisms involved in endothelial permeability changes induced by HTLV-1-infected lymphocytes. We demonstrated that IL-1α and TNFα secreted by infected lymphocytes are responsible for BBB disruption, associated with the disorganization of tight junctions (TJ) between endothelial cells, and changes in expression patterns of tight junction...
proteins such as Zonula Occludens 1. Such a disruption could be confirmed in sections of spinal cord from HAM/TSP patient. In vitro, these changes were associated with an enhancement in lymphocyte migration across the barrier. Such BBB disruption could be prevented by inhibiting the NFκB pathway or MLCK activity. Our results provide, in a human in vitro model, evidence of the central role of proinflammatory cytokines in BBB endothelial TJ disorganization during HAM/TSP, with involvement of NFκB and MLCK. We propose that such a mechanism could be a general initial step in pathogenesis of retroviral associated neurodegenerative diseases.

Non-clathrin Non-caveolin Vascular Cells Involved in Transcytosis
D. N. Predescu, S. Predescu, I. Knezevic, R. Neamu, N. Knezevic, A. Malik; Pharmacology, University of Illinois, Chicago, IL
Transcytosis is an active process by which, in fluid-phase or receptor mediated, some toxins, viruses, certain growth factors, secreted and circulating proteins are transported across different cell types in a polarized mode within a membrane bound carrier. For a long period of time it was believed that only caveolin and clathrin coated vesicles are selectively moving material between two environments without affecting the cellular milieu. Taken into account the importance and the uniqueness of endothelial transcytosis and of its corresponding carriers the endothelial caveolae, we decided to investigate what happens in a model from which caveolin1 was removed genetically. Here we present data showing that in caveolin 1 knockout mice: i) the transendothelial transport is not shifted toward clathrin-mediated transcytosis, ii) non-clathrin non-caveolin (double NC carriers) are present in different vascular segments, and iii) the double NC carriers are involved in transcytosis. Using an in situ perfusion system we were able to find out that the double NC carriers: i) have an average dimension of 100nm (90-110nm), fact that place them between the classical caveolae (60-80 nm) and clathrin coated vesicles (120-150 nm), ii) are less numerous even than the clathrin coated pits that occupy < than 0.2% of endothelial surface and have a small or very limited contribution to the ability of the cells to internalize fluid volumes, iii) depend on cholesterol for their function and subsistence and iv) seem to use the same basic targeting and fusion machinery for their movement across the endothelial cells. In the same in situ perfusion system it appears that the double NC carriers are different from the vesicular carriers used by SV40 viruses to enter the cells. The reality of double NC vesicles has been in time controversial, but our data demonstrate their existence and more than that prove their functionality.

Thrombin Peptide, TP508, Upregulates Expression of eNOS and Prevents Hypoxia-induced eNOS Downregulation in Human Endothelial Cells
B. Olszews-PAzdrak, A. R. Hart-Van Tasse, D. H. Carney; Biochemistry & Molecular Biology, UTMB, Galveston, TX
TP508 (Chrysin®) is a nonpeptidic peptide representing a portion of human thrombin involved in receptor binding with cellular effects distinct from those of proteolytically active thrombin. TP508 is an angiogenic factor currently undergoing human clinical trial testing for healing of bone fractures and diabetic foot ulcers, and preclinical testing for myocardial revascularization. In animal models, TP508 accelerates repair and revascularization of dermal and muscoskeletal tissue, and increases the number and density of blood vessels in ischemic myocardium. We therefore studied the effects of TP508 on endothelial cells and signals related to angiogenesis. Impaired nitric oxide (NO) production reduces the responsiveness of endothelial cells to angiogenic factors and causes loss of endothelial function in ischemic and inflamed blood vessels contributing to a number of chronic diseases. We hypothesized that TP508 may produce angiogenic and other tissue repair effects by activating or upregulating nitric oxide synthase (NOS) in endothelial cells, and if so, that it may have potential therapeutic value in tissues and diseases exhibiting endothelial dysfunction. In our studies, TP508 increased phosphorylation of eNOS at Ser 1177, relative to controls, in human coronary artery endothelial cells cultured under normoxic and 1% hypoxic (1% O2) conditions (1.8 ± 0.2-fold and 2.5 ± 0.2-fold, respectively). TP508 also upregulated eNOS mRNA and protein expression in normoxic and hypoxic conditions as determined by real time PCR and Western blots. Moreover, TP508 prevented hypoxia-induced decreases in eNOS protein expression. In contrast, TP508 stimulation had no significant effect on TNFα-induced downregulation of eNOS mRNA and protein expression, but increased phosphorylation of eNOS when compared with TNFα alone. These studies demonstrate that TP508 initiates signals that increase eNOS phosphorylation, upregulate eNOS expression, and selectively inhibit effects of hypoxia. Therefore, TP508 may exert its effects in a number of tissues by modulating endothelial cell eNOS and NO production.

Laser Capture Analysis of Endothelial Tip Cells, a Vascular Counterpart to Axonal Growth Cones
G. A. Strasser; Genentech, South San Francisco, CA
The vascular and nervous systems form extensive and often parallel networks that control, monitor, and nourish all the tissues of the body. Recently, a number of secreted and membrane bound factors known to be required for the proper wiring of the nervous system have been found to be involved in the development of the vasculature as well. Like the guidance of a neuronal axon to its synaptic partner, the growing endothelial stalk appears to be guided to its target through the activity of a specialized cell located at its tip. This tip cell, like an axonal growth cone, is highly motile and characterized by the presence of dynamic filopodia. However, little is known about how these specialized cells detect guidance cues and translate this information into motility and, subsequently, vascularization of a tissue. To analyze the gene expression patterns of tip cells, we have developed a method to isolate them using laser capture microdissection, permitting subsequent expression analysis. We have found that tip cells express genes indicating they are highly motile and characterized by the presence of dynamic filopodia. We therefore studied the function of heparanase in controlling arterial remodeling. Under normal physiological conditions endothelial cells produce soluble factors that inhibit the growth of vascular smooth muscle cells (vSMCs). This process is fundamental to vascular and nervous systems form extensive and often parallel networks that control, monitor, and nourish all the tissues of the body. Translational Regulation of VEGF Expression by Akt in Tumor Derived Endothelial Cells in Hepatocellular Cancer

F. Meng, R. Henson, H. Webbe, T. Patel, Internal Medicine, Scott & White Hospital, Temple, TX

Angiogenesis is essential for the growth and metastasis of human hepatocellular carcinoma (HCC). Tumor derived endothelial cells are phenotypically distinct and genetically unstable compared to normal endothelial cells. Targeting tumor derived endothelial cells may be a promising new strategy for HCC. Akt / PKB can regulate the expression of key mediators of angiogenesis and cell survival but the role of Akt in liver cancer is unknown. Our aims were to determine the role of Akt kinase regulation in VEGF-mediated angiogenesis and tumor growth in HCC. Liver tumors were experimentally induced in male mice by i.p. injections of N-diethylnitrosamine (Den). Microvascular endothelial cells (EC) were isolated from HCC tumor as well as normal liver tissues using a magnetic bead immunoaffinity technique. Angiogenesis was quantitated using an in vitro assay, and the expression of Akt and VEGF were analyzed by Western blot. Transfection with NF-κB increased Akt phosphorylation and VEGF expression in both normal and tumor-derived EC. However, co-transfection of dominant negative Akt with NF-κB blocked VEGF up-regulation only in the tumor derived EC. Transfection of Akt directly increased VEGF expression as well as the angiogenesis index only in tumor derived ECs. Moreover, overexpression of Akt conferred resistance to gemcitabine induced apoptosis in tumor derived MVEC, but not in non tumor derived MVEC. Thus, there are differences in the role of Akt in VEGF dependent angiogenesis and cell survival in tumor and normal liver EC. Next, we examined the effect of the translational inhibitor cycloheximide. Pre-incubation with 50 μg/mL cycloheximide prevented the increase in VEGF expression by Akt, suggesting the need for new mRNA translation. These results highlight a novel function of Akt kinase: direct involvement VEGF dependent HCC tumor angiogenesis. It is suggested that Akt can contribute to angiogenesis in hepatocellular carcinoma via translational regulation of VEGF mRNA expression.

The Anti-cancer Effect of Combination Therapy with Conditionally Replicating Adenovirus and Adenovirus-expressing P33/β or P53 in Cervical and Ovarian Cancer Cell Lines

S. Kim, J. Lee, S. Park, D. H. Lee, J. Park, J. Lee, Cancer Research Institute, Seoul National University College of Medicine, Seoul, Republic of Korea, 2Department of Internal Medicine, Seoul National University College of Medicine, Seoul, Republic of Korea

Gene therapy is most often described as a technique for introducing the foreign genetic material into cells with a correction of a dysfunctional gene as its final goal. Consequently, we need to develop new therapeutic strategies. Conditionally replicating adenoviruses (CRAds) enhance the tumor specificity and thus avoid damage to other tissues. We were exploring the combination therapy effect of CRAds and non-replicating adenovirus in cervical cancer cell and ovarian cancer cell. Therefore, we reconstitute adenoviruses expressing the β-isoform of P33/β, a p53 homologue, by CMV promoter (Ad/CMVp73β) and the p53 by CMV promoter (Ad/CMVp53). Expression of protein level and induction of target genes was analyzed by Western blot. Infection of human ovarian cancer cell (SKOV3) and human cervical cancer cell (C33A) with Ad/CMVp73β or Ad/CMVp53 resulted in several folds increase of p73β and p53 levels. And so p21WAF1/CIP1 and BAX protein, the apoptosis and growth arrest related proteins which are responsive to p73β and p53, increased in SKOV3 and C33A. We then evaluated the inhibitory effect of Ad/CMVp73β or Ad/CMVp53 in SKOV3 and C33A using MTT assay and crystal violet staining. Also, we monitored the induced expression of p73β, p53, p21WAF1/CIP1 and BAX upon Ad/CMVp73β or Ad/CMVp53 infection. Ad/CMVp73β-infected cells showed several times higher amounts of p73β, p53, p21WAF1/CIP1 and BAX in comparison to Ad/CMVp73β, Ad/CMVp53 or CRAds alone. Further study of cell death with combination gene therapy will be discussed by cell cycle analysis. The effect by combination therapy of CRAds and non-replicating adenovirus was more effective than by non-replicating adenovirus in human ovarian cancer cell (SKOV3) and human cervical cancer cell (C33A). These results suggest that CRAds + non-replicating adenoviruses containing a therapeutic gene can improve gene transfer.

Over-expression of Rab25 Causes Transformation of Intestinal Epithelial Cells

L. A. Lapierre,1,2 C. M. Caldwell,1 R. J. Coffey,1 R. D. Beauchamp,1 J. R. Goldering1,2,1 Surgery/Epithelial Biology, Vanderbilt Univ. Medical Center, Nashville, TN, 2Vanderbilt-Ingram Cancer Center, Nashville, TN

Epithelial cells regulate their cell surface compositions through selective endocytosis and recycling of membrane proteins. Little is known of how membrane recycling pathways influence transformation and neoplasia. We have previously identified the small GTPase Rab25 as an epithelial-specific modulator of membrane recycling. Recent studies have demonstrated that Rab25 expression is up-regulated in a number of epithelial cancers and over-expression may increase the aggressive phenotype of cancers. Recently we have utilized the non-transformed Rat Intestinal Epithelia (RIE) cell line to examine the influence of Rab25 on cell transformation. Tetracycline-regulated overexpression of GFP-Rab25 in RIE cells leads to transformation including morphological transformation, growth in soft agar and tumor formation in nude mice. These results have led us to hypothesize that Rab25 acts as a tumor promoter with activation of specific downstream signaling cascades. In the presence of doxycycline (off) the cells form an orderly monolayer with organized cell-cell contacts. However, removal of doxycycline (on) elicits a marked alteration in cell morphology with disruption of cell contacts and adoption of a scattered morphology. This induced morphological transformation was not observed in an RIE line that inducibly overexpressed GFP-Rab11b. We do not see any increased phosphorylation of either MAPK (p44/42) or AKT (Ser473) in the GFP-Rab25 overexpressing cells. In addition, we have found that over-expression of Rab25 does not alter phospho-Smad2 levels, indicating that altered TGFβ-signaling is not responsible for transformation. We also did not observe any changes in EGFR receptor phosphorylation and addition of EGFR tyrosine kinase inhibitors did not alter transformation. These results suggest that over-expression of GFP-Rab25 can transform intestinal epithelial cell using mechanism separable from classical EGFR receptor mediated signal transduction.

mDia1 Knockout Mice Phenocopy Human Pre-Leukemic/Myelodysplastic Syndromes

While acting as effectors for Rho GTPases, mammalian Diaphanous-related (mDia) form families participate in cytoskeletal remodeling events triggered by migratory and/or proliferative signaling. Using mDia1 deficient mice, we have found that over-expression of Rab25 does not alter phospho-Smad2 levels, indicating that altered TGFβ-signaling is not responsible for transformation. We also did not observe any changes in EGFR receptor phosphorylation and addition of EGFR tyrosine kinase inhibitors did not alter transformation. These results suggest that over-expression of GFP-Rab25 can transform intestinal epithelial cell using mechanism separable from classical EGFR receptor mediated signal transduction.

Characterization of Heparanase from Malignant Breast Cancer Cells

M. Yu,1 Y. Wang,2 R. S. Beek,2 M. A. Kosin2,2 Surgery, Wayne State University, Detroit, MI, 1Immunoology, Wayne State University, Detroit, MI, 2Surgical Service, John D. Dingell VA Medical Center, Detroit, MI, 3Breast Program, Karmanos Cancer Institute, Detroit, MI

Heparanase is an endo-beta-D-glucuronidase that degrades glycosaminoglycan chains of heparin sulfate proteoglycans (HSPG) at specific sites. Elevated levels of mammalian heparanase (known as HPSE) are associated with the tumor cell proliferation, invasion, angiogenesis, and metastasis. Extracellular heparanase activity that is not HPSE has been identified as an 80-kDa heparanase (and 97-kDa precursor) from malignant breast cancer cells (MCF-10CA1A11 cells) that shares homology to the CXC chemokines of the platelet basic protein (PBP) family (also known as CXCL17). To identify and characterize the extracellular heparanase activity in malignant breast cancer cells several approaches were used: 1) Heparanase activity chromatography of conditioned medium (CM) followed by Western blot antibody to the homologous C-terminal domain and verification of heparanase activity. Finally, 2-D gel to separate isoforms. 2) Immunoprecipitation of cell lysates from malignant MCF-10 CA1C11 cells by anti-human CXCL7/NAP2 monoclonal antibody. RESULTS: Cell lysate and CM of MCF-10 CA1C11 cells demonstrated 80-kDa PBP-like protein by immunoblot. In the CM, an 80-kDa PBP-like protein was identified as responsible for heparanase activity. Furthermore, separation of molecular weight of heparanase was observed by immunoblotting CM from MCF-10 CA1C11 cells with anti-human CXCL7/NAP2 monoclonal antibody. This suggested that the 80-kDa heparanase is not NAP2 like protein but a PBP-like protein. In conclusion, malignant breast cancer cells show another heparanase activity in CM and cell lysates with homology to the
chemokine CXCL7. The 80-kDa heparanase, a PBP-like molecule rather than HPSE 1 is likely responsible for the heparanase activity in the CM of MCF-10 CA1A.C11 cells. This may be specific to malignant human breast cancer, or result from additional mechanisms in malignant cells that are yet to be elucidated.

Identifying Desmoplakin's Contribution to Prostate Cancer

C. M. MacCarthy; Biochem. and Molecular & Cellular Biology, Georgetown University, Washington, DC

We have found a relationship between desmoplakin and prostate cancer cell phenotype in vitro (i.e. increased cell division, decreased contact inhibition). Desmoplakin is known primarily for its crucial role in cell-cell adhesion complexes, desmosomes. Preliminary data reveal an additional function for desmoplakin as a cell signaling intermediate in the Rho signaling pathway, which is shown to regulate cell growth, cell motility and cytokinesis. We hypothesize that overexpression of desmoplakin in prostate cancer cells hyperactivates the Rho pathway which leads to excessive cell proliferation and potential metastasis. To determine if desmoplakin contributes to the prostate cell cancer phenotype, we have begun to use small interfering RNA (siRNA) against desmoplakin mRNA to knockdown protein translation in PC3 prostate cell cultures. Knocking down desmoplakin levels in PC3 cells resulted in decreased cell division and the recurrence of contact inhibition. Additionally, a Constitutively active Dsp-GFP vector was transfectioned into a less aggressive cancer cell line, CA-HPV-10, and reverse characteristics were observed. Morphological changes as well as protein distribution were determined by a combination of immunofluorescence staining and microscopy. Cells stained with fluorescein labeled molecules specific for desmoplakin, E-cadherin and F-actin provided an image of protein distribution as well as relative proximity of mentioned proteins. Confocal microscopy images revealed desmoplakin and active Rho proximally localized in the cytoplasm. It also showed disorganized F-actin networks. A Rho specific activity assay was used on the same cell types under the same or similar conditions to establish a link with Rho activity. Elevated levels of active Rho corresponded to elevated levels desmoplakin. The combination of these results further indicates that desmoplakin may have a non-canonical function as a signaling intermediate in prostate cancer. There is potential for this research to uncover a novel signaling mechanism of oncogenic transformation possibly leading to improved targeted cancer therapy and prevention.

Coronin-1C Regulates Actin Dynamics during Metastasis

D. W. Roadcap, J. E. Bear; Lineberger Comprehensive Cancer Center, University of North Carolina, Chapel Hill, NC

Coronins are highly conserved F-actin binding, WD repeat proteins that have been implicated in cell motility in model organisms. Research from our laboratory suggests that the type 1 family of Coronins (1A, 1B, and 1C) coordinate Arp2/3 and Cofilin activity at the leading edge. Coronin 1C is transcriptionally regulated, and microarray analysis suggests that it is overexpressed in multiple forms of cancer. We examined Coronin 1C expression in both melanoma and astrocytoma by immunohistochemistry, and found a strong correlation between Coronin 1C expression and cancer progression, with particularly high levels in metastatic cancers. Furthermore, we have found that Coronin 1C expression correlates with phospho-ERK levels in melanoma, which indicates that Coronin 1C expression may be linked to the mutual activation of the upstream regulators of ERK activity, N-Ras and B-Raf, which are commonly found in melanoma. Taken together, these data support a role for Coronin 1C in regulating migration and invasion during metastasis. To further examine Coronin 1C's in vivo significance, we have generated a Coronin 1C gene-trap mouse. Analysis of this mouse is currently underway, and embryonic fibroblasts (MEFs) have been isolated from gene-trap embryos. We interrogated these cells using a panel of motility and invasion assays to determine exactly how loss of Coronin 1C alters cell behavior. These studies reveal a critical role for Coronin 1C regulation of the actin cytoskeleton during migration, and demonstrate that Coronin 1C plays an important role in promoting the changes in cytoskeletal regulation that drive metastasis.

Expression and Function of Pyk2 in Pancreatic Cancer

A. Galloway, J. Hubbard, Y. Yan, D. J. Cole; Surgery, MUSC, Charleston, SC; Alexion Pharmaceuticals, Cheshire, CT

Pancreatic cancer (PC) is the fourth leading cause of cancer related deaths in the US. However, the mechanisms underlying the highly invasive and metastatic phenotype of PC have not been fully elucidated. The focus of our study is the non-receptor tyrosine kinase Pyk2, which has been implicated in several cancers, but has not been fully explored in PC. Overexpression of Pyk2 mRNA in PC was demonstrated by real time RT-PCR analysis of patient-matched PC and normal pancreatic tissue. Increased Pyk2 activation in PC was also observed by immunohistochemical analysis of a tissue core array stained for Pyk2 phosphorylation on tyrosine 402. As the epidermal growth factor (EGF) and lysosphosphatic acid (LPA) pathways have been implicated in PC proliferation and metastasis and have been shown to signal through Pyk2 in other cell contexts, their activation of Pyk2 in PC cell lines was analyzed. Pyk2 was found to be phosphorylated at tyrosine 402 in a time and dose dependent manner following stimulation of both the human AsPC1 and murine Panc02 PC cell lines with EGF or LPA. Further, infection of PC cell lines with a dominant negative Pyk2 adenoviral construct, AdPy2 Y402F, reduced proliferation and induced an accumulation of cells in G2 phase. Expression of this Pyk2 dominant negative mutant also significantly reduced wound healing. Taken together, these results suggest that Pyk2 may contribute to the aggressive phenotype of this disease and may represent a potential therapeutic target.

A Role for the Lactate Transporter MCT4 in Regulating Cell Surface Expression of CD147 in the Metastatic Breast Cancer Cell Line MDA-MB-231

S. M. Gallagher, D. Wang, Z. Jiang, N. J. Philip; Pathology, Anatomy and Cell Biology, Thomas Jefferson University, Philadelphia, PA

The matrix metalloproteinase inducer, CD147, plays an important role during tumor invasion. In metastatic cancer cells, CD147 is expressed at high levels and stimulates the production of matrix metalloproteinases in the stroma, thereby enhancing tumor cell migration and facilitating angiogenesis. CD147 has also been shown to form heteromeric complexes with members of the monocarboxylate transporter family (MCT) and is required for the trafficking of these transporters to the plasma membrane. While MCT1 is widely expressed, MCT4 is primarily detected in tissues dependent on glycolysis for the production of ATP. Since a switch from oxidative to glycolytic metabolism is a key feature of metastatic cells, we investigated whether the increase in CD147 in cancer cells is linked to the expression of MCT4. Using the metastatic breast cancer cell line MDA-MB-231, we find that MCT4 expression is increased at both the message and protein level compared to non-metastatic cancer cell lines and cells derived from normal mammary tissue. Immunofluorescence microscopy and co-immunoprecipitation studies reveal that the MCT4/CD147 heteromeric complex co-localizes to the plasma membrane and membrane blebs that are shed from the cell surface. Silencing of MCT4 with siRNA impairs the maturation and trafficking of CD147 to the cell surface, resulting in accumulation of CD147 in the endoplasmic reticulum. Likewise, silencing CD147 causes a reduced expression of MCT4 which leads to a decrease in lactate efflux and cellular levels of ATP. Also, when cells are treated with CD147 siRNA, MCT4 is not trafficked to the plasma membrane, but is targeted instead to endosomes. These studies establish that the increase in CD147 observed in metastatic cancer cells is mediated through its association with MCT4. Therefore, our results suggest that upregulation of MCT4 may be critical for cancer progression and metastasis making it a potential target for anti-cancer therapies.

The Selectivity of Ras Signaling in Tumor Formation

C. Cheng, B. Onken, M. R. Philip, E. C. Chang; Molecular and Cellular Biology, Baylor College of Medicine, Houston, TX; Cell Biology and Pharmacology, New York University School of Medicine, New York, NY

The Ras G-protein signaling pathways are very complex in humans. There are four Ras proteins. The N-termini of these Ras proteins are over 90% identical in primary sequences, which include the effector-binding domains, and in vitro they interact with many effectors with nearly the same efficiency. However, how a given Ras protein selectively activates a particular effector is poorly understood. One leading model suggests that the C-termini of Ras proteins undergo specific post-translational modification, e.g., lipidation, and that such modifications allow Ras to localize and signal from at least two distinct compartments: the plasma membrane and the endomembrane. To unambiguously test this model, we have turned to the fission yeast Schizosaccharomyces pombe, which has only one Ras protein, but it is still capable of controlling two highly conserved pathways. Our data show that J. pombe Ras selectively activates a MAP kinase pathway to mediate periodic signaling at the plasma membrane, while it activates Cdc42 at the endomembrane to control cell polarity and mitosis. Ras also appears to act via Cdc42 to transform mammalian cells, and Cdc42 can be found at the endomembrane. We have transformed fibroblasts with endomembrane-restricted Ras and showed dominant-negative Cdc42 can block endomembrane-restrictive Ras induced transformation. Together, these results suggest that Ras in mammalian cells can interact selectively with Cdc42 in the endomembrane. In the current study, we plan to test this idea and to determine if such interaction between Ras and Cdc42 may be important for tumour formation.
2668 Tumor Suppression by Inhibition of p130Cas/BCAR1 Signaling in Tamoxifen Resistant Breast Cancer Cells
S. Soni; Biochemistry, Boston University School of Medicine, Boston, MA

Breast cancer cell lines and primary breast carcinomas express high levels of p130Cas/BCAR1 (breast cancer anti-estrogen resistance-1) in the cytoplasm. Elevated protein expression in mammary tumors is a marker of poor prognosis and poor overall survival. Moreover, p130Cas (CAS) signaling has been associated with anti-estrogen resistance. The central objective of our research is to investigate the effects of inhibition of CAS on breast tumor formation and resistance to Tamoxifen. We employed the human breast cancer cell lines MCF7 and its Tamoxifen resistant derivative TAM-R. For our studies we established cells that were stably infected with a dominant negative CAS - blocking signal transduction downstream of the CAS substrate domain ([CAS]D). Kirsch et al., 2002, BMC Cell Biol 3:18 - as well as CAS knockdown cell populations established by siRNA. These cells were monitored for effects on proliferation, morphology, migration, survival and sensitivity to growth inhibition or apoptosis upon treatment with Tamoxifen. The expression of the dominant negative CAS as well as CAS siRNA induced morphological changes, which were consistent with a more normal epithelial-like phenotype. This reversion was accompanied by reduced cell proliferation and migration. Interestingly, we observed cytostatic effect using the dominant negative CAS, whilst the expression of CAS siRNA had a cytotoxic effect. The signaling pathways affected by inhibition of CAS in this system are currently under investigation. In summary, our findings suggest that targeting the product of the BCAR1 gene may provide a new molecular avenue for treatment of anti-estrogen resistant breast cancers. This work has been supported by the NIH CA106468 to S.H. Kirsch. Reference: Kirsch K.H., M. Kensinger, H. Hanafusa and A. August . 2002. A p130Cas tyrosine phosphorylated substrate domain

2669 Regulation of Proteasome Dynamics and Assembly by Int6/yin6
Z. Sha,1 H. Yen,2 E. Chang1; 1The Breast Center, Baylor College of Medicine, Houston, TX, 2Harvard University, Houston, MA

INT6 is a target of MMTV, whose insertion generates truncated proteins that induce tumor. Our lab demonstrates an evolutionarily conserved function of Int6 in the model system Schizosaccharomyces pombe: regulation of proteasome transport and assembly. The overall objective of this study is to better understand how Int6 regulates this process. By FRAP/FLIP assays, we found that the proteasome submit Rpn11-GFP is highly dynamic, and is actively entering and exiting the nucleus. The dynamics increases when deleting int6 or rpn11, a proteasome subunit regulated by int6. These results are consistent with our previous findings that proteasome become disassembled when int6 or rpn11 is deleted. Furthermore, the dynamics of Rpn11-GFP appears to increase when treated with MIB, a microtubule-depolymerizing drug, but decrease when treated with canavanine, an arginine analog, which generates proteasome stress. These results raise interesting questions whether proteasome assembles into larger complexes when they are required for protein turn-over, and whether microtubules play a role in proteasome assembly. I am also carrying out a structure-function analysis focusing on the fact that many proteasome subunits and Int6 contain a PCI domain, whose truncation induces mouse breast tumors. I have characterized a gene encoding a novel PCI proteasome subunit, Rpn7, which was isolated as a high copy suppressor to rescue growth defects in int6 mutants. I showed that Rpn7 is essential for proper chromosome segregation, and PCI subunits could preferentially interact. For example, both Rpn5 and Rpn7 bind Rpn9 and Int6 interacts with this complex via binding to Rpn9. Through protein sequence analyses and mutagenesis, I identified a conserved leucine residue in Rpn7, which is critical for its localization and binding with Rpn9. The importance of this residue has been further verified in Int6. These data imply that PCI domain facilitates protein-protein interaction that is pivotal for the assembly of the proteasome.

2670 Appropriate Localization of Retinoblastoma Protein (pRB) in the Nucleus Correlates with Tumor Suppressor Activity
L. A. Collins,1 F. K. Kornelak,1 University of Washington, Seattle, WA

Past studies have shown that the retinoblastoma protein (pRB) exists in the nucleus as a mobile pool, associating with different nuclear subcompartments, such as the nucleolus and the soluble nucleoplasm. pRB transiently localizes to the nucleolus during passage through G1, which can be disrupted by the presence of viral oncoproteins. In order to gain insight into whether nuclear localization is necessary for pRB’s tumor suppressor activity, we have screened various point mutants including low penetrance tumor alleles, C712R and R661W, for their localization patterns compared with wild-type pRB in cells lacking endogenous pRB. We find that C712R cannot attain nuclear localization, whereas another point domain mutants, such as R661W and K713A, can reside at the nucleolus but at lower frequencies than wild type pRB. Importantly, pRB’s localization at nucleoli coincides with induction of senescence in SAOS2 cells, and persists during the formation of large condensed nucleoli as determined using simultaneous GFP and senescence-associated ß-gal labeling. One exciting possibility is that pRB localization to the nucleolus induces large-scale chromatin condensation of rDNA resulting in the morphologically distinct single nucleolus observed in senescent cells. Possible causes for different localization of RB alleles are being examined, and include altered phosphorylation status and protein stability. The substitution of different residues at C712 results in different frequencies of nucleolar residence, suggesting that strongly destabilizing substitutions are more likely to abrogate localization. The failure of mutants to accumulate at sites of activity is being explored in light of a proposal by Otterson et al. 1999 that low penetrance tumor-derived alleles of pRB fail in their function as tumor suppressors due to fact that they are less stable.

2671 In Silico Modeling of ERK2 Docking Domains and Development of Substrate Selective Inhibitors
F. Chen, A. Macias, A. D. MacKerell, P. Shapiro; Pharmaceutical Science, University of Maryland School of Pharmacy, Baltimore, MD

Extracellular signal regulated kinase proteins (ERK1 and ERK2) are important in regulating cell growth, proliferation, and differentiation. Over-activation of the ERK pathway by mutations in upstream components is thought to play a significant role in the development and progression of cancer. However, ERK substrates are not only involved in cancer cell proliferation and survival, but also participate in physiological functions of non-cancerous cells. Therefore, selective inhibition of ERK regulation of substrates involved in cancer cell proliferation may be a potential approach to improve existing therapies for treating cancers with elevated ERK pathway activity and reduce drug toxicity in normal cells. In these studies, we used computer aided drug design (CADD) with the 3D structure of active ERK2 to identify novel compounds that have the potential to selectively disrupt ERK2 interactions with substrate proteins. CADD identified small molecular weight compounds that potentially targeted a groove between the CD domain (Aspartate 316 and 319) and ED domain (Threonine 157 and 158) on ERK2. These compounds were analyzed in immunoblotting, cell proliferation and ERK2 binding assays. The results revealed that several compound can effectively inhibit phosphorylation of the ERK substrate, ribosomal S6 kinase-1 (RSK-1), which interacts with the CD domain, and proliferation of cultured cancer cells. Importantly, none of the test compounds inhibited phosphorylation of ERK by the upstream MKK1/2 or p38 MAP kinase mediated phosphorylation of the transcription factor, ATF2. In addition, active test compounds showed ERK2-specific binding using fluorescence quenching assays. These studies demonstrate the utility of using CADD in silico modeling and biological assays to rapidly identify small molecular weight compounds that are non-competitive for ATP binding and show selective inhibition of ERK interactions with substrate proteins.

2675 Mono and Dual Phosphorylated Erk1 and Erk2 Measured in Breast Cancer Cell Lines
K. Hacker,1 U. Nguyen,1 E. Gentlen,1 J. Knittle,1 N. Parker,1 K. Voss,1 R. Neve2; 1Cell Biosciences, Palo Alto, CA, 2Lawrence Berkeley National Laboratory, Berkeley, CA

Multiple techniques are being used to discover biomarkers to stratify cancer biopsies and predict response to drug therapies. Erk1 and Erk2 are key kinases in the MAP kinase cascade that play a roll in cell growth. Erk1 and Erk2 are activated by phosphorylation of a threonine and a tyrosine. Here we use a capillary system to separate singly and doubly phosphorylated forms of Erk1 and Erk2. We then measure the percent phosphorylation without phospho specific antibodies. Western blotting, which separates proteins based on size, is unable to resolve these different phosphorylated forms. In our initial studies, three breast cancer cell lines were compared with a normal tissue culture line, MCF10A. We observed significant differences in the ratios and levels of mono and dual phosphorylation forms of Erk1 and Erk2 across the breast cancer cell lines. We are now expanding our studies to look at Erk and other protein phosphorylations in a panel of 50 breast cancer cell lines.

2676 Fast Dissociation of Cancer Cell Colonies by Lysophosphatidic Acid (LPA) Causes ß-Catenin Dependent Gene Expression Changes by a Novel Perinuclear Accumulation Mechanism
Y. Kann, H. Yamashita, V. Quaranta; Department of Cancer Biology, Vanderbilt University, Nashville, TN

Lysophosphatidic acid (LPA) has been suggested as a potent modulator of motility and proliferation of epithelial cancer cells through its specific G-protein coupled receptors. We previously reported that LPA induces rapid colony dispersal in A431 carcinoma cells (Jouquin et al. (2006) J. Cell Physiol.). The colony dispersal is accompanied by rapid dissociation of cell-cell adherens junctions (AJ) and robust cell migration. Here we report that AJ components including E-cadherin, α-catenin and β-catenin were internalized within minutes and accumulated at the perinuclear region upon LPA stimulation. Even before dissociation of cell-cell adhesion became obvious, β-catenin rapidly reached a perinuclear region that appeared to overlap with early
endosome distribution. E-cadherin was colocalized in the same region. Perinuclear β-catenin was translocated into nucleus when GSK-3β was inactivated by LiCl, or proteasome functions were impaired by MG132. However, LiCl or MG132 alone could not effectively induce β-catenin nuclear translocation. After 12-24 hours from LPA stimulation, changes in cell motility-associated gene expression were detectable by real-time PCR. Nuclear β-catenin has been directly implicated in cancer cell phenotypic changes (e.g., epithelial-mesenchymal transition) that prelude to invasion. Our results unveil a novel intracellular transport mechanisms whereby β-catenin can reach the nucleus, via a previously unknown perinuclear sorting compartment. More generally, our results suggest that LPA, released in the tumor microenvironment (e.g., by platelets, due to the frequent occurrence of inflammatory or remodeling processes in tumor tissue), may play an immediate and long-lasting role in inducing invasive behavior in cancer cells.

2677
Mig-7 Expression Allows Carcinoma Cells to Sense a 3D Environment, to In invade and to Form Vessel Structures
A. P. Petty,1 K. L. Garman,1 J. S. Lindsey2; 1School of Molecular Biosciences, Washington State University, Pullman, WA, 2Pharmaceutical Sciences, Washington State University, Pullman, WA
Cancer cell interactions with the tumor microenvironment are critical for disease progression. However, the molecular mechanisms are not fully understood. We hypothesize that an atypical gene expression, Mig-7, which is induced by receptor tyrosine kinase and src55 integrin signaling, plays a role in this process because cancer cell dissemination in vivo requires these signal transduction. Specifically, we hypothesize that Mig-7 expression causes tumor cells to masquerade as endothelial cells, a process called vasculogenic mimicry thought to be important for cancer progression. We base this hypothesis on our previous data that suggest Mig-7 expression is limited to embryonic cytrophoblast cells (CTB) that invade and undergo pseudovascularization during placenta formation and to invasive carcinoma cells from multiple tissue types. Our results show that tumor microenvironment growth factors (HGF, IGF-1 and EGF) that regulate PI3K, a signaling pathway required for vasculogenic mimicry, induced Mig-7 expression in src55-positive carcinoma cells. In 3D cultures, stably transfected colon carcinoma cells expressing Mig-7 formed vessel-like structures in contrast to empty vector transfected cells that formed colonies. Mig-7 expression significantly diminished adhesion to laminin, an extracellular matrix heterotrimer that has a y chain cleaved during vasculogenic mimicry and invasion. We also found that melanoma cells previously characterized to invade aggressively and undergo vasculogenic mimicry expressed Mig-7 while noninvasive melanoma cells lacked Mig-7 expression. In our nude-mouse model of metastasis, immunohistochemistry revealed Mig-7 protein predominantly co-localized with Factor VIII-associated antigen, a plasma protein and endothelial cell marker, to vessel-like structures of metastasized lymph node. Given these findings, we speculate that Mig-7 expression allows cancer cells to sense their environment, to invade and to undergo vasculogenic mimicry. Therefore, Mig-7 may serve as a molecular target for future therapies aimed to modulate tumor progression.

ROCK II Modulates Tumor Cell Invasion in Colon Cancer via Invadopodia
S. C. Glover,1 J. Huq,1 R. Vishnubhota,2 G. Guzman,3 M. Bulic,4 S. Sun,4 M. Cho5; 1Medicine, University of Illinois at Chicago, Chicago, IL, 2Pathology, University of Illinois at Chicago, Chicago, IL, 3Bioengineering, University of Illinois at Chicago, Chicago, IL
MET in the colon follows a strict 2-D axis as stem cells differentiate into enterocytes and migrate up the crypt-villus axis. In colon cancer, this axis is disrupted and tumor cells undergo migratory reversal allowing them to invade into the submucosa and beyond. One major pathway that has been shown to be critically influenced by the tumor microenvironment is the Rho/ROCK pathway. Evaluation of these proteins in resected human colon cancers revealed up-regulation of ROCK II, a downstream effector of Rho, at the invasion front. ROCK II has been linked with other greater invasion and metastasis in other solid tumors but its role in colon cancer invasion has yet to be fully defined. The goal of this study was to evaluate the behavior of ROCK II in non-malignant (NCM 460) and malignant (Caco-2 EP90 and SW 620) colon epithelial cell lines grown in a 3-D type 1 collagen scaffolds. Scaffolds were evaluated at 1, 3, and 5 days post invasion for phenotypic appearance of cells, depth of invasion, ROCK II expression and localization, proliferation, collagenase activity, and overall ROCK activity. Multiphoton images revealed that both NCM 460 and Caco-2 EP90 cells invaded the scaffolds and formed "crypt-like" structures. SW 620 cells penetrated deeply into the scaffold, degraded collagen two-fold more, but had significantly lower proliferation. When probed with antibodies specific for ROCK II, structures resembling invadopodia were noted in both Caco-2 EP90 and SW620 cells but not in NCM 460 cells. Finally, ROCK activity was three fold higher in the SW 620 cells 24 hours post invasion as compared with the other cell lines evaluated. This data suggests that ROCK II may play a direct role in colon cancer invasion through its action at the site of invadopodia.

Midkine, a Potential Tumor Biomarker, Is Enhanced in Huh7 and HepG2 Human Hepatoma Cells
Y. Zhou, H. Xu; R & D, AbboMax Inc, San Jose, CA
Midkine (MK) is currently discovered as a new member of a unique heparin-binding neurotrophic factor or cytokine family which is composed of MK and PTN (Pleiotrophin). MK plays important roles in development, neuronal survival and differentiation, tissue remodeling and carcinogenesis. The augmented expression of midkine has been revealed in many advanced tumors at very high frequency in non-tissue specific manner. The serum midkine level is increased in many cancer patients, making the detection level of MK a potential tumor marker in clinical diagnosis. We have developed immunoassays to detect midkine based on a panel of high affinity and specificity antibodies against human midkine. The Huh7 and HepG2 hepatoma cells were grown in high-glucose DMEM with essential supplements. The culture mediums were collected at 4th passage with 80% confluence for midkine ELISA detection. The protein extracts were prepared from 10 7 cells/ml by adding lysis buffer, half of the samples were used for midkine ELISA detection, and the other half were fractionated by sodium deoxycholate-sulfate-polyacrylamide gel electrophoresis (10% SDS-PAGE). We found that the antibodies can recognize ~14 kDa protein from the hepatoma cell lysates, these immunoreactive bands can be blocked by recombinant protein midkine. Further more, MK levels are detectable in the hepatoma cell culture mediums (12.6ng/ml, n=20, CV=9.8%) as well as the cell lysate preparations (15.1 ng/10 6 cells, n=10, CV=14%) compared to the non-detectable MK levels from the negative controls. In conclusion, the fast and sensitive ELISA method for midkine detection can be a potential tool for clinical diagnosis. The attempt of targeting midkine might be a plausible approach to illustrate the midkine in anti-apoptotic, angiogenic and other carcinogenesis-related activities.

Ubiquitination of Mitochondrial Proteins Triggers Apototic Cell Death in Cell Culture Models of Parkinson's Disease: A Novel Regulatory Function of Lysine 48 and -63 Ubiquitin Sites
F. Sun, V. Anantharam, A. Kanthasamy, A. G. Kanthasamy; Biomedical Sciences, Iowa State University, Ames, IA
Ubiquitin proteasome system (UPS) dysfunction and mitochondrial impairment have been linked to neurodegeneration of Parkinson's disease (PD). Recently, we demonstrated that environmental neurotoxic, estrogen, dieldrin, and Mg-2+ enhanced UPS function in dopaminergic cells and that the proteasomal inhibitor MG-132 promotes nigral dopaminergic degeneration in both in vitro and in vivo models. To further determine the inter-relationship between UPS dysfunction and mitochondrial impairment, we systematically examined the sequence of cellular events in dopaminergic neuronal (N27) cells following exposure to dieldrin and MG-132. Subcellular analysis of ubiquitinated protein revealed a rapid and profound accumulation of polyubiquintinated proteins in mitochondria. The magnitude of mitochondrial ubiquitinated accumulation was much more than that of cytosolic accumulation, indicating that mitochondria are

2006 ASCB Annual Meeting Abstracts

491
early sensors of ubiquitinated protein stress. Time course studies revealed that accumulation of ubiquitinated proteins in mitochondria precedes activation of mitochondrial apoptotic cascade. To determine whether the accumulation of polyubiquitinated proteins in the mitochondria is involved in the mitochondria apoptosis events, we established cell lines stably expressing wild type or two ubiquitin site mutants lysine 48 (K48R) and lysine 63 (K63R). Results showed that K48R mutant ubiquitin significantly suppresses dieldrin and MG-132 induced caspase-9, and -3 activation, suggesting that accumulation of K48R polyubiquitin tagged proteins plays a critical role in activating mitochondrial apoptosis. Interest in A53T alpha-synuclein mutation at lysine 63 (K63R), which is not required for dieldrin polyubiquitination, is increasing for its potential for UPS degradation, greatly sensitized N27 cells to dieldrin or MG-132 induced apoptosis, indicating that lysine 63 may have some protective function during ubiquitinated protein stress. Collectively, these novel findings demonstrate an intrinsic link between mitochondrial ubiquitination, UPS dysfunction and apoptotic cell death in dopaminergic neuronal cells and also suggest that polyubiquitination sites may determine the fate of cell survival by regulating the mitochondrial dependent apoptotic cascade (supported by NIH grant NS45133).

Budding Yeast Model for Alpha-Synuclein: Evaluation of E46K, Catalase Deletion, and Multi-Vesicular Body (MVB) Disruption
M. D. White, M. Vahedi, M. Zorniak, K. Brandis, S. Herrera, T. Saylawala, J. Price, S. DebBurman; Biology, Lake Forest College, Lake Forest, IL
Parkinson’s disease (PD) is a common neurodegenerative disorder that results from the selective loss of midbrain dopaminergic neurons. Misfolding and aggregation of the protein α-synuclein, oxidative damage, and degradation impairment are all hypotheses for the molecular basis of this selective neurotoxicity. Here, we extend our Saccharomyces cerevisiae model to evaluate α-synuclein misfolding, aggregation, and toxicity (Sharma et al. 2006, J Mol. Neurosci. 28, 161-178). First, we describe the toxicity-inducing ability of the recently discovered E46K α-synuclein mutant and familial combination mutants (A30P/E46K, A53T and A30P/E46K/A53T). Unlike wildtype, A30P and A53T α-synuclein, the E46K mutants were strongly toxic to several, but not all, strains. They retained plasma membrane localization of α-synuclein with cytoplasmic aggregates developing after 24 hours of induction. When yeasts were challenged with an oxidant (hydrogen peroxide), α-synuclein was extremely lethal to cells that lacked manganese superoxide dismutase Mn-SOD (sod2Δ), but not to cells that lacked copper, zinc superoxide dismutase Cu,Zn-SOD (sod1Δ). Despite the toxicity, sod2Δ cells never displayed intracellular aggregates of α-synuclein. We suggest that the toxic α-synuclein species in yeast are in smaller aggregates and may involve α-synuclein membrane association and is particularly sensitive to mitochondrial oxidative stress.
Lastly, to assess lysosomal involvement in α-synuclein degradation, we assessed if α-synuclein was toxic to yeast that were deficient in the Vps family of proteins critical to the endosome-based multivesicular body pathway and thus far shown that α-synuclein accumulated and caused toxicity in only one Vps deletion strain. Thus, yeasts have emerged effective organisms for characterizing factors and mechanisms that regulate α-synuclein toxicity in PD. (Supported by NSF-MRI, NSF-CCLI & NIH R15)

Functional Validation of the Neuroprotective Capacity of Small Molecule Effectors of Alpha-Synuclein Misfolding
A. M. K. Clark, 1 C. Makowsky, 1 R. Thomas, 1 X. Meng, 3 M. Zhu, 1 J. Li, 1 A. L. Fink, 2 G. A. Caldwell, 1 K. A. Caldwell 1; 1Biological Sciences, The University of Alabama, Tuscaloosa, AL, 2Department of Chemistry and Biochemistry, University of California-Santa Cruz, Santa Cruz, CA
Parkinson’s disease (PD) involves the progressive loss of dopamine (DA) neurons over the course of aging. Mutations or multiplication of wildtype gene encoding human α-synuclein are among the most common causes of familial Parkinson’s disease. Mitochondrial dysfunction, oxidative stress, and misfolded α-synuclein contribute to the cell death in PD. This model for α-synuclein-induced DA neurodegeneration. Worms overexpressing wildtype human α-synuclein undergo a reproducible DA neuron decline that worsens with age. This degeneration can be arrested by the addition of transgene expressing either human torsinA, a protein that exhibits molecular chaperone activity, or mammalian Rub1, a guanosine triphosphatase (GTPase). Importantly, select compounds identified from the in vitro α-synuclein misfolding assays are also effective in significantly reducing the degeneration of DA neurons in vivo. This screening strategy facilitates our ability to prioritize specific candidate molecules in determining their suitability as potential disease modifying agents in mammalian models of PD.

Fission Yeast Model for Alpha-Synuclein: Evaluating Concentration Threshold to Induce Aggregation in Living Cells
L. Kukreja, M. Zorniak, K. Brandis, S. DebBurman; Biology, Lake Forest College, Lake Forest, IL
Despite fission yeast's history of modeling salient cellular processes, it has not been extensively used to model human neurodegeneration-related protein misfolding. Since α-synuclein misfolding and aggregation are linked to Parkinson's disease (PD), we recently reported a fission yeast model that evaluated alpha-synuclein misfolding, aggregation, and toxicity (Brandis et al. 2006, J Mol. Neurosci 28, 179-191). Using thiamine repressible promoters (pNMT1, pNMT4, pNMT1), wild-type alpha-synuclein and familial mutants were expressed in increasing concentrations to directly test in living cells the nucleation polymerization hypothesis for alpha-synuclein misfolding and aggregation. In support of this hypothesis, both wild-type and A53T alpha-synuclein formed cyttoplasmic aggregates within fission yeast cells in a concentration and time-dependent manner. A53T alpha-synuclein formed aggregates faster than wild-type alpha-synuclein and at a lower alpha-synuclein concentration. Here, we characterized alpha-synuclein's aggregation pattern further in live cells to determine the threshold protein concentration needed to seed aggregation. When moderately expressed (pNMT4 vector), alpha-synuclein began forming aggregates, but at just slightly lower expression (pNMT1 vector), it remained completely soluble, indicating that the concentration threshold was in between these two concentrations. Despite alpha-synuclein's extensive aggregation, it was surprisingly non-toxic to fission yeast; future genetic dissection may yield molecular insight into this protection against toxicity. Unexpectedly, different from budding yeast, wild-type and A53T alpha-synuclein did not localize to the plasma membrane in fission yeast, not even at low alpha-synuclein concentrations or as an early precursor to forming aggregates. We speculate that alpha-synuclein toxicity may be linked to its membrane binding capacity. Thus, fission yeast sheds provocative insight into alpha-synuclein's role in PD pathogenesis. (Supported by NSF-MRI, NSF-CCLI & NIH R15)

Intrabodies as Potential Therapeutics for Parkinson’s Disease
S. M. Lynch, 1 C. Zhou, 1 S. Emadi, 2 M. Siekiers, 1 A. Messer 2; 1Wadsworth Center, New York State Department of Health, Albany, NY, 2Department of Biomedical Sciences, University at Albany, Albany, NY
Misfolded proteins have been implicated in a number of progressive neurodegenerations, including Parkinson’s Disease (PD). In PD, alpha-synuclein probably plays a critical pathologic role, since it accumulates, causes toxicity when overexpressed, or when harboring specific mutations. In its native form, alpha-synuclein has an unstructured conformation, but can assume a beta-sheets configuration that predisposes it to an aggregated oligomeric form, thought to be involved in toxic gain of function. Therapeutic approaches involving the prevention of misfolding or aggregation of alpha-synuclein, or precluding it from reaching its toxic state, should prove valuable as direct therapeutics and rational drug design tools. Single-chain Fv (scFv) intracellular antibodies (intrabodies) against alpha-synuclein can be selected, engineered, and delivered as genes. They have the potential to bind and stabilize monomeric alpha-synuclein, reduce the presence of higher oligomeric forms, and counteract toxicity. Screening involved using transient transfections of cell lines ST14A, BI03, and human cells H4, with wild-type or mutant alpha-synuclein +/- the intrabody of interest, followed by Toxicity and MTT assessment of toxicity and viability, in 96-well plates. Transfection of A53T alpha-synuclein into ST14A cells (a conditionally-immortalized rat striatal cell line) gave the most consistent results. We have also tested for correction of synuclein-mediated growth impairment in HEK-293 cell lines stably transfected with alpha-synuclein. Intracytochemistry to localize a-syn and intrabody, plus Western blots, are used to more fully assess effects of the intrabodies on overexpressed alpha-synuclein. The intrabodies selected and tested to date target monomeric alpha-synuclein (apparent conformational epitope), oligomerized alpha-synuclein (selected using atomic force microscopy), the putative hydrophobic interaction region of alpha-synuclein, and peptides covering the A30P mutation region. Protection in one or more of the assays has been observed with one intrabody from each of the first three categories, validating a role for engineered antibody fragments in neurological therapeutics. Identification of Putative Genetic Susceptibility Factors Associated with Parkinson’s Disease
R. N. Rivas, S. Hamamichi, K. A. Caldwell, G. A. Caldwell; Biological Sciences, The University of Alabama, Tuscaloosa, AL
Investigations into familial forms of Parkinson’s Disease (PD) have identified several mutated single gene products associated with protein mishandling and oxidative stress. For example, mutant or overexpressed alpha-synuclein results in the formation of characteristic protein inclusions called Lewy bodies. Human torsinA (torA), a protein linked to another hereditary movement disorder termed early-onset torsion dystonia, is highly expressed in dopaminergic neurons, and has been detected in Lewy bodies. We investigated the functional relationship between alpha-synuclein
and torA by generating an isogenic line of C. elegans that co-expresses TOR-2 (C. elegans torA homolog) and human alpha-synuclein fused to GFP in the body wall muscles. We found that overexpressed TOR-2 could ameliorate the formation of alpha-synuclein aggregates in vivo. We then employed RNAi feeding methods to systematically screen for factors that affect alpha-synuclein misfolding at a threshold of misfolding maintained by TOR-2 co-expression. A total of 900 candidates were analyzed including worm homologs of known PD genes, gene products co-expressed or interacting with these proteins, and gene targets with roles in protein folding and degradation. We identified 20 positives that result in increased alpha-synuclein misfolding and determined that 14 of these may function in a TOR-2-independent manner. We previously reported that tormis expressed in C. elegans dopamine neurons protect these cells from neurodegeneration. By generating transgenic worms in which cDNAs encoding prioritized candidates from these 20 positive gene products are overexpressed in dopamine neurons, we have thus far demonstrated that at least two of these proteins also display neuroprotection from alpha-synuclein-induced neurodegeneration in vivo. Further analysis is underway to determine if additional gene products identified through our screen function in a similar manner. These data provide a paradigm for investigating factors that influence protein misfolding and the management of intracellular stress associated with movement disorders.

The E46K Mutation in Alpha-Synuclein Associated with Early-Onset Parkinson's Disease Modulates SERCA2b Levels
S. Keller, Y. Yu, O. Platoshyn, J. Yuan; Medicine, University of California, San Diego, La Jolla, CA
Three mutations (A30P, A53T and E46K) in the gene encoding the pre-synaptic protein alpha-synuclein are associated with inherited early-onset Parkinson’s disease, which like the common age-related sporadic form, has the hallmark of dopaminergic neuron decline in the substantia nigra. The mechanisms associated with expression of the mutant alpha-synucleins and dopaminergic neuron death have not been fully resolved. The E46K alpha-synuclein was discovered in a large Spanish family, with complete segregation for disease onset in the heterozygous configuration. Previous studies have demonstrated that E46K alpha-synuclein has a higher affinity for phospholipid membranes compared to wild-type alpha-synuclein and other mutant alpha-synucleins. We performed heterologous expression experiments in HEK-293 and CHO cells to elucidate characteristics of E46K alpha-synuclein that may elicit pathological mechanisms leading to Parkinson’s disease. Although lacking a signal sequence, E46K alpha-synuclein associates with the endoplasmic reticulum (ER) membrane, as well as the cell surface membrane, as detected in immunofluorescent microscopy images. Expression of E46K alpha-synuclein appears to increase cell surface membrane permeation, deplete intracellular calcium stores and elevate store-operated calcium influx, as detected by calcium imaging technology. Furthermore, expression of E46K alpha-synuclein reduces the steady-state expression levels of the SR/ER calcium ATPase SERCA2B, which is involved in replenishing the ER with calcium. Based on this heterologous cell expression model, a combination of dysregulated calcium fluxes from the cell surface and a reduced ability to regulate ER calcium levels may impair the longevity of dopaminergic neurons.

Mitochondrial Localization of Mutant SOD1 Recapitulates the Mitochondrial Dysfunction Associated with ALS
I. Hervias, M. S. Henning, M. Dumont, G. Manfredi; Neurology/Neuroscience, Weill Medical College of Cornell University, New York, NY
Amyotrophic lateral sclerosis (ALS) is a progressive, neurological disorder characterized by motor neuron degeneration. Mutations in Cu,Zn-superoxide dismutase (sOD1) are responsible for 20% of familial ALS cases, via a toxic gain of function mechanism. SOD1 is mostly cytosolic, but a portion is localized in the mitochondrial intermembrane space (IMS). In this study, we have attempted to elucidate whether the IMS localization is responsible for the mitochondrial abnormalities observed in SOD1-ALS, or if a secondary mechanism via cytosolic SOD1 is at fault. We have stably transfected NSC34 motor neuronal cells with wild-type sOD1, as well as G93A and G85R mutant sOD1, either with or without an IMS targeting signal. The toxic effects of various cellular substrates were compared in cells expressing IMS and those in which IMS was deleted. Under metabolic stress conditions, such as serum deprivation and growth in poorly fermentable substrates, both IMS and untargeted sOD1 mutants resulted in increased toxicity. Mitochondrial oxidative stress with rotenone, coupled with glutathione depletion, also caused increased toxicity, in both targeted and untargeted mutants. We have recently generated transgenic mice expressing IMS-targeted G93A sOD1, and performed an initial phenotypic and biochemical characterization. Despite very low protein expression in the IMS, male transgenic mice (but not females) were chronically hypoxic and displayed a moderate motor impairment, as compared to non-transgenic littermates. Similar to their non-IMS targeted counterparts, these mice do not have a cognitive impairment. At ten months of age, male transgenic mice had impaired respiratory chain function in neural mitochondria. The difference between males and females is intriguing and needs to be further elucidated. These results indicate that IMS localization of mutant sOD1 can recapitulate the mitochondrial dysfunction found in cells and mice expressing mutant sOD1, and suggest that the IMS portion of the mutant protein is responsible for this dysfunction.

Nuclear Import-related Protein Expression at Multiple Steps Is Altered Following Inhibition of Long-term Potentiation (LTP) in a Rat Model
L. G. Sheffield; Pathology, SUNY Downstate Medical Center, Brooklyn, NY
In Alzheimer’s disease (AD) brain, a close association between nuclear pores and the paired helical filaments that form neurofibrillary tangles has been observed ultrastructurally. In addition, neuronal contour irregularity was more common in AD than controls and was frequently associated with neurofibrillary tangles. Moreover, cytoplasmic accumulation of nuclear transport factor 2 (NTF2) was found in a subset of hippocampal neurons in AD cases (J Neuropath Ex Neurol 65:45-54, 2006). In ongoing studies of the distribution of cytoplasmic transport-related proteins in brain, sections from rat brain were immunohistochemically labeled using antibodies directed against four nuclear import-related proteins: Nup62 (nucleoporin p62, BD Transduction), NTF2 (BD Transduction), karyopherin-α (NPI-1, Zymed), and importin-β1 (NTFp97, Affinity BioReagents). In an earlier study (J Neurophysiol Exp Neurophysiol 64:443, 2005), we reported that sparse neurons in the dentate gyrus and cortex were labeled with karyopherin-α, while importin-β1 immunoreactivity was found in neuronal nuclei throughout the rat brain. In the present study, Nup62 labeling was consistent with that found in human brain (e.g., all nuclei exhibited punctate labeling of the nuclear contour), however NTF2 labeling was not visible in normal cells. For all four antibodies, immunoreactivity was much more extensive in areas affected by prior induction and subsequent inhibition of LTP. Strong immunopositive labeling was observed in neuronal cytoplasm extending with the dendrites of numerous neurons in the ipsilateral treated hemisphere as well as in the most medial hippocampal neurons of the contralateral hemisphere. These results lend support to the hypothesis that neuronal expression of nuclear import-related proteins may be activity dependent. Changes in neuronal activity during neurodegeneration may lead to alterations in expression and localization of the nuclear import system, and contribute to formation of pathophysiological markers such as neurofibrillary tangles.

Abundance of Gigaxonin in the Nervous System and Determination of the Ubiquitination Activity of the Gigaxonin Mediated E3 Ligase in Disease
P. Bonnot, K. Yamazaki, D. Cleveland; Cell Biology, LICR, La Jolla, CA
Mutations in the gene encoding gigaxonin are causative for the fatal, early-onset recessive neurodegenerative disorder Giant Axonal Neuropathy (GAN). A crucial role for gigaxonin in neuronal maintenance was suggested by impairment of the motor/sensory tracts of the peripheral and central nervous systems. GAN, as many other neurodegenerative disorders points to the essential role of cytoskeleton architecture in neuronal function, and especially to the implication of Intermediate Filament disorganization in neurodegeneration. We studied here the expression pattern and the abundance of gigaxonin in various nervous tissues and compared the activity of the gigaxonin-E3 ligase with the wild type protein and the disease associated mutants. Using monoclonal antibodies directed against gigaxonin and extracts from lymphoblast cell lines derived from GAN patients, multiple disease causing GAN mutants are shown to be unstable, demonstrating that GAN is caused by the loss of function of gigaxonin. Gigaxonin is shown to accumulate only to an extremely low level throughout the peripheral and central nervous systems and to be unaffected in multiple mouse models that develop progressive motor neuron disease from expression of an ALS-linked mutation in SOD1. In order to determine the activity of the
A Metabolic Insight into the Dopaminergic, Glutamatergic, and Na+-K+-ATPase Interactions of Schizophrenia

E. K. Nanitos1, T. Wallis2, S. B. Parekh3, W. A. Bubba4, C. Race,5 V. J. Balcar2; 1Anatomy and Histology, The University of Sydney, Camperdown, Australia, 2School of Molecular and Microbial Sciences, The University of Sydney, Camperdown, Australia, 3Pathology, The University of Sydney, Camperdown, Australia, 4Prince of Wales Medical Research Institute, The University of New South Wales, Randwick, Australia

The neuronal death in schizophrenia is thought to involve the interactions of both the dopaminergic and glutamatergic systems. This is partly because various dopamine antagonists are able to alleviate some of the symptoms of schizophrenia and there have been some shown to down-regulate glutamate transport (GLuT). Additionally the glutamate N-methyl-D-aspartate (NMDA) receptor antagonism ketamine was able to show some of the positive and negative symptoms of schizophrenia. The present study explores the effect of dopamine agonist bromocriptine mesylate and antagonists (remoxipride hydrochloride and haloperidol) in order to determine the acute effect of the dopaminergic modulation on brain metabolism. Ouabain, a potent inhibitor of the Na+-K+-ATPase and also an inhibitor of GLuT was used to examine a possible link between these systems as dopamine antagonists have previously been shown to cause decreases in GLuT without direct interaction with the transporters. The distribution of 13C label into isomers of brain metabolites was studied in Sprague-Dawley rat brain cortical tissue slices using 13C and 1H NMR spectroscopy. Bromocriptine (10μM and 100μM) caused a significant dose-dependent decrease in the net flux of 13C into Krebs cycle intermediates and the glutamate-glutamine cycle. Decreases in metabolite pool sizes also occurred. Remoxipride hydrochloride (20μM) and haloperidol (10μM) caused significant increases in remoxipride and haloperidol (10μM) were greater than those at 20μM. Consequently the effects of ouabain could be placing the tissue in a state of metabolic deprivation due to a lack of glutamate entering the astrocytes upon clearance from the synaptic cleft, thus resulting in compensatory increases in 13C flux into Krebs cycle intermediates. This suggests that the link between dopaminergic and glutamatergic systems does not involve regulation of, or, signalling by, Na+-K+-ATPase.

SMN Knockdown in PC12 Cells: Assessing a Role for SMN in Neuronal Differentiation

M. Bowserman, D. Shalley, R. Kohary; Cellular and Molecular Medicine, Ottawa Health Research Institute, and the University of Ottawa, Ottawa, ON, Canada

Spinal muscular atrophy (SMA) is the most common genetic disease resulting in infant mortality due to severe loss of α-motor neurons. SMA is caused by mutations or deletions of the ubiquitously expressed survival motor neuron (SMN) gene. The SMN protein is found in all cells studied in both the cytoplasm and punctate nuclear structures called Gemini of coiled bodies, which play a role in RNA metabolism. The Smn protein is also a part of a multiprotein complex, an assembly of ribonucleoproteins (RNP). Thus, SMN is considered an important housekeeping gene playing a role in fundamental cellular events such as snRNP assembly and processing of most pre-mRNAs. Although this housekeeping function of SMN is very well described, why a motor neurons of SMA patients are specifically affected is not clear. Using PC12 cells as our model system for neurogenesis, we have established a clonal line (C-59) with an 85% decrease in Smn levels, achieved through the use of short hairpin RNA interference (shRNAi). We demonstrate that Smn knockdown in PC12 cells leads to defects in neurogenesis, an increased incidence of beading and swelling along the neurites, defects in modulation and localization of F-actin and GAP-43, an increase in RhoA activity, and a decrease in Cdc42 activity. Furthermore, we observed an alteration in profilin II mRNA splicing, resulting in an increase in the neuronal-specific profilin IIa (pIIa) isoform. Moreover, the depletion of Smn, a known interacting partner of pIIa, further contributes to the increased pIIa availability. This leads to an increased formation of the ROCK/pIla complex and an inappropriate activation of the RhoA/ROCK pathway, resulting in the observed defects in neurogenesis and altered cytoskeletal integrity. Taken together, this study results in the first description of a molecular mechanism underlying SMA pathogenesis and highlights new targets for therapeutic intervention for this devastating disorder.

Episodic Ataxia Type 2 Mutants Disrupts the Membrane Trafficking of Human P/Q-type Ca2+ Channels

C. Jeng, 1M. Sun; 2T. O. Tang; 1Institute of Anatomy & Cell Biology, National Yang-Ming Univ., College of Medicine, Taipei, Taiwan, 2Dept. of Physiology, National Taiwan Univ., College of Medicine, Taipei, Taiwan

Episodic ataxia type 2 (EA2) is an autosomal dominant neurological disorder associated with mutations in the gene encoding pore-forming α1A subunits of human P/Q-type calcium (CaV2.1) channels. Virtually all CaV2.1 channels harboring EA2-related mutant α1A subunits display loss-of-function phenotypes. The exact mechanism of how mutant α1A subunits cause such clinical EA2 features as cerebellar dysfunctions, however, remains unclear. Our previous functional studies in Xenopus oocytes support the idea that both missense and nonsense EA2 mutants may exert prominent dominant-negative effects on wild-type CaV2.1 channels. To further pursue the mechanism underlying this dominant-negative effect, we examined the effect of EA2 mutants on the subcellular localization pattern of GFP-tagged wild-type CaV2.1 channels in HEK293T cells. In the presence of EA2 mutants, wild-type CaV2.1 channels displayed a significant deficiency in membrane targeting and a concurrent increase in cytoplasm retention. The cytoplasmic fraction of wild-type CaV2.1 channels co-localized with an endoplasmic reticulum (ER) marker, suggesting that a significant amount of wild-type CaV2.1 channels was trapped in ER in the presence of EA2 mutants. Taken together, our data suggest that EA2 mutants may induce significant ER-retention of wild-type α1A subunits, thereby disrupting the membrane trafficking property and suppressing the functional expression of CaV2.1 channels.

Studies of Hirano Bodies and Oxidative Stress in Neuroglioma Cells

R. Furukawa, C. Cubenas, M. Fechheimer; Cellular Biology, University of Georgia, Athens, GA

Hirano bodies are paracrine-stabilizing F-actin aggregations associated with a variety of conditions including aging, Alzheimer’s, Parkinson’s, diabetes, and other diseases. The physiological function of Hirano bodies is unknown. In an in vitro model for Hirano body formation was developed by expressing mutated forms of the 34 kDa actin-bundling protein (Maselli et al., 2002, 2003). The altered forms of the protein are termed α1A (aa 124-295) which lacks an amino terminal inhibitory region, and ΔEF1, which has mutations that affect intramolecular domain-domain interaction. Both forms exhibit activated actin bundling that causes formation of Hirano bodies. Because Hirano bodies are associated with aging and late onset diseases in which oxidative stress is implicated as a major factor, we investigated possible relations between oxidative stress and Hirano bodies. Experiments were conducted in WT (wild-type) H4 neuroglioma cells, and H4 cells transfected with either the enhanced green fluorescence protein (EGFP) or CT-EGFP. Application of oxidative stress results in formation of numerous Hirano bodies visualized by fluorescence microscopy. Later, large inclusions are present within large membrane bound organelles resembling autophagosomes. The viability of cells with and without Hirano bodies was assessed 24 hours after application of oxidative stress. All cell lines showed increased cell death with either increasing H2O2 or menadione sodium metabisulfitel concentrations. The cells expressing CT-EGFP had a significantly greater level of death, indicating that Hirano bodies increased cell susceptibility to oxidative stress. Pretreatment of the cells with the anti-oxidant N’N-dimethyl-thiothiourea restored cell viability to control levels in all cell lines, indicating that the cell death was caused by oxidative stress. Future experiments will investigate mechanistic details of these findings to better understand a possible relationship between Hirano bodies, oxidative stress, and late onset diseases. Supported by NIH NS 04645101.

The SPG20 Spastic Paraplegia Protein Spartin is Monoubiquitinated and Involved in the Degradation of Epidermal Growth Factor Receptor

J. C. Bakowska, 1H. J. Japil, 2P. Fatshedinn, 3R. Puertolato, 1C. Blackstone; 1NYU Medical Center, MD, 2NIHLAB, Bethesda, MD

Troyer syndrome (SPG20), one form of the hereditary spastic paraplegia (HSPs), characterized by spasticity of the lower limbs, dysarthria and shortness of stature is caused by a frameshift mutation in the spartin gene, which encodes a predicted 666-amino acid protein of unknown function. We have previously demonstrated by using yeast two-hybrid and pull-down assays that spartin interacts with the receptor protein tyrosine phosphatase (RPTP) and prompted us to test the function of spartin in the process of endocytosis and sorting of the cargo proteins. Immunoprecipitation experiments revealed that endogenous spartin is constitutively monoubiquitinated and examination of different deletion constructs suggested that spartin is polymonoubiquitinated. In addition, spartin binds to ubiquitin as shown by pull-down assays and yeast-two hybrid tests. Immunofluorescence microscopy studies demonstrated that over-expressed full-length spartin was predominantly cytoplasmic with distinct vesicular staining. The vesicular localization of spartin is a highly mobile fraction as revealed by fluorescence recovery after photobleaching analysis. We found that spartin is recruited to endosomes by the dominant form of GFP- Vps4-A and HA-tagged spartin co-localized with Flag-Exp15 within vesicular structures in HEK cells at steady state. We also investigated the localization of over-expressed spartin after EGF stimulation. We uncovered extensive co-localization of HA-spartin with Flag-Exp15 and EGF-Alexa at 5, 10, and 30 min after stimulation with labeled EGF. Over-expression of full-length 494
spartin in HeLa cells resulted in the significant decrease in the degradation of EGFR as demonstrated by Western blot and immunofluorescence staining. A similar effect to a lesser degree was observed after depletion of spartin by a specific siRNA. Our results suggest that spartin might play a role in the sorting of ubiquitinated endosomal cargo.

**Cellular Localization and Interactions of the Hereditary Spastic Paraplegia (SPG21) Protein, ACP33/maspadrin**

M. C. Hanna, C. D. Blackstone; Cellular Biology Unit, NINDS/NIH, Bethesda, MD

Hereditary spastic paraplegias comprise a group of disorders characterized by lower extremity weakness and spasticity, sometimes accompanied by dementia and other neurological impairments. Most syndrome, one form of hereditary spastic paraplegia, is caused by a mutation in the ACP33/maspadrin gene, whose protein product, while ubiquitously expressed in most cell types, remains functionally unknown. Our objective is to gain insight into ACP33/maspadrin function by investigating its subcellular localizations, protein-protein interactions, and consequences of gene expression elimination. As a first step toward determining ACP33/maspadrin function, we investigated potential involvement of the protein in membrane trafficking in neurons. Using Western blot analysis in combination with specific antibodies the protein was detected in mouse, monkey, and lamprey brain extracts. Using immunofluorescence, ACP33/maspadrin was observed in punctate structures in neuronal cell bodies, where it partially co-localized with gamma-adaptin, a marker for the trans-Golgi network (TGN), as well as down the axon length, and at the axon terminal with where it colocalized with synaptophasin. Immunoprecipitation experiments followed by excision of Coomassie-stained protein bands and analysis by matrix assisted laser desorption ionization (MALDI) mass spectrometry identified a possible interaction with ALDH1H1A, an aldehyde dehydrogenase family member of unknown function. Co-immunoprecipitation of myc-ALDH1H1A with endogenous ACP33 using various ACP33 antibodies confirmed the interaction, and negative results with other antibodies against other aldehyde dehydrogenase subtypes suggests relative specificity. As an attempt to create a marine model of SPG21 and further investigate the loss of function of the protein an ACP33/maspadrin knockout mouse has been generated, which is currently being characterized. Our results show subcellular localization of ACP33 in the TGN and at the axon terminal in neurons. These results support the protein a role in membrane trafficking events and may function in conjunction with a metabolic enzyme, ALDH1H1A, to fulfill this function.

**Differential Synaptic Protein Expression Profiling of Rats Fed with a High Fat Diet and Correlation with Brain-derived Neuronal Diseases Using a Proteomics Approach**

W. Lan, J. Guhaniyogi, M. J. Horn, B. Graham, J. Xia; 1Prospect Biosystems, LLC, Newark, NJ, 2Pel-Freez Biologicals, Rogers, AR

It is well known that a diet high in saturated fat (HF) not only leads to hyperlipidemia and hypercholesterolemia which increase the risk of cardiovascular diseases, but also increases oxidative stress in brains and leads to synaptic dysfunction. Despite tremendous progress, there are still some limitations for completely explaining the correlation of neuronal diseases and HF diet. Recently developed neuroproteomics has made it possible to understand the brain function in system-based approaches. However, the current proteomics technologies face a huge challenge due to the brain complexity, such as large numbers of post-translational modifications and the wide dynamic range of protein abundance. We have developed a powerful and robust technology (Edge™) for proteomics sample fractionation to reduce sample complexity and increase importance for low abundance protein isolation and biomarker discovery. In this study, we applied Edge technology and other proteomics techniques to perform a comparative analysis of synaptic protein expression profiles of rat brains with a HF diet and a control diet. Both rat brain cortex and control diet were homogenized and fractionated using Edge technology. Synaptosomal protein fractions were analyzed by western blot. The amounts of oxidized proteins containing carbonyl groups were measured by an Oxyblot kit. Selected fractions were further separated by two-dimensional gel electrophoresis. Interesting protein spots were excised, digested and identified by MALDI-TOF/TOF. The results demonstrated a possible new avenue to understand the correlation between HF diet and many neuronal diseases. In addition, Edge technology combined with other proteomics techniques likely will result in the discovery of novel biomarkers for HF diet related neuronal diseases.

**Neuregulin Enhances Nerve Regeneration through Synthetic Biocompatible Tubes**

I. Alcalde, I. De la Fuente-Ayuso, O. L. Gamboa; 1Dept. of Cell Biology, Histology and Pharmacology, University of Valladolid, Valladolid, Spain, 2Incyel, University of Valladolid, Valladolid, Spain

**Objectives:** When in a sectioned nerve the proximal and distal stumps are separated due to traumas, retractions, surgical resections, etc., and surgical approximation is not possible, it is necessary a bridge so that regeneration of nerve fibers can occur. In this study we have used tubes of biocompatible material embedded in Neuregulin (NRG-1) as a bridge between sectioned nerve stumps. **Methods:** Sciatic nerves from New Zealand rabbits were sectioned under anaesthesia and a segment was removed to create a 3 cm gap between proximal and distal stumps. In this gap we inserted and sutured a poly (L-lactide-co-glycolide) tube coated with NRG-1 10 nM. The animals survived for 75 days after which they were perfused under anaesthesia using paraformaldehyde fixative and tissue was processed for immunohistochemistry and semithin sections. Results: Rabbits treated with NRG-1 exhibits great Schwann cell proliferation from proximal and distal stumps. Schwann cells invade the tubes and form bands of Bügner. Axonal regeneration is enhanced in these treated animals and great amounts of remyelinating fibers are present. Conclusions: A poly (L-lactide-co-glycolide) tube filled only with NRG-1 is an interesting model of prosthesis to achieve correct axonal regeneration and remyelination in long distances gaps. (Supported by a grant FIS PI03/1533)

**Lethal Giant Larvae (Lgl) Controls the Polarized Delivery of Fragile X Protein and mRNA in Drosophila Neurons**

M. Pinter, P. Estes, S. Srivivasan, D. C. Zarsenus; Molecular and Cellular Biology, University of Arizona, Tucson, AZ

Fragile X protein (Fmrp) is an RNA binding protein thought to function in neural development and plasticity by controlling the transport and translation of target mRNAs. Fmrp deficiency leads to defects in neural morphology and function and causes Fragile X syndrome, the most inherited form of mental retardation. Recently, we took a forward genetic approach to identify novel functional interactors of Fmrp in Drosophila and identified lethal giant larvae (lgl), a tumor suppressor involved in the establishment and maintenance of cell polarity. Through a combined genetic, biochemical and cell biological approach, we have shown that Lgl as well as the PAR cell polarity complex are novel functional partners of Fmrp. Furthermore, we have identified a subset of mRNAs associated with the Fmrp/Lgl complex. Taken together, our previous work suggests that Lgl functions with Fmrp and a subset of target mRNAs during synaptic development and/or function. To elucidate the molecular mechanism by which Lgl regulates Fmrp/mRNA complexes during neural development we have developed an imaging system for Lgl/Fmrp/mRNA in Drosophila neurons. Primary neurons derived from the larval central nervous system exhibit well-developed and polarized neurites, which contain motile Fmrp/Lgl particles. Furthermore, Fmrp colocalizes with target mRNAs within developing neurites. We examined the distribution Fmrp granules in an lgl mutant background and found that despite the presence of normal neuronal morphology, most Fmrp is distributed in the cell soma and excluded from neurites. Interestingly, overexpression of a phospho-mutant form of Lgl (LglDA) specifically abolishes the localization of Fmrp in the axon but not in the dendrites. Together, our data suggest that we have uncovered a novel mechanism for the polarized delivery of Fmrp and associated target mRNAs in neurons, which may provide new insights into the molecular mechanisms of neuronal development and Fragile X syndrome.

**Investigating Potential Bacterial Sources of Dopaminergic Neurotoxicity in C. elegans**

J. Armagost, J. Blalock, T. Hodges, J. B. Olson, G. A. Caldwell, K. A. Caldwell; Biological Sciences, The University of Alabama, Tuscaloosa, AL

Parkinson’s disease (PD) involves the progressive loss of dopamine (DA) neurons from the substantia nigra pars compacta (SNCs). Genetic forms of PD account for only 5-10% of known cases and environmental factors appear pivotal to sporadic causality. Evidence from both environmental and genetic studies of PD suggests that overloading the ubiquitin-proteasome system is a causative risk factor for PD. Furthermore, when proteasome inhibitors were injected directly into the brains of rats, PD-like symptoms resulted (McNaught et al., 2004; Ann Neurol. 56:149-162). Many proteasome inhibitors are isolated from bacterial strains within the order Streptomycetales, which are well known for the production of secondary metabolites. To determine if exposure to Actinomycetes could cause DA neurodegeneration in C. elegans, we exposed worms to four species of Streptomycetes (S. lividans, S. venezuelae, S. griseus, and S. coelicolor). When worms were exposed to either S. griseus or S. coelicolor, worms exposed to S. lividans showed no detectable neuronal degeneration. However, worms exposed to S. venezuelae displayed neuronal degeneration that increased over time and was specific to DA neurons. The causal factor is excreted by these species, as conditioned media are sufficient for inducing the neurodegenerative effect. Initial efforts to purify the factor(s) revealed that the same factor may be excreted by both species. Furthermore, it is lipophilic and does not fit the molecular profile of known proteasome inhibitors. A systematic analysis of various enriched media is underway to determine which formulations elicit production of this secondary metabolite. We are also analyzing the effect of the excreted factor in combination with known genetic factors linked to PD, such as excess endogenous DA production, as well as LRKK2 and alpha-synuclein expression in C. elegans DA neurons.

Genetic Interactions Among Cortical Malformation Genes Mediate Susceptibility to Epileptic-Like Convulsions in C. elegans
C. J. Locke, S. N. Williams, E. M. Schwarz, G. A. Caldwell, K. A. Caldwell; 1Biological Sciences, The University of Alabama, Tuscaloosa, AL, 1Division of Biology, California Institute of Technology, Pasadena, CA

Haplosufficiency of LIS1 results in isolated lissencephaly sequence (ILS) or Miller-Dicker syndrome (MDS), neurological disorders characterized by intractable seizures long associated with defects in neuronal migration. Notably, MDS is typically more severe than ILS due to an additional deletion of a LIS1-localizing gene, I4-3-4episilop. Along with I4-3-4episilon, other genes have been shown to function in the ILS pathway, such as those encoding Nde1, dynec, CDK5, and p35. Accordingly, we have demonstrated that lis-1 mutants and dynec (dc-1) RNAi-treated escapee animals of C. elegans can exhibit epileptic-like convulsions in the presence of low concentrations of pentyleneetetrazeol (PTZ), an antagonist of GABAreceptor. Moreover, such worms do not have overt neuronal migration defects. Instead, LIS-1 pathway defective worms expressing unc-25::SNB-1::GFP (synaptobrevin) reproducibly exhibit a presynaptic clustering of vesicles, implicating aberrant release of GABA as causative for the convulsive phenotype. To determine if other genes functioning in the LIS1 pathway regulate vesicle trafficking and neuronal excitability, we identified putative orthologous worms of ILS1 pathway members through bioinformatics resources, such as CarpeDB (http://www.carpedb.ur.edu), and targeted them for phenotypic knockdown by RNAi feeding. Indeed, we observed significant changes in the distribution of unc-25::SNB-1::GFP at GABAergic synapses with multiple RNAi targets, including putative LIS1-1 pathway members, in wild-type (N2) and sensitized (lis-1 and unc-25 mutant) backgrounds. We hypothesize that diminished rates of GABA release contribute to postsynaptic overexcitation, which, like in LIS-1 pathway defective worms, is manifested as enhanced susceptibility to PTZ-induced convulsions. These findings illustrate an evolutionary conservation of LIS1 pathway function between C. elegans and humans and implicate cytoskeletal genes in the epileptic consequences of classical lissencephaly.

A Defect in the Metabolism of the Signaling Lipid, PI3,5P2, Causes Neurodegeneration in Mice
Y. Zhang, C. Y. Chow, S. C. Richardson, R. C. Piper, J. R. Westrick, M. H. Meisler, L. S. Weissman; 1Department of Cell and Developmental Biology, Life Sciences Inst., University of Michigan, Ann Arbor, MI, 2Department of Human Genetics, University of Michigan, Ann Arbor, MI, 3Department of Physiology, University of Iowa, Iowa City, IA

The low abundance signaling lipid, phosphatidylinositol 3,5-bisphosphate (PI3,5P2) is produced in the endocytic pathway. Its physiological functions are not known. PI3,5P2 is unique in that its levels change dramatically in response to specific stimuli. For example, in the yeast, S. cerevisiae, exposure to hyperosmotic shock, causes PI3,5P levels to transiently rise more than 20 fold within 5 minutes. The return to basal levels, even in the continued presence of osmolyte, is achieved by 30 minutes. As an approach to determine the physiological roles of PI3,5P2 in mammals, we have tested and found that proteins required for synthesis and turnover of PI3,5P2, are present in all tissues examined. This wide distribution suggests that PI3,5P2 plays multiple roles in signaling events that occur on internal membranes. Here we report that mice hypomorphic for the PI3,5P2 regulator, Vac14, die soon after birth. While development appears to be normal, there is massive neurodegeneration in both the central and peripheral nervous system. Cell bodies of multiple neurons are vacuolated, and large holes are present in areas where neurons should be present. Vacuolation appears specifically in neurons, however, other cell-types have the potential to form large vacuoles. These vacuoles appear first in neurons that suggest that either PI3,5P2 functions in a neuronal-specific compartment and/or that neurons by virtue of their long processes are more sensitive to general defects in membrane transport. These findings strongly suggest that the general signaling lipid, PI3,5P2, is specifically essential for neuronal survival, and raise the possibility that selected human neuropathies are caused by mutations in PI3,5P2 signaling pathways.

Matrix Metalloproteinase Inhibition Modulates the Correlation between Lipid-induced Atherosogenesis and Lipid-induced Platelet Activation
D. F. Saladin; Chemistry/Biochemistry, College Misericordia, Dallas, PA

Our model of lipid-induced early atherosogenesis in 300 g male Sprague-Dawley rats has been well characterized by transmission electron microscopy (TEM), showing typical myofoibroelastic changes in the aorta. These changes are seen after the rats receive IV infusions of Lipofundin-S dosed at 6 g fat/day/kg body wt for 10 days. Hyperglycieridemia results after one day. At day 10, platelet hyperactivity (hyperaggregation) is noted in rats receiving lipids vs. controls given an equivalent volume of saline (p<0.001), cAMP (a second messenger platelet inhibitor) generation measured in pmol/mg ptoein/min was generated linearly from isolated platelet membranes. However, cAMP levels were lower (P<0.05) vs. those observed in controls. A forskolin probe demonstrated that these lowered levels were caused by a triglyceride-induced change in the catalytic subunit of adenylyl cyclase. A separate series of experiments were performed with 25 rats. Five were no-treatment controls, 5 were saline controls, 5 received the 10-day lipid treatment, 5 received a MMP inhibitor intraperitoneally, and 5 were given lipid plus MMP inhibitor. As expected, the aortas showed no changes in both of the control groups, but neither did the MMP inhibitor alone. The lipid-treated animals showed the previously-described focal myofibroelastic changes indicative of early atherosogenesis. However, almost no such changes were seen in the rats receiving lipid plus MMP inhibitor. Although we have not yet tested the effect of the MMP inhibitor on the platelets directly, the MMP inhibitor was shown to significantly inhibit the atherosogenesis, well-known to be enhanced by activated (hyperactive) platelets, in the present model induced by hyperglycieridemia.

Glucocorticoid-induced TNFR Family-related Receptor Signaling Exacerbates Hapten-induced Collitis by CD4+ T Cells
B. Choi, S. Lee, S. Lee, Y. Kim, W. Kang, K. Kim, S. Sakaguchi, J. Suh, T. Kim, B. Kwon; 1Immunology, Immunomodulation Research Center, Ulsan, Republic of Korea, 2Experimental Pathology, Institute for Frontier Medical Science, Kyoto, Japan, 3Pathology, Ulsan University Hospital, Ulsan, Republic of Korea, 4LSU Eye Center, New Orleans, LA

Glucocorticoid-induced tumor necrosis factor receptor family-related gene (GTR) has been reported to be expressed on the activated T and CD4/CD25 regulatory T cells (Treg). GTR stimulation not only neutralizes the suppressive effect of Treg, but also augments activation, proliferation and cytokine production of effector T cells. To test the role of GTR in 2,4,6-trinitrobenzene sulfonic acid (TNBS)-induced colitis, TNBS-injected Balb/c mice were treated with agonistic anti-GITR mAb. Anti-GITR treatment increased the death rate compared to rat IgG- treated mice. Typically the death occurred within 4 days after the TNBS injection when the mice were treated with anti-GITR. The mice that survived anti-GITR treatment suffered from severe inflammation in their entire intestines. CD4+ T-depletion protected the mice from colitis; even anti-GITR effect was not apparent. In contrast, CD8+ T-depletion showed less protective effect than CD4+ T-depletion did. Stimulation of GITR enhanced the production of pro-inflammatory cytokines including IFN-γ, TNF-α, IL-6, and IL-12. It also enhanced the humoral response such as serum levels of IgG, which was completely dependent on CD4+ T cells. Taken together, this study demonstrated that GTR signaling on CD4+ T cells is involved in the development and progression of colitis by enhancing both Th1 and Th2 type responses.

E-Selectin Overexpression in HUVECs of Healthy Newborns from Mothers with Inactive Systemic Lupus Eritematosus Is Not Downregulated by Estradiol
E. Rodriguez, M. Collados, E. Zapata, A. Paez, L. Montano; 1Hoy Celular, Instituto Nacional de Cardiología, Mexico, Mexico, 2Instituto Tecnológico de Monterrey, Mexico, Mexico, 3Biotecnología, Instituto Tecnológico de Monterrey, Mexico

Systemic lupus erythematosus (SLE) is a severe autoimmune disease that affects mainly young adult women in reproductive age. There is ample evidence showing that a family history of SLE development and progress of colitis by enhancing both Th1 and Th2 type responses.

Novel Chemotherapeutic Agents for Readthrough of Nonsense Mutations
M. Shiouzka, K. Shimada, M. Arakawa, Z. Shijun, A. MacKerell, Y. Takahashi, D. Ikeda, Y. Nonomura, R. Matsuda; 1Dept. of Life Sci., The Univ. of Tokyo, Tokyo, Japan, 2The Institute of Microbial Chemistry, Tokyo, Japan, 3Dept. of Pharmacological Sci., Univ. of Maryland, Baltimore, MD

2006 ASCB Annual Meeting Abstracts

496
Translation of rudimentary pathway induction is a promising method of therapy in a large variety of genetic disorders. We previously reported that megaminogly, a dipetide antibiotic, that binds to the ribosomal decoding site and alters translational accuracy, successfully restored dystrophi expression with less toxicity than gentamicin in mdx mouse which carries a premature termination codon (PTC) in the dystrophin gene. In order to investigate more potent pathway inducer with less toxicity and measure readthrough efficiency with quantitative accuracy, we have established three transgenic mouse strains containing dual-reporter gene composed of beta-galactosidase and luciferase connected with different PTC (Ochre, Amber, Opal) region. Using these Tg mice, we confirmed the evaluation of readthrough activity in each tissue in vivo and the efficacy of antibiotic treatment in a dose-dependent manner by transdermal administration. Moreover, we found five novel compounds which targets nonsense mutations, such as C10H11N3O4, C6H10N2O4, C10H14N2O7, C8H15N3O4, and C2H15N3O8. These low-molecular weight drug candidates are sterically related negaminoglycine-like molecules identified via in silico screening from over one million compounds, and allows the cellular machinery to bypass the nonsense mutation and continue the translation process with subcutaneous injection daily for 7 days at 4mg/kg. The first and second series presented had similar efficacy to gentamicin in a dose-dependent fashion without subacute toxicity. The fifth series resulted in the most potent compounds with efficiency. The chemotherapeutic agents that overrides PTCs and its translational drug delivery may provide significant value in treating genetic diseases caused by nonsense mutations. This work was supported by a Research Grant for Nervous & Mental Disorders and by a grant for Research in Brain Science from the Ministry of Health, Labor and Welfare, Japan.

2707 Characterization of Alternatively Spliced Transcripts of the NOD2 Gene: Intrinsic Modulation of the NOD2/RIP2 Signaling Pathway

P. C. Rosenstein,1 K. Huse,2 A. Till,3 S. Billmann,4 C. Sina,3 M. Platter,5 S. Schreiber;6 Institute for Clinical Molecular Biology, Kiel, Germany, 2Genome Research, FLI Leibniz Institute Jena, Jena, Germany, 3FLI Leibniz Institute Jena, Jena, Germany

Background: Alternative splicing contributes to the regulation of gene function by generating endogenous inhibitor or activator molecules. NOD2 is an intracellular receptor for the bacterial cell wall component muramyl dipeptide and plays an important role in initiating immune responses against cytovasive pathogens. NOD2 overexpression sensitizes intestinal epithelial cells towards bacterial cell wall components, activates the pro-inflammatory transcription factor NF-kB and induces the subsequent release of the chemotactic cytokine IL-8. Aims&Results: We assessed the function and regulation of several transcription isoforms of NOD2 generated by the skipping of the exons in the CARD-CARD and LRR region. It is shown that NOD2 splice forms are preferentially expressed in the normal colon and are upregulated by the anti-inflammatory cytokine IL-10 (CARD exon splicing) or infection with intracellular bacteria (LRR exon splicing). Most spliceforms lacking LRR exons interfere with the NOD2-induced NF-kB activation (reporter gene assay) and IL-8 release (ELISA). A short CARD-only isoform generated by skipping of exon3 with a subsequent frameshift interferes with the assembly of the “nodosome”, as it interacts with both, NOD2 and RIP2 and inhibits NOD2/RIP2 oligomerization upon ligand sensing. Conclusions: These data unveil another level of complexity in the regulation of intracellular innate immunity and may have important implications for the molecular understanding of NOD/NALP protein-driven disease pathophysiology.

2708 Sabiporide, a Specific Na+/H+ Exchanger Inhibitor, Attenuates the Blood-Brain Barrier Damage through Intracellular Ca2+ Overload

S. Patr1,2,3, S. Y. Lee,4 Y. Y. Jung1,4, E. Bak,5,6 C. Moon,1,4, Y. Jung1,4, 1Department of Physiology, Ajou University, Suwon, Republic of Korea, 2Brain Korea 21 Project, Brain Korea 21 for Molecular Science and Technology, Suwon, Republic of Korea, 3Medical Science Division, Korea Research Institute of Technology, Daejon, Republic of Korea, 4Brain Korea 21 for Medical Science, School of Medicine, Suwon, Republic of Korea

Cerebral ischemia induces disruption of blood-brain barrier (BBB), which leads to increased vascular permeability and the formation of brain edema. Formation of cerebral edema caused by vascular leakage is a major problem in various injuries of the central nervous system (CNS), such as stroke. Therefore, we examined the effect of a selective NHE inhibitor, sabiporide, on the BBB damage using in vitro and in vivo models. In mouse brain microvessel endothelial cells (bEnd.3 cells) exposed to oxygen-glucose deprivation (OGD), a significant increase in intracellular calcium ([Ca2+]i) was observed, and this was inhibited by sabiporide. Sabiporide and Ca2+ chelator treatment attenuates OGD-induced BBB permeability increase. Disruption of TJ proteins (ZO-1, Claudin-1) during OGD were significantly inhibited by treatment with sabiporide and Ca2+ chelator. In addition, sabiporide treatment decreased the BBB permeability and inhibited TJ proteins disruption in rat brain middle cerebral artery (MCA) occlusion model. These results suggest that sabiporide, has an important role in regulating [Ca2+]i during ischemia and thereby, preventing BBB damage. Therefore, sabiporide might be a potential therapeutic agent for cerebral edema. This work was supported by a grant (CRB2-300-001-1-0-02) from the Center for Biomedical Innovators of the 21st Century Frontier R&D Program, the Ministry of Science and Technology and by a grant (R-01-2005-000-10510-0) from Basic Research Program of the Korea Science and Engineering Foundation.

2710 Genetic Pathways That Regulate Stress Response, Aging, and Immunity in Caenorhabditis elegans

A. Aballay; Molecular Genetics and Microbiology, Duke University, Durham, NC

Genetic studies have led to the identification of Caenorhabditis elegans signaling pathways that are required for defense response in both nematodes and mammals, suggesting that despite the vast evolutionary gulf between nematodes and mammals, some of the underlying mechanisms of defense response may be similar. Our laboratory has recently dissected two conserved pathways required for C. elegans immunity. A p38 MAPK/CEG-3 pathway and a heat shock transcription factor HSF-1 pathway that is elicited by increased temperature independently of p38 MAPK/CEG-3. A number of genes encoding conserved effector molecules of the innate immune system as well as potentially relevant signaling molecules and transcription factors were identified. Transgenic lines carrying promoter-gfp reporters indicate that many of these genes are expressed in tissues that are in direct contact with pathogens and are crucial to prevent bacterial invasion. The HSF-1 defense response regulates heat-shock-mediated immunity independently of the p38MAPK/CEG-3 pathway and through a system of chaperones including small and 90 kDa inducible heat shock proteins. In addition, HSF-1 is needed for the effects of the DAF2 insulin-like pathway in defense to pathogens, indicating that interacting pathways control stress response, aging, and immunity. Our results also show that the HSF-1 pathway is required for C. elegans immunity against Pseudomonas aeruginosa, Salmonella enterica, Terixia pestis, and Enterobacter aerogenes, indicating that HSF1 is part of a pan-pathogen defense pathway. Fever is an ancient immune mechanism used by metazoans in response to microbial infections. While homothoraces are capable of internally increasing the body temperature, poikilothersms migrate towards warmer environments to increase their temperature in response to infections. The activation of the HSF-1 pathways by heat shock and its function in C. elegans immunity provides both a molecular explanation for the beneficial role of behavioral fevers in poikilothersms and a mechanism by which fever works in metazoans.

2711 Apoptosis and Achalasia in Pneumomiasis

M. G. Pacheco-Tovar,1 J. J. Bollain-y-Goytia,1 E. Vega-Memije,2 L. López-Robles,1 R. Herrera-Esparza,1 E. Avalos-Díaz;2 1Immunology, UABE, Universidad Autónoma de Zacatecas, Zacatecas, Mexico, 2Department of Dermatology, Hospital "Sanborns" Doctor Manuel Gonzalez, Mexico, DF, Mexico

Pneumomiasis is an autoimmune disease, characterized by intraepidermal blisters due to anti-desmoglein 1 and 3 autoantibodies. These autoantibodies target the desmosomal antigens inducing epithelial cell detachment, such phenomenon is called achalasia. Pneumomiasis autoantibodies are pathogenic because cause achalasia, their binding on the epidermal cell surface triggers a kinase mediated down signal transduction that results in cell detachment and desmosomal breaking down. Another mechanism involved in blistering is inflammatory cytokines such as TNF that possible induce apoptotic features on keratinocytes near to the blisters. Present work assesses the role of apoptosis in the blister formation in pneumomiasis. Twenty Pneumomiasis biopsies were studied by H&E staining, apoptotic features were defined by TUNEL. Expression of pro-apoptotic molecules such as Fas, Fasl and Caspase 3 and Hax were studied by in situ hybridization and immunohistochemistry. Cells subset infiltrated were studied by direct immunofluorescence with anti-CD3, CD4 and CD8 antibod...

The Heat-Shock Factor HSF-1 Pathway Regulates Stress Response and Innate Immunity in C. elegans

V. Singh, A. Aballay; Mol Genetics & Microbiol, Duke University, Durham, NC

The heat shock transcription factor HSF-1 boosts immunity. HSF-1 is required for immunity against four bacterial pathogens—both insect and vertebrate hosts. This led us to examine other conserved pathways which might regulate immunity in C. elegans. Our work opens up the possibility that HSF-1 activators could be used for boosting immunity against bacterial infections, possibly also in an immunodeficient background.

E2 of Hepatitis C Virus Modulates Cellular Proteins Related with TNF-Signaling

S. Lee, M. Lee, S. Jang; Dept. of Life Science, POSTECH, Pohang, Republic of Korea

Hepatitis C virus (HCV) is a major human pathogen to which about 170 million people are succumbing currently. HCV is a causative agent of acute and chronic hepatitis, which often leads to liver cirrhosis and hepatocellular carcinoma. It has been speculated that HCV possesses mechanisms capable of modulating host defense systems such as innate and adaptive immunity since it causes chronic disease in most of infected patient (about 80%). Recently, we reported that E2 of HCV augments persistent infection of HCV by blocking apoptosis of infected cells (Lee et al., 1995). In order to understand the molecular basis of the anti-apoptotic activity of HCV, we monitored cellular proteins related with TNF-signaling that is responsible for cell survival and pro-inflammatory responses. The subcellular localizations of the proteins related with TNF-signaling (TNFR1 and TNFR2) were monitored by immunocytochemical methods and a fractionation of cell extracts. TNFR1 and TRAF2 were enriched in lipid raft together with E2 in an E2-expressing cell line. Moreover, the amounts of these proteins and other TNF-signaling-related proteins (XIAP and survivin) were greatly increased in the E2-expressing cell. We also observed activation of NF-κB in the E2-expressing cell. We speculate that E2 of HCV modulates innate immunity of host cells by triggering pro-inflammatory response through the activation of TNF-signaling.

Bafilomycin A1-Sensitive Pathway Is Required for the Maturation of Cystic Fibrosis Transmembrane Conductance Regulator

A. Niibori, T. Okiyoneda, K. Harada, T. Kohno, H. Kusuhara, T. Takada, T. Shuto, M. Suico, Y. Sugiyama, H. Kai; Molecular Medicine, Kumamoto University, Kumamoto, Japan

The maturation pathway of CFTR is thought to be non-conventional since CFTR maturation is inhibited by dysfunction of syntaxin 13, which is involved in protein recycling via endosomal pathway. In this study, to clarify whether the endosomal trafficking is required for CFTR maturation, we utilized a specific vacuolar H+ ATPase inhibitor, bafilomycin A1 (BafA1), which inhibits the protein trafficking from early endosomes. Our data showed that BafA1 decreased mature CFTR and induced accumulation of immature CFTR. Pulse-chase analysis showed that BafA1 inhibited the maturation of CFTR, but it slightly stabilized immature CFTR. Immunocytochemical analyses revealed that BafA1 induced the accumulation of CFTR in the juxta-nuclear region containing an endosomal marker. These results indicate that BafA1-sensitive pathway is required for CFTR maturation and emphasize that endosomal trafficking pathway is involved in the maturation of CFTR.

Ectopic Calcification in mdx Mouse Skeletal Muscle III

N. Kikkawa, M. Shiozuka, T. Kogure, M. Suico, T. Takada, T. Shuto, H. Kusuhara, H. Kai; Molecular Medicine, Kumamoto University, Kumamoto, Japan

Duchenne muscular dystrophy (DMD) is a lethal, progressive muscle disorder caused by mutations in dystrophin gene. Structures of high electron density were observed in skeletal muscles of mdx mouse, an animal model of DMD, using an x-ray micro CT scanner. We referred to this structure as “ectopic calcification”, as its component was identified as hydroxyapatite from the x-ray diffraction pattern. No such calcification was found in B10 mouse, the normal control. Serum of mdx mice, compared with B10 mice, contained high level (40%, p < 0.05) of inorganic phosphate (Pi), while serum calcium level showed no significant difference. Pi being perceived as a factor for the ectopic calcification in mdx mice, cells obtained from mdx skeletal muscle tissue were cultured in media containing high level of Pi. Expression of osteopontin, an osteogenic marker, was detected by indirect immunofluorescence staining. Osteopontin expression in cells cultured in the presence of high Pi concentrations increased over time, whereas the expression was unchanged in cells cultured in media containing normal Pi level, suggesting that Pi induces ectopic calcification. As macrophage accumulation was found to be colocalized with ectopic calcification in mdx mice, relations between ectopic calcification and inflammation or degeneration/regeneration of muscle were suggested. The calcification is able to observe in live animals using x-ray micro CT, therefore it may serve as a non-invasive diagnostic marker to evaluate the therapeutic effects of DMD therapy.

Antibodies against C-Terminus of Dengue Virus Nonstructural Protein 1 Show Cross-Reactivity with Endothelial Cells via a Molecular Mimicry Mechanism

S. Wan, C. Lin, Y. Lin; Microbiology and Immunology, National Cheng Kung University Medical College, Tainan, Taiwan

Infection with dengue virus (DV) causes diseases ranging from self-limited dengue fever (DF) to life-threatening dengue hemorrhagic fever and dengue shock syndrome (DHF/DDS). Vascular leakage, thrombocytopenia, and bleeding are the clinical manifestations associated with DHF, yet the mechanisms are not fully defined. Previous studies in our laboratory showed that anti-DV nonstructural protein 1 (NS1) antibodies (Abs) cross-reacted with endothelial cells. The potential candidate proteins recognized by anti-DV NS1 Abs include ATP synthase β-chain, vimentin, heat shock protein 60, and protein disulfide isomerase. The C-terminal amino acids (a.a.) 311-352 of DV NS1 show sequence homology with the candidate proteins. In this study, the role of NS1 C-terminus on dengue autoimmunity was investigated. We have deleted the a.a. 277-352 of DV NS1 to prepare truncated NS1 (nNS1), and generated anti-DV nNS1 Abs in mice. The endothelial cell binding activity of anti-DV nNS1 Abs was lower than that of anti-DV NS1 Abs. In addition, the endothelial cell binding activity of anti-DV NS1 Abs was inhibited by preabsorption with DV NS1 but not with DV nNS1 proteins. The anti-P311 (a.a. 311-330) and P331 (a.a. 331-350) titers of dengue patient sera were positively correlated with the binding
activity of dengue patient sera IgM with endothelial cells. Dengue patient sera showed lower binding activity to DV IN5N1 than to DV IN5N1 proteins. The endothelial cell binding activity of dengue patient sera could be inhibited by preabsorption with DV IN51, P311, and P331. These studies help to understand the molecular mechanisms of autoimmunity mediated by anti-DV NS1 Abs, and the potential implications of IN51 in dengue vaccine development.

Identification of the Transcription Factors Responsible for Enhancement of Endothelin-1 Expression in Spontaneously Hypertensive Rats Vascular Smooth Muscle T. Yang,1,2 C. Chen-Kung,1 L. Mei-Hua,1 C. Jang-Yi,1 C. Chuang-Fay,1 C. Li-Tze,1 Graduate Institute of Basic Medical Sciences, Chang Chung University, Kwei-Shan Tao-Yuan, Taiwan, 1Institute of Biology and Anatomy, National Defense Medical Center, Taipei, Taiwan

Endothelin-1 (ET-1) expression in vascular smooth muscle cells (VSMC) of spontaneously hypertensive rats (SHR) at prehypertensive stage is higher than age matched Wista-Kyoto rats (WKY). ET-1 promoter and deletion mutants activity assay demonstrated at region -1309 to -1143 of ET-1 promoter was responsible for higher expression of ET-1 in SHR than WKY rats. At the region -1309 to -1143 contains GHF-Iand C/EBP binding sequence. However, there is no GHF-I expression in SHR VSMC, the other transcription factors POU homeodomain family will concern. By RT-PCR and EMSA assay, we found that the Oct-2, and CEBPβ1 expression in VSMC of SHR higher than WKY rats but no different expression of Oct-1. By EMSA and super shift assay, the results showed the Oct-1, Oct-2 and CEBPβ1 can all bind to the -1309 to -1143 of ET-1 promoter probe. It is conclude that the over expression of ET-1 in VSMC SHR than WKY rats were due to over expression of Oct-2 and CEBPβ1 in VSMC SHR.

Apolipoprotein F Secreted by Antigen-presenting Cells Regulates the Secretion of Interleukin-1β in Human Endothelial Cells J. Jin,1 M. Rubin,1 R. Haeussler,1 H. Lehrauch,1 P. Rosenberg1, Cell Biology, Institute of Clinical Molecular Biology, Kiel, Germany

Apolipoprotein F (ApoF), a 10 residue protein, is secreted by antigen-presenting cells upon TLR/IL-1 receptor engagement. ApoF is a witness of the endoplasmic reticulum (ER) and is involved in the homeostasis of the protein quality control network. Our previous studies demonstrated that ApoF binds to the extracellular domain (ECD) of TLR4/5 (lipopolysaccharide) and IL-1R1, and regulates the synthesis and secretion of IL-1β. The objective of the present study was to further examine the role of ApoF in the regulation of IL-1β secretion. Human umbilical vein endothelial cells (HUVECs) were treated with LPS in the presence or absence of ApoF and the levels of IL-1β and other pro-inflammatory cytokines were measured by ELISA. Our results showed that treatment of HUVECs with LPS in the presence of ApoF, significantly inhibited the secretion of IL-1β. In contrast, treatment of HUVECs with LPS in the absence of ApoF, increased the secretion of IL-1β. These findings suggest that ApoF is a negative regulator of IL-1β secretion in human endothelial cells.

PYPAF3, a PYRIN-containing Apaf-1-like Protein, is a Feedback Regulator of Caspase-1-dependent Interleukin-1β Secretion M. Rubin,1 R. Haeussler,1 J. Jin,1 J. P. Hafner,1 T. Suda,1 Immunology and Molecular Biology, Kanazawa University Cancer Research Institute, Kanazawa, Japan

PYPAF3 is a member of the PYPAF family of proteins which includes PYPAF1, 2, 5, 7, and 10 and are thought to play a role in the regulation of inflammation. PYPAF3 inhibits caspase-1-mediated IL-1β secretion in THP-1 cells. Previous studies have shown that PYPAF3 binds to caspase-1 and interferes with its activation. In the current study, we examined the role of PYPAF3 in the regulation of IL-1β secretion in THP-1 cells. THP-1 cells were differentiated into macrophages with PMA. The cells were then treated with LPS in the presence or absence of ApoF and the levels of IL-1β and other pro-inflammatory cytokines were measured by ELISA. Our results showed that treatment of THP-1 cells with LPS in the presence of ApoF, significantly inhibited the secretion of IL-1β. In contrast, treatment of THP-1 cells with LPS in the absence of ApoF, increased the secretion of IL-1β. These findings suggest that ApoF is a negative regulator of IL-1β secretion in human endothelial cells.

Systematic Analysis of NOD2-dependent Transcriptome and Proteome Signature Patterns upon Muramyl-dipeptide Stimulation T. Kinoshita, Y. Wang, M. Hasegawa, R. Imauma, T. Suda; Immunology and Molecular Biology, Kanazawa University Cancer Research Institute, Kanazawa, Japan

The NOD2-dependent global cellular proteome characterized previously (Weichart et al., J Biol Chem 2005). These data identify a complex cellular network of proinflammatory and autoregulatory mechanisms that regulate the expression of NOD2, and the potential implications of tNS1 in dengue vaccine development.

Associative Gag Multimers with Filamentous Actin Is Required for Equine Infectious Anemia Virus Production C. Chen,1 J. Jin,2 M. Rubin,1 L. Huang,1 T. Sturgeon,1 K. M. Wexel,1 D. B. Stolz,1 S. C. Watkins,1 J. R. Banburg1, D. A. Weiss,2 R. C. Montelaro2; 1Biochemistry and Molecular Biology, Colorado State University, Fort Collins, CO, 2Molecular Genetics and Biochemistry, University of Pittsburgh School of Medicine, Pittsburgh, PA

A role for the actin cytoskeleton in retrovirus assembly and budding has long been speculated. However, the molecular and cellular mechanisms by which retroviruses exploit actin dynamics to produce progeny virion remain largely undefined. Our previous studies demonstrated differential effects of experimentally modified actin dynamics on virion production of equine infectious anemia virus (EIAV), a lentivirus related to HIV-1, suggesting an involvement of Gag-actin association in retrovirus production. In the current study, we have employed bimolecular fluorescence complementation (BIFC) to reveal intimate (<10nm) and specific interactions between EIAV Gag and actin, but not tubulin. A specific interaction between Gag and filamentous actin (F-actin) was also demonstrated by co-immunoprecipitation experiments involving the common seier protein gelsolin to solubilize F-actin. Mutagenesis analyses of Gag polyprotein revealed that deletion of capsid (CA) or nucleocapsid (NC) genes reduced Gag association with F-actin by 40% and 95%, respectively. Interestingly, a leucine zipper motif derived from a yeast transcription factor of the PAMPs within human cells. Variants in NOD2/CARD15, a member of the NLR gene family, which is pivotal in innate immune responses by recognition of pathogen-associated molecular patterns (PAMPs) within human cells. Variants in NOD2/CARD15 are thought to function in apoptotic and inflammatory pathways, and are characterized by three distinct domains: an amino-terminal pyrin domain, a nucleotide-binding and oligomerization domain, and a variable number of carboxy-terminal leucine-rich repeat domain. Recent studies have shown that Gag association with F-actin was increased by the PYD domain of Gag, which is essential for Gag association with F-actin. CA-mediated homologous dimerization of Gag contributed to the formation of Gag multimers as well. The transcription factor GCN4 could substitute for the NC domain function in mediating F-actin association, indicating that multimerization of Gag polyproteins, induced by the NC function but not specific sequence of the NC domain, is essential for F-actin association. CA-mediated homologous dimerization of Gag contributed to the formation of Gag multimers as well. The transcription factor GCN4 could substitute for the NC domain function in mediating F-actin association, indicating that multimerization of Gag polyproteins, induced by the NC function but not specific sequence of the NC domain, is essential for F-actin association. Identification of C. elegans Genes Linked to Sensory Cilia Formation and Function
O. E. Blasco, M. R. Leroux; Molecular Biology and Biochemistry, Simon Fraser University, Burnaby, BC, Canada.
Sensory cilia play essential functions in the monitoring and physical environment and are now associated with several critical signaling and developmental processes. To uncover novel genes that are required for sensory cilia biogenesis/function, we took several complementary approaches using C. elegans as a model system. The studies include (i) comparison of the expression profiles of ciliated cells versus non-ciliated cells, (ii) bioinformatic identification of genes regulated by the ciliogenic transcription factor DAF-19, (iii) identification of DAF-19 target genes by microarray analysis comparisons of wild-type and daf-19 mutant strains, and (iv) screening for mutants with abrogated cilia function (e.g., dyf, or dye-filling defective mutants, where the cilia are abrogated and are not exposed to the external environment). To validate if the candidate genes identified possess roles in cilia biogenesis or function, we then assess if their expression is specific to ciliated sensory neurons, determine the localization of the protein using time-lapse microscopy, or for example, if they encode ciliary/infraflagellar transport components, and finally, analyze the corresponding mutant strains for ciliary defects and behavioral (e.g., sensory) phenotypes. Our studies have led to the identification of many novel putative ciliary genes, and we have gathered evidence for ciliary functions for several of these. Two basic classes of ciliary genes appear to exist, namely those that are required for the formation of cilia, and others that likely play specific roles in the sensory functions of cilia or perhaps in the differentiation of the various ciliated sensory neuron types. The ultimate aim of these studies is to identify all of the components required for cilia biogenesis, to define the components and molecular pathways used by cilia for its sensory functions, and finally, to uncover new ciliary proteins associated with human diseases.

Role of ErbB4 in the Regulation of Cardiomyocyte Biology
B. Icli,1 X. Peng,2 D. Sawyer3; 1Molecular Medicine, Boston University School of Medicine, Boston, MA, 2Medicine, Vanderbilt University, Nashville, TN
ErbB4 is essential for cardiac development, and transmits a prosurvival signal in cardiac myocytes when activated by its ligand Neuregulin. However, alternatively spliced ErbB4 isoforms are known to exist that can transactivate a proapoptotic signaling. The purpose of this study was to examine whether these isoforms exist in rat ventricular myocytes and allow for reciprocal regulation of cell fate by ErbB4 ligands. We demonstrate that adult rat cardiomyocytes express all known ErbB4 isoforms: J1M-a, J1M-b, CYT-1 and CYT-2. Cloning of the full-length ErbB4 showed that JM-b and CYT-1 are the dominant isoforms in adult rat ventricular myocytes (ARVM). Treatment of ARVMs with PMA or Doxorubicin induced ErbB4 nuclear translocation. However, we did not observe the proteolytic cleavage of ErbB4 following the PMA or Doxorubicin treatments, and a gamma-secretase inhibitor did not prevent nuclear translocation of ErbB4. In addition to ErbB4 nuclear translocation, doxorubicin treatment induced p53 and p21 levels without increasing Bax expression. AG1478, an EGFR and ErbB4 kinase inhibitor, inhibited doxorubicin-induced induction. Hence ErbB4 may not be a classical EGFR. However, ErbB4 functions as a novel EGFR and its role in cardiac disease remains to be determined.

Progerin, the Abnormal Protein Expressed in Hutchinson-Gilford Progeria Syndrome, Interferes with Mitosis in Both Progeria and Normal Cells
K. Cao,1 B. Capell,1 M. Erdos,1 K. Djabali,2 P. Collins1; 1National Human Genome Research Institute, Bethesda, MD, 2Columbia University, New York, NY
Classic Hutchinson-Gilford progeria syndrome (HGPS) is caused by a de novo point mutation (G600G) in exon 11 of the LMNA gene. This mutation activates a cryptic splice donor, resulting in a mutant lamin A protein (known as “progerin”) with a 50 amino acid internal deletion near the carboxy-terminus. During interphase, progerin anchors to the nuclear membrane and causes characteristic nuclear blebbing. Progerin’s localization and activity during mitosis, however, are completely unknown. We have analyzed progerin during mitosis in GFP-progerin-transfected HeLa cells and in human HGPS fibroblasts. In contrast to the diffuse cytoplasmic signal of GFP-lamin A in metaphase, GFP-progerin associated with membrane structures and formed large insoluble aggregates in the cytoplasm. Fluorescence recovery after photobleaching (FRAP) and fluorescence loss in photobleaching (FLIP) studies revealed slower protein turnover and the presence of an insoluble fraction of GFP-progerin during mitosis. Blocking farnesylation with farnesyltransfase inhibitors (FTIs) or the farnesylate incompetent CAAAX mutant Progerin-SLAM effectively restored the localization and dynamics of GFP-progerin to those of normal lamin A. In HGPS fibroblasts, double immunofluorescence studies with a lamin A/C antibody and a progerin specific antibody revealed similar abnormal aggregation of progerin in metaphase, and a delay in the reassembly of progerin into the nuclear envelope compared with wildtype lamin A in late mitosis. In addition, we found an increase in lagging chromosomes and binucleation in HGPS fibroblasts. Last, we present evidence that small amounts of progerin exist in normal cells as indicated by immunofluorescence, RT-PCR and Western blotting. Importantly, a significant portion of the normal cells that express progerin are also binucleated, implicating progerin causing similar mitotic defects in normal aging. Our findings provide the first evidence of mitotic abnormality in HGPS, and may shed light on the general phenomenon of normal aging.

Loss of Usp14 Alters ISG15 Levels
P. C. Chen,1 D. E. Zhang,2 G. A. Korbel,3 H. L. Ploegh,3 S. M. Wilson1; 1Department of Neurobiology, University of Alabama at Birmingham, Birmingham, AL, 2Department of Molecular and Experimental Medicine, The Scripps Research Institute, La Jolla, CA, 3Department of Pathology, Harvard Medical School, Boston, MA
Usp14 is a member of the ubiquitin-specific protease (UBP) family of deubiquitinating enzymes. Usp14 has been shown to associate with the proteasome and its ubiquitin-hydrolyase activity is greatly enhanced following proteasome binding. In axiata mice, loss of Usp14 results in reduced level of ubiquitin, which suggests that Usp14 is required for recycling ubiquitin at the proteasome. Since ubiquitin and ubiquitin-like proteins have similarity in both sequence and structure, we investigated if Usp14 also has activity toward other ubiquitin-like proteins. Here we show that Usp14 has catalytic activity toward ISG15-VS in vitro, which suggests that Usp14 may function to de-conjugate ISGylated proteins in vivo. Consistent with this, immunoblot analysis of tissues extracts from axiata mice shows that monomeric ISG15 levels are significantly reduced in lung, kidney, and spleen. To further study the role of Usp14 as a de-conjugation enzyme for ISGylated proteins, we use mouse embryonic fibroblasts (MEFs) to study ISG15 signaling. Both monomeric and conjugated forms of ISG15 levels are reduced in the Usp14−/− MEFs. To investigate the relationships between ISG15, Usp14, and the proteasome, MEFs were treated with proteasome inhibitor MG132. In wild-type MEF, MG132 dramatically enhanced the production of ISG15 in wild-type MEFs. In contrast, inhibition of proteasome in Usp14−/− MEFs only resulted in a slight increase of monomeric ISG15 levels. These results suggest that the decrease of ISG15 in Usp14 deficient cells is not only caused by proteasome-dependent degradation of ISG15. Furthermore, semi-quantitative RT-PCR shows that mRNA levels of both ISG15 and UBE1L, the ISG15 conjugating enzyme, are decreased in the Usp14−/− MEFs. These results suggest that Usp14 may function to control both protein and mRNA levels of ISG15. Our findings provide a new evidence for a link between Usp14 and ISG15 regulation in the ubiquitin-proteasome system.

Silencing of the Desmosomal Protein Plakophilin-2 in Neonatal Rat Cardiac Fibroblasts Affects Localization of the Gap Junction Protein Connexin43
E. M. Oxford, W. Coombs, S. Taffet, M. Delmar; Pharmacology, SUNY Upstate Medical University, Syracuse, NY
The cardiac intercalated disc is comprised of 3 different macromolecular protein complexes. Desmosomes and adherens junctions maintain mechanical stability between cardiac myocytes, while gap junctions are responsible for electrical and metabolic continuity. It has been hypothesized that a disruption of the mechanical junctions may interfere with the formation of gap junctions at the intercalated disc. However, the possible cross-talk between specific desmosomal proteins and the gap junction protein Connexin43 remains to be addressed. Of recent relevance, generic analysis has linked a number of cases of Arrhythmogenic Right Ventricular Dysplasia (ARVD/C; an inherited disease associated with sudden cardiac death) to mutations in the gene coding for plakophilin 2 (PKP2), an integral desmosomal protein. Here, we tested the hypothesis that loss of PKP2 leads to disruption in gap junction structure and function. Stealth RNAi (Invitrogen) was used to silence PKP2 expression in primary cultures of neonatal rat cardiac fibroblasts. A “scrambled” RNAi (same bases; random sequence) served as control. Western blot analysis demonstrated loss of detectable PKP2 from cells treated with the pertinent RNAi. Subcellular distribution of PKP2 and Cx43 was assessed by immunofluorescence. As expected, silencing of PKP2 led to the loss of detectable PKP2 protein. Interestingly, the absence of PKP2 signal was accompanied by redistribution of the Cx43-reactive signal. Gap junction plaques were absent, and Cx43 was detected only in the intracellular space. Western blot analysis revealed significant reduction (p<0.05) in the fraction of phosphorylated Cx43 in PKP2-deficient cells, as compared to control. Our data show that loss of PKP2 expression in neonatal rat cardiac fibroblasts causes significant Cx43 remodeling. These results support the notion that disruption of molecular integrity in the desmosome may lead to significant changes in intercellular communication. The latter may represent an important substrate in the genesis of ventricular arrhythmias in patients afflicted with ARVD/C.

Role of Autophagy in CFTR Degradation
L. Fu, E. Itzhak; Department of Cell Biology, University of Alabama at Birmingham, Birmingham, AL
Cystic Fibrosis (CF) is a lethal disease caused by mutations in the Cystic Fibrosis Transmembrane Conductance Regulator (CFTR). Most CF patients (>70%) have the ΔF508 mutation that leads to CFTR misfolding and prevents the protein from reaching the plasma membrane to function as a chloride channel. ΔF508 CFTR is retained in the endoplasmic reticulum (ER) and eventually degraded. We have used yeast S. cerevisiae as a model system to study mechanisms regulating CFTR degradation. GFP-tagged CFTR was introduced into yeast under the control of a copper-inducible promoter. The expression, localization and degradation of GFP-CFTR were followed by time-lapse imaging in live yeast. We show that in wild-type cells, GFP-CFTR first appears along the ER ring 30-45 min after induction. Subsequently, GFP-CFTR follows two distinct pathways: it either gradually disappears from the ER, or is sequestered into structures called ER-associated complexes (ERACs). ERACs containing GFP-CFTR persist till about an hour after formation, and then rapidly disappear. This behavior suggests that CFTR may be degraded by multiple pathways. CFTR is known to be degraded by the proteasome. We compared the GFP-CFTR degradation pattern in wild-type yeast with that in the pre1-1 yeast deficient in proteasomal degradation. In pre1-1 strain, GFP-CFTR is synthesized along the ER ring and then concentrated in ERACs. There appears to be no degradation of GFP-CFTR from the ER, but degradation from ERACs still occurs. These results suggest that degradation of CFTR from the ER is proteasome-dependent, while degradation from the ERACs is proteasome-independent. To explore whether the proteasome-independent pathway for CFTR degradation involves autophagy, we tested GFP-CFTR behavior in autophagy mutants. We found that GFP-CFTR is sequestered into ERACs in the atg6Δ and vps38Δ strains. However, CFTR ERACs are not degraded in these strains. These results suggest that autophagy, specifically the VPS30 complex II, participates in CFTR degradation.

HIV-1 and Influenza Virus Exit from Cells via Separate Microdomains
M. Thali; University of Vermont, Burlington, VT

Tetraspanins are thought to laterally organize cellular membranes via specific associations with each other and with distinct integrins. Utilizing fluorescence microscopy and electron microscopy, we recently mapped tetraspanin-enriched microdomains (TEMs) containing CD9, CD81, CD82 and CD63 (JCB 173: 795-807). Our data also documented size, composition and distribution of these surface TEMs. Further, human immunodeficiency virus type 1 (HIV-1) components, together with constituents of the mammalian ESCRT1 complex which is part of the cellular extravesiculation machinery critical for HIV-1 budding, were demonstrated to accumulate at surface TEMs, suggesting that HIV-1 egress is gated through these microdomains. In vivo, HIV-1 is thought to be transmitted predominantly at virological synapses, for example at cell-cell junctions within lymph nodes. In contrast, influenza virus is released into the airways of the respiratory tract from free surfaces at the apical side of epithelial cells. Using various imaging techniques and also by applying release blockades with anti-tetraspanin antibodies, we now demonstrate that such differential release of HIV-1 and influenza virus is paralleled, at the subcellular level, by particle egress from different segments of free surface areas in non-polarized cells. The surface TEMs which we find to function as exit ports for HIV-1 are always located adjacent to or even overlapping with clathrin-coated areas of the plasma membrane. We are thus testing the hypothesis that these sub-micron sized membrane segments, together with viral components, can be sequestered in the endosomal compartment to be mobilized for the formation of a virological synapse upon attachment to a target cell. supported by NIH grants RO1 AI 47727 and R03 AI 060679 to M.T., SNSF 3100A0-104489/1 to M.F.
